**34.7.4.2 Limitations—Practical Rule of Thumb.** It is useful to have a practical limit to express an understanding of where the technologies may limit performance. In the case of etched linewidth, it has been expressed that the total of the resist thickness plus the etched foil thickness would limit the gap between the etched features. Therefore, for 1.2-mil dry-film resist over 1-oz copper foil, the total thickness is 2.6 mil. This could be used as a practical limit for both the trace and gap. Further limits can be determined by the undercut and etch factor experienced for the same type of etched features. Therefore, using the  $R/B = 1$  data from Table 34.2 ( $U = 0.525$  mil), a 2.6-mil resist line would be 2.6 mil at the trace bottom and would have a 1.5-mil etched top reduction, leaving only a 1.1-mil top surface. It must then be determined if these dimensions (with allowance for variations) are sufficient for the design functionality.

**34.7.4.3 Thinner Is Better.** In general, it follows that thinner foil and thinner resist allow for smaller features. However, if thin foil ( $9\ \mu\text{m}$ ,  $\frac{1}{4}$  oz) is used, the traces may be plated to achieve better current capability. Thin resist may be used, but the image may be susceptible to handling damage or damage in the process equipment. However, for coated resists of 0.4 mil and  $\frac{1}{4}$ -oz. foil (0.35 mil), the result could indicate a limit of 0.75 mil ( $19\ \mu\text{m}$ ). In fact, there has been a process using 3- and  $5\text{-}\mu\text{m}$  foil to produce  $30\text{-}\mu\text{m}$  line- and spacewidth patterns with  $14\ \mu\text{m}$  additional plated copper (total trace height of 17 and  $19\ \mu\text{m}$ ). This method uses both panel and pattern plating.<sup>41</sup> The original foil was etched from thicker commercial foil laminate to the working thickness.

**34.7.4.4 Changing the Microchannel Flow.** As previously explained, the flow in the microchannels surrounding the features is critical in achieving uniform and accurate etching results. There is a unique process development using fibers to affect localized fluid mixing in these channels.<sup>42</sup> This approach requires specific patented equipment and processing methods.<sup>43</sup> Reported results down to  $50\text{-}\mu\text{m}$  (2-mil) lines and spaces in 1-oz ( $34\text{-}\mu\text{m}$ ) copper have been produced with 1.4-mil ( $37\text{-}\mu\text{m}$ )-thick resist. This is a very unique and important result because conventional foil and resist technology can be used to make features significantly smaller than conventional capability through improved fluid application mechanics.

**34.7.4.5 Beyond Fine? HDI Impacts.** High-density interconnect (HDI) technology involves several technology changes to form the circuitry. The highlight, as the name implies, is small via structures made in a layer-by-layer methodology with a built-up thin insulator and thin foil structure. To achieve the interconnection, thin and precisely controlled traces are required. The technologies, such as the two previous items, are becoming available to attack the needs of the products. As layer counts increase, the accumulating yield implications are significant, so that each process must produce minimum defects. For etching, one of the challenges is to make the resist conform to the surface—which forces the structural materials and processes to engage planarity of the end stage process as an issue. Etching capability requires improving the precision, stability, and capability of processing. The flowchart in Fig. 34.6 graphically illustrates the effects required for etching concerns and approaches to address these.<sup>44</sup> It is significant that there are no new concerns added to previous discussions.

**FIGURE 34.6** Flowchart for study of resolution of HDI etched product limitations. Profile and uniformity limitations may be studied for process improvement by progressing down the chart for contributing elements.

**34.7.4.6 Stability and Control.** It is important to measure and understand sources of variation in order to eliminate them. The gauging tools mentioned previously are very useful for collecting the data for analysis. One important feature is the positional and orientational variation in line geometry. Various conclusions can be taken from feature variation by location across the panel and orientation relative to the direction of motion. Repeating the gauging technique on a regular basis can allow observation of changing conditions within the process (such as plugged nozzles and other defects).

Another type of variation can be obtained by examining a series of gauge panels progressively processed with specific time-lag variations. If etching chemical controls are not adequate, the etch rate may vary in the sequence and therefore cause line variation with time. Usually, regeneration equipment can be adjusted or modified to minimize these variations, but the value of such instrument upgrades can be determined easily by data recorded about the type and extent of defects incurred.

## 34.8 EQUIPMENT AND TECHNIQUES

Etching equipment for circuit line formation has developed many variations on spray processing equipment. Often, as members of a coordinated automatic immersion plating process line, there are immersion etching tank varieties for microetching and surface preparation. However, for individual panels, conveyorized spray processing is clearly established because of efficient part handling and processing effectiveness.

### 34.8.1 Spray Equipment Basics

**34.8.1.1 Construction.** Etching equipment must be made from materials for long life, good dimensional stability, and resistance to chemicals and temperatures (130°F and higher). The basic construction includes rigid plastics (PVC, polypropylene, CPVC, and PVDF), metals (titanium, Hastalloy C), elastomers (vinyl, Viton A, Kel F, ethylene-propylene), specialized composites (epoxy-glass, graphite, and carbon-filled polymers, and other specialized formulations), and glass or clear and translucent polymers for visibility. The challenge is to select proper grades, compositions, and properties for mechanical strength, functionality, and durability. Equipment manufacturers perform these tasks in their design process.

**34.8.1.2 Controls.** Controls and electronics are significant because the increasing robustness and precision can have a large impact on cost. Therefore, the compromise on cost-effectiveness/technology trade-off often is made with a market-price primary goal. Therefore, cost-benefit analysis must be made by purchasers to evaluate available upgrades in instrumentation. The key controls are temperature, pressure, conveyor speed, and safety interlocks. Temperature is especially important because the etching reactions are usually exothermic and heat must be removed by cooling water coils to maintain stable rates. Conductivity, pH, density, ORP, and other process chemical control instruments may be added to monitor and control the processes. These instruments may be integrated into a PLC or computerized control system or may be individual control-panel stand-alone instrumentations. The wiring and the control cabinet itself must be suitably fume and hazard protected for water and chemical splashes as well as corrosive fumes. It is desired to have critical condition displays available to operators in the machine environment as well as some means of monitoring and recording process information.

**34.8.1.3 Spray Strategies.** Individual equipment designers have implemented very different types and mechanisms of spray attack on the panels. It is important to realize that the spray system design must be carefully integrated with the conveyor and mechanical design to minimize the effect of rods, wheels, panel control devices, and other mechanisms to achieve both uniformity and geometry of the features produced. It must be realized that the effect of the sprays is not merely the attack by droplets on the surface, but that the sprays are the prime drivers of the direction and effectiveness of the microchannel fluid flow on the panels. Therefore, separate controls and gauges must be provided for top and bottom spray arrays. For maximum precision, four quadrant controls are often beneficial. The mechanical spray arrays can be described as a variation of the following types.

*Fixed Spray Array.* This is a system of spray tubes containing multiple nozzles connected transversely across the conveyor to a header pipe on one or both sides. The spray nozzles are placed into the tubes in a pattern designed to optimize the effect. Care must be taken to install and orient the nozzles properly for designed effect. Mechanical intervention to selectively activate (or deactivate) portions of the design to effect the fluid dynamics of particular patterns should be included.

*Oscillating Sprays.* This system uses spray tubes that are connected generally to be aligned with the conveyor direction (often at a slight angle). The ends of the spray tubes are made with rotating seals so that the tubes can be moved back and forth by an oscillating crank or gearing mechanism. The nozzles move the liquid in a pattern generally across the conveyor travel. Individual spray tubes may be throttled and/or selectively activated.

*Reciprocation.* These nozzles are usually placed in an array similar to the fixed system, and the entire array is moved by a cranking mechanism in a direction across the conveyor. Maximum precision offerings include various patterns of nozzles that can be separately valved and selectively activated by computer controls.

*Spray Nozzles.* Spray nozzles are available in several types, sizes, and materials. For etching it has been established that PVDF nozzles are robust and consistent. The nozzle patterns are flat fan, full cone (round and squared), and open cone designs. Generally, flat fan nozzles have large openings and high impact for a given flow rate, while round cones have lower impact and orifice restrictions to ensure the pattern is filled. One of the principal failings of nozzles is simply clogging. The best array design can become dangerously nonuniform simply by plugging a small number of sprays. There is a commercially available nozzle that has a self-clearing fan design. Many are installed. For some applications, filtration between the pump and sprays has been installed to prevent plugging.

*Selection.* All of these combinations of nozzles, arrays, and mechanisms offer benefits and drawbacks that are often counterintuitive to the end user. It is necessary, therefore, to test and evaluate the performance of the spray systems for the work type and working environment. Testing of performance must be evaluated in a carefully controlled trial or by comparison with a standardized gauging tool.

### 34.8.2 Spray Equipment Options

#### 34.8.2.1 Vertical Panel Orientation

*Batch Operation.* Some of the earliest equipment is still useful for prototype manufacture. This equipment holds a single panel on a workpiece that is generally rotated about an axis and sometimes oscillated as well. The sprays are addressed from one or both sides of the work and may be fixed or oscillating. This type of equipment usually is limited to small panels. The liquid all drains off the panel and falls into a collection sump. The panels must be removed after etching is complete and placed into a separate rinse vessel. (Some equipment has been designed to divert the drain and spray water onto the same work orientation.) This equipment is not capable of high capacity but has been able to etch high-quality work.

*Conveyorized Operation.* There are several versions of large machines that accept vertically oriented workpieces, convey them on a series of rollers from beneath the panel, and stabilize the work with rollers or wires. There are some machines that suspend the panels from the top surface. Vertically oriented nozzle arrays, either stationary or moving, spray the panel surfaces. These machines have been more successful in developing than etching because the depth of the image to be developed is formed by the exposure rather than completely depending on the etching fluid dynamics. All the liquid sprayed on the panels is removed by running downward off the bottom panel edge; therefore, the nozzles must be specifically designed to offset the effects of higher amounts and speeds of downflowing etchant progressively toward the panel's lower edge. It is obvious that very thin workpieces can have difficulty being conveyed through this design.

#### 34.8.2.2 Horizontal Panel Orientation

*General Operation.* The most widely used configuration of etching equipment handles the panels horizontally on a roller table support. The panels placed on the rollers move constantly through arrays of sprays above and below the work. One of the principal design challenges is the fluid flow control of the liquid pool that builds up on (and runs off) the top surface of the panel. The various designs of the spray system must allow equally good and equally fast etching beneath the panel as on top. In a well-conceived design, the simple adjustment of spray pressures can achieve this balance.

*Conveyance.* The conveyor design is particularly critical. Rollers must turn at constant speed to ensure that the surfaces are not rubbed and damaged. Chains and gear designs have been successfully used. The potential problem areas are the entrance and exit squeegee rollers and the changes from one machine drive section to another. The roller wheels themselves need to be made of compliant materials that have flat area contact with the panels (rounded contact areas allow points that can cause resist damage, especially if the rollers harden with age). The wheels must be spaced far enough apart to allow the bottom spray to hit the panel with minimum shadowing, but close together enough to convey thin work without sagging or deforming.

Thin panels (0.0015- to 0.003-in insulation core) are difficult to convey because the leading edges must feed consistently from one roller to the next in spite of the downward force of the fluid. In addition, the deflection of the panels between rollers due to fluid loading can cause lack of uniformity in etching. Often, special mechanical guides such as clips or wires are used to overcome these difficulties. Problems occur when the guides stretch or are misplaced during production. If one panel jams, then the others behind it continue to jam and pile up, resulting in a major problem when discovered. The clearing of the jam often requires removal of rollers that are usually enmeshed in the mass of displaced guides and work. Not only are damaged panels costly, the downtime to renew the equipment and reestablish production causes significant production delay. One particular patented design features a combination of rollers and spray force that assures robust transport while simultaneously improving planarity for spray action.<sup>45</sup>

Truly flexible circuitry requires even more enhancements for reliable transport. Frames and screens have been used in the past, but these fixtures require extra handling and cause drag-over and cleaning problems. For sheet-cut panels, the best solution is a leading edge support attached to the panel by tape or mechanical clips. Usually these panels are attached and removed manually, but automatic systems could be provided. Flexible circuits can also be

manufactured in continuous rolls that can be threaded through multiple processes. In addition to the previous difficulties with planarity and drag-over, the precise synchronization of roller speed throughout all the processes is mandatory. Therefore, machine and processing speeds must be carefully planned at original manufacture to allow proper dwell settings and latitudes. Rinsing and drag-over present problems.

### 34.8.3 Rinsing

Rinsing is a process technology that needs particular attention because of the multiple needs of uncontaminated panels, conservation of rinse waters, and environmental discharge limitations. It is no longer sufficient to flood the panel with large amounts of water that are then discharged to sewers. The capability of technical analysis of this process has been published.<sup>46</sup>

**34.8.3.1 Cascade Rinsing.** The principal tool to effect the required change is the concept of multiple-stage cascade rinsing. This process includes the concept that a robust flow recirculated on a panel can reduce the concentration to a level in equilibrium with a much lower circulated water stream. The lower stream passes through a series of chambers of increasing concentration, while the work passes through a series of chambers of increasing cleanliness (in reverse order from the water). The end result is a small use of water capturing a relatively high level of contamination. The contamination level is many times the discharge limit for direct environmental discharge. However, the fact that the stream is relatively small and highly concentrated allows for reasonable treatment and recovery of by-products by ion exchange, direct electrowinning, or membrane cell concentration. In certain circumstances, the waste stream may be comingled with a main process stream for recycling (see Fig. 34.1).

**34.8.3.2 Drag-over Minimization.** All of the contamination that eventually ends up in the water stream is that introduced by drag-over from the process itself (or from a recirculated environmental rinse). Therefore, the first step in successful rinsing is the reduction or prevention of materials from the panel. The conventional means of attempting this is by a set of pinch or squeegee rollers at the output of the chemical module. These rollers may be increased in effectiveness by softness or by pressure. Often, rollers made of PVA foam have been employed effectively. However, these rollers must be kept clean and moist to be effective. Other methods include improved baffling, ensuring capture of overspray, and low-velocity air blow-off. Proper management of drag-over on conveyorized equipment has reduced residues by a factor of 10 or better. Thin panels cause difficulties because the compromise made between conveying reliability devices and planarity and contact of squeegee rollers and surface tension reduces effectiveness of retention. Thick panels (over 0.125 in) also cause problems because squeegee rollers and baffles must lift to clear the panels, allowing gaps for solution escape. It is therefore a subject for engineering study and process management trade-off decisions that must be considered during the specification process.

---

# MACHINING AND ROUTING

---

**Gary Roper**

*One Source Group, Dallas, Texas*

---

## 35.1 INTRODUCTION

---

Laminate machining consists of the mechanical processes by which circuit boards are prepared for the vital chemical processes of image transfer, plating, and etching. Such processes as cutting to size, drilling holes, and shaping have major effects on the final quality of the printed board. This chapter will discuss the basic mechanical processes that are essential to producing the finished board.

---

## 35.2 PUNCHING HOLES (PIERCING)

---

### 35.2.1 Design of the Die

It is possible to pierce holes down to one-half the thickness of XXXPC and FR-2 laminates and one-third that of FR-3 (Fig. 35.1). Many die designers lose sight of the fact that the force required to withdraw piercing punches is of the same magnitude as that required to push the punches through the material. For that reason, the question of how much stripper-spring pressure to design into a die is answered by most toolmakers: "as much as possible." When space on the dies cannot accommodate enough mechanical springs to do the job, a hydraulic mechanism can be used. Springs should be so located that the part is stripped evenly. If the board is ejected from the die unevenly, cracks around holes are almost certain to occur. Best-quality holes are produced when the stripper compresses the board an instant before the perforators start to penetrate. If the stripper pressure can be made to approach the compressive strength of the material, less force will be required and the holes will be cleaner.

If excessive breakage of small punches occurs, determine whether the punch breaks on the perforating stroke or on withdrawal. If the retainer lock is breaking, the cause is almost certain to be withdrawal strain. The remedy is to grind a small taper on the punch, no more than 11.2 in. and to a distance no greater than the thickness of the material being punched. If the grinding is kept within those limits, it will have no measurable effect on hole quality or size. The other two causes of punch breakage are poor alignment, which is easily detected by close examination of the tool, and poor design, which usually means that the punch is too small to do the job required.

**FIGURE 35.1** Illustration of the proper sizing and locating of pierced holes with respect to one another and to the edge of paper laminates. Minimum dimensions are given as multiples of laminate thickness  $t$ .

**35.2.2 Shrinkage of Paper-Based Laminates**

When paper-based laminates are to be punched, it must be remembered that the materials are resilient and that their tendency to spring back will result in a hole slightly smaller than the punch that produced the hole. The difference in size will depend on the thickness of the material. Table 35.1 shows the amount by which the punch should exceed the print size in order to make the holes within tolerance. The values listed should not be used for the design of tools for glass-epoxy laminates, the shrinkage of which is only about one-third that of paper-based materials.

**TABLE 35.1** Shrinkage in Punched Hole Diameters, Paper-Base Laminates

Material at thickness	Material at room temp.	Material at 90°F or above
1.64	0.001	0.002
1.32	0.002	0.003
3.64	0.003	0.005
1.16	0.004	0.007
3.32	0.006	0.010
1.80	0.010	0.013

**35.2.3 Tolerance of Punched Holes**

If precise hole size tolerance is required, the clearance between punch and die should be very close; the die hole should be only 0.002 to 0.004 in. larger than the punch for paper-based materials (Fig. 35.2 and Table 35.2). Glass-based laminates generally require about one-half that tolerance. Dies have, however, been constructed with as much as 0.010 in. all-around clearance between punch and die. They are for use where inspection standards permit rough-quality holes.

**FIGURE 35.2** Example of proper tolerance of a punch and die.

A die with sloppy clearances is less expensive than one built for precision work, and wide clearance between punch and die causes correspondingly more break and less shear than a tight die will cause. The result is a hole with a slight funnel shape that makes insertion of components easier.

Always pierce with the copper side up. Do not use piercing on designs with circuitry on both sides of the board, because lifting of pads would probably occur.

**35.2.4 Hole Location and Size**

Designs having holes whose distance from the edge of the board or from other holes approaches the thickness of the material are apt to be troublesome. Such designs should be avoided; but when distances between holes must be small, build the best die possible. Use tight clearance between punch and die and punch and stripper, and have the stripper apply plenty of pressure to the work before the punch starts to enter. If the distance between

**TABLE 35.2** Tolerances for Punching or Blanking Paper-Base Laminate

Material thickness	Base material	Tolerance on hole size, in.	Tolerances, in., on distance between holes and slots, 90°F				Tolerances for blanked parts, overall dimension, in.
			Up to 2 in.	2 to 3 in.	3 to 4 in.	4 to 5 in.	
To and including 1.16 in.	Paper	0.0015	0.003	0.004	0.005	0.006	0.003
Over 1.16 in to and including 3.32 in.	Paper	0.003	0.005	0.006	0.007	0.008	0.005
Over 3.32 in to and including 1.8 in.	Paper	0.005	0.006	0.007	0.008	0.009	0.008

holes is too small, cracks between holes may result even with the best of tools. If cracks between holes prove troublesome, plan the process so that the piercing is done before any copper is etched away. The reinforcing effect of the copper foil will help eliminate cracks. Most glass-epoxy laminates may be pierced, but the finish on the inside of the holes is sometimes not suitable for through-hole plating.

### 35.2.5 Warming Paper-Based Material

The process of punching paper-based laminates will often be much more trouble-free if the parts are warmed to 90 or 100°F. That is true even of the so-called cold-punch or PC grades.

Do not overheat the material to the point at which it crumbles and the residue is not ejected as a discrete slug. Overheated material will often plug the holes in the die and cause rejects.

Opening the taper on the takeaway holes will reduce plugging, but the most direct approach is to pierce at a lower temperature. Glass-epoxy is never heated for piercing or blanking.

### 35.2.6 Press Size

The size of the press is determined by the amount of work the press must do on each stroke.

The supplier of copper-clad sheets can specify a value for the shear strength of the material being used. Typically, the value will be about 12,000 lb./in.<sup>2</sup> for paper-based laminate and 20,000 lb./in.<sup>2</sup> for glass-epoxy laminate. The total circumference of the parts being punched out multiplied by the thickness of the sheet gives the area being sheared by the die. If all dimensions are in inches, the value will be in square inches. For example, a die piercing 50 round holes, each 0.100 in. in diameter, in 0.062 in. thick laminate will be shearing, in square inches:

$$50 \times 0.100 \text{ in.} \times 3.1416 \times 0.062 \text{ in.} = 0.974 \text{ in.}^2$$

If the paper-based laminate has 12,000 lb./in.<sup>2</sup> shear strength, 11,688 lb. of pressure, or about 6 tons, is required just to drive the punches through the laminate. Bear in mind that, if a spring loaded stripper is used, the press will also have to overcome the spring pressure, which ought to be at least as great as the shear strength. Therefore, a 12 ton press would be the minimum that could be considered. A 15 or 20 ton press would be considerably safer.

## 35.3 BLANKING, SHEARING, AND CUTTING OF COPPER-CLAD LAMINATES

### 35.3.1 Blanking Paper-Base Laminates

When parts are designed to have shapes other than rectangular and the volume is great enough to justify the expense of building a die, the parts are frequently punched from sheets

by using a blanking die. A blanking operation is well adapted to paper-based materials and is sometimes used on glass-based ones.

In the design of a blanking die for paper-based laminates, the resilience, or yield, of the material previously discussed under Piercing applies. The blanked part will be slightly larger than the die that produced it, and dies are therefore made just a little under print size depending on the material thickness. Sometimes a combination pierce and blank die is used.

The die pierces holes and also blanks out the finished part.

When the configuration is very complex, the designer may recommend a multiple-stage die: The strip of material progresses from one stage to the next with each stroke of the die.

Usually in the first one or two stages, holes are pierced, and in the final stage, the completed part is blanked out.

The quality of a part produced from paper-based laminates by shearing, piercing, or blanking can be improved by performing the operation on material which has been warmed. Caution should be exercised in heating over 100°F because the coefficient of thermal expansion may be high enough to cause the part to shrink out of tolerance on cooling. Paper-base laminates are particularly anisotropic with respect to thermal expansion; that is, they expand differently in the x and y dimensions. The manufacturer's data on coefficient of expansion should be consulted before a die for close-tolerance parts is designed. Keep in mind that the precision of the manufacturer's data is probably no better than  $\pm 25$  percent.

### 35.3.2 Blanking Glass-Based Laminates

Odd shapes that cannot be feasibly produced by shearing or sawing are either blanked or routed. Glass blanking is always done at room temperature. Assuming a close fit between punch and die, the part will be about 0.001 in. larger than the die which produced it. The tools are always so constructed that a part is removed from the die as it is made. It cannot be pushed out by a following part, as is often true when the material has a paper base. If material thicker than 0.062 in. is blanked, the parts may have a rough edge.

The life of a punch, pierce, or blank die should be evaluated with reference to the various copper-clad materials that may be used. One way to evaluate die wear caused by various materials is to weigh the perforators, or punches, very accurately, punch 5,000 pieces, and then reweigh the punches. Approximately 5,000 hits are necessary for evaluation, because the initial break-in period of the die will show a higher rate of wear. Also, of course, the quality of the holes at the beginning and end of each test must be evaluated. Greatly enlarged microphotos of the perforator can be used for visual evaluation of changes in the die.

### 35.3.3 Shearing

When copper-clad laminates are to be sheared, the shear should be set with only 0.001 to 0.002 in. clearance between the square-ground blades (Fig. 35.3). The thicker the material to

FIGURE 35.3 Typical adjustable shear blades for copper-clad laminates.

be cut, the greater the rake or scissor angle between the top and bottom shear blade. The converse also is true: The thinner the material, the smaller the rake angle and the closer the blades.

Hence, as in many metal shears, the rake angle and the blade gap are fixed; the cutoff piece can be twisted or curled. Paper-base material can also exhibit feathered cracks along the edge that are due to too wide a gap or too high a shear angle. That can be minimized by supporting both piece and cutoff piece during the shear operation and decreasing the rake angle. Epoxy-glass laminate, because of its flexural strength, does not usually crack, but the material can be deformed if the blade clearance is too great or the shear angle is too large. As in blanking, the quality of a part produced from paper-based laminates by shearing can be improved by warming the material before performing the operation.

### 35.3.4 Sawing Paper-Base Laminates

Paper-base laminates are much harder on sawing tools than are the hardest woods, and therefore a few special precautions are necessary for good saw life. Sawing paper-based laminates is best accomplished with a circular saw with 10 to 12 teeth per inch of diameter at 7500 or 10,000 ft/min. Hollow-ground saws give a smoother cut; and because of the abrasive nature of laminated materials, carbide teeth are an excellent investment. (See Fig. 35.4 for tooth shape.)

When a saw does not last long enough between sharpenings, use the following checklist. (These steps could have a cumulative effect and change saw life by a factor of 4 to 5.)

1. Check the bearings for tightness. There should be no perceptible play in them.
2. Check the blade for run-out. As much as 0.005 in. can be significant.
3. When carbide teeth are used, inspect them with a magnifying glass to make sure a diamond tool no coarser than 180 grit was used in sharpening them.
4. If the saw has a thin blade, use a stiffening collar to reduce vibration.
5. Use heavy pulleys with more than one V belt. Rotating parts of the system should have sufficient momentum to carry the saw tooth through the work smoothly and without variation of speed.
6. Check the alignment of the arbor and the motor mounting.

All these steps are intended to reduce or eliminate vibration, which is the greatest enemy of the saw blade. If vibration is noticed, find the source and correct it.

### 35.3.5 Sawing Glass-Base Laminates

When glass-based laminates are to be sawn, carbide-tooth circular saws can be used; but unless the volume of work is quite low, the added investment required for diamond-steel-bonded saws will be paid for in future savings. The manufacturer's recommendation of saw speed should be followed; usually it will be for a speed in the neighborhood of 15,000 ft/min. at the periphery of the saw blade. When economics dictate the use of carbide-tooth circular saws for cutting glass, use the instruction previously given for paper-based laminates (see Fig. 35.4 for tooth shape)

**FIGURE 35.4** Commonly used saw tooth designs for paper and cloth laminates. At left, two successive teeth on a 15° alternate-bevel saw. At right, two successive teeth on a 30° alternate-corner-relieved (AC-30) saw.

and remember that each caution regarding run-out, vibration, and alignment becomes more important when glass-reinforced laminates are sawn.

## 35.4 ROUTING

---

Modern circuit board fabricators rely principally on routing to perform profiling operations.

The high cost and extended lead times for blanking dies, combined with the problem of design inflexibility of hard tooling, limit the punching operation generally to very high volumes or designs specific to die applications. Shearing or sawing are limited to rectangular shapes and generally are not accurate enough for most board applications.

In the modern circuit board fabrication industry, rapid response to customer lead times and economies of universal process application are well served by routing, especially multiple-spindle computerized numerical controlled (CNC) routing. Routing consists of two similar, yet vastly different fabrication processes:

- CNC multiple-spindle routing
- Manual pin routing

The similarities consist of the use of high-speed spindles, utilizing carbide cutting tools, and generating high cutting rates.

### 35.4.1 Pin Routing

Pin routing is a manual routing process utilizing a template that has been machined of aluminum, FR-4 laminate, or a fiber-reinforced phenolic. The template is made to the finished board dimensions and has tooling pins installed to register to the board's tooling holes. The package (which can have up to four pieces in a stack) is routed by tracking the template against a pilot pin protruding from the router table. The pin height is less than the template thickness. Usually, the machine pilot pin is the same diameter as the router bit and can be offset adjusted to give the operator flexibility in optimizing dimensions. Work should be fed against the rotation of the cutter to prevent the cutter from grabbing.

Pin routing can be an economical process when a small generation of boards is profiled, or if the shapes required are relatively simple. For pin routing to be effective, generally a very skilled operator is required to fabricate the template and to route the boards. Outside machine shops can build aluminum route fixtures for each customer application; however, lead times and costs per order must be considered. Pin routing is usually used by small shops not able to invest in the CNC equipment and its associated support, or as a specialty process, off-line from CNC routing.

In the best pin-routing operations, the volumes produced cannot be compared with those of multiple-spindle routing.

### 35.4.2 CNC Mechanical Routing Applications

The applications of CNC routing extend well beyond merely cutting board profiles. The ability to produce boards in multiple-image modules reduces handling not only in the board shop, but in every subsequent operation, from packing, component assembly, wave solder, and test.

This is of special value when dealing with a postage-stamp-size part or wire-bondable gold surfaces. Where handling must be minimized, the module acts as a pallet throughout these operations. In addition, unusual or irregular shapes, small or large, can be palletized to simplify handling and conveyance. In Fig. 35.5, examples of tab-routed, or multiple-image, modules are shown.

**FIGURE 35.5** Examples of tab-routed, or multiple-image, modules.

In Fig. 35.6, each part is shown attached to the frame with breakable or removable tabs and can include features permitting tab removal below the board edge of the image periphery.

Note on Fig. 35.6 the use of a score line to ease tab removal. Scoring, alone or in concert with routing (as discussed in Sec. 35.5), can play a large role in board and pallet separation.

**FIGURE 35.6** Each part is shown attached to the frame with breakable or removable tabs. A variety of breakable tabs is shown. Also shown is a score line for ease of tab removal.

**FIGURE 35.7** Multiple-image palletization.

Beyond multiple-image palletization, as shown in Fig. 35.7, CNC routing can provide a variety of board requirements including:

- Internal cutouts
- Slots
- Counter bores
- Board edge conditioning for plating

There are many benefits available through CNC routing beyond those of efficient part profiling. A little planning before the release to production can improve manufacturability as well as provide many no-cost benefits to assembly, soldering, and so on.

### 35.4.3 CNC Operation

CNC router equipment has the ability to process high volumes of circuit boards very accurately and economically, yet it is coupled with features to enable quick program and setup.

This coupling enables the same processing used for high volume to be utilized for prototypes and short-lead-time production. With circuit board data files so universally available, the part programming time has dropped to a few minutes, as opposed to the hours it once took, while setups remain at about 15 to 20 min., plus cutter labyrinth and first article routing.

Router operation consists of multiple spindles (two to five) capable of operating from 6,000 to 36,000 r/min. or more. The router path (x-y table movement and spindle plunge and retract) is determined by program. This permits any number of paths and any location.

The preferred method of registration of the panel to the machine table is to use the full panel and the tooling holes previously drilled. Tooling holes internal to the part provide for the highest accuracy, although manufacturing panel tooling may be used if considered earlier in the process.

### 35.4.4 Mechanical Routing with CNC Equipment

Mechanical routing is the most common technology used for rigid circuit board routing. The cuts are obtained with a metal cutter.

**35.4.4.1 Cutter Offset.** Since the cutter must follow a path described by its centerline, it must be offset from the desired board edge by an amount equal to its effective radius. This is the basic cutter radius, and it will vary with the cutter tooth form. Most newer-generation equipment will automatically adjust for the cutter radius. However, either manually or automatically, this is a basic element of routing planning. Since the cutters deflect during the

**FIGURE 35.8** Effect of cutter deflection on part size and geometry: (a) Clockwise cutting (recommended for outside cuts) deflects cutter away from part. That leaves outside dimensions large on first pass unless compensated for in programming. (b) Counterclockwise cutting (recommended for inside cuts and pockets) deflects cutter into scrap. Therefore, inside dimensions of holes or cutouts will measure small unless compensated for in programming.

routing operation, it is necessary to determine the amount of deflection to be added to the basic cutter radius before expending large amounts on programming parts (Fig. 35.8). Cutter compensation values can be varied.

Variables that affect deflection are thickness, type of material, direction of cut, feed rate, and spindle speed. To reduce those variables, the manufacturer should:

- Standardize on cutter bit manufacturer, selected diameters, tooth form, and end cut.
- Fix spindle speed (24,000 r/min. is recommended for epoxy-glass laminates).
- Rout in clockwise direction on outside cuts, counterclockwise on inside cuts.
- Standardize on single or double pass.
- Fix feed rates for given materials. (Note that higher rates will increase part size, and slower feed rates will decrease part size.)
- Develop documented process controls after experimenting with varied parameters.

**35.4.4.2 Direction of Cut.** A counterclockwise direction of feed (climb-out) will leave outside corners with slight projections and inside corners with small radii. A clockwise direction of feed (rake cut) will give outside corners a slight radius, and perhaps give inside corners a slight indentation. You can minimize such irregularities by reducing the feed rate or cutting the part twice.

**35.4.4.3 Cutter Speed and Feed Rate.** The variables affecting cutter speed are usually limited to the type of laminate being cut and the linear feed rate of the cutter. A cutter rotation of 24,000 r/min. and feed rates up to 150 in./in. may be used effectively on most laminates, although cutter feed direction may require a lower feed rate. Teflon-glass and similar materials, the laminate binder of which flows at relatively low temperatures, require slower spindle speeds (12,000 r/in.) and high feed rates (200 in./in.) to minimize heat generation. The graph in Fig. 35.9 shows recommended feed rates and cutter offsets for most standard laminates at various stack heights. The cutter used is a standard 1.8 in. diameter burr type.

**FIGURE 35.9** Recommended feed rate of 24,000 r/min. for varying stack heights of specific thickness of material using 0.124 in. diameter burr cutter.

**35.4.4.4 Cutter Bits.** Because of the precise control of table movement in CNC routing, cutter bits are not subjected to shock encountered in pin routing and stylus routing, and therefore small-diameter cutters (0.031 in. diameter) may be used successfully. However, the fabricator would do well to standardize on 0.124 in. diameter cutters because they are suitable for most production work and are readily available from a number of manufacturers in a variety of types. The resulting 0.062 in. radius on all inside corners is usually acceptable if the board designer is aware of it.

Cutter tooth form is more important in CNC than in other routing. Because of the faster feed rates possible, it is important that a cutter have an open tooth form that will release the chip easily and prevent packing. Many standard diamond burrs available on the market will load with chips and fail rapidly. The carbide cutting bit will normally cut in excess of 15,000 linear in. of epoxy-glass laminate before erosion of the teeth renders the cutter ineffective or too small.

If extremely smooth edges are required, a fluted cutter may be used. Single- or two-flute cutters with straight flutes should be used when cutting into the foil if minimum burring is desired. It should be noted that such cutters will be more fragile than a standard serrated cutter, and feed speeds should be adjusted accordingly. When a slightly larger burr can be tolerated, two- and three-flute left-hand spiral cutter bits should be used because of their greater strength. The left-hand spiral will force the work piece down rather than lift it, assuming a right-hand turning spindle.

### 35.4.5 Laser Routing with CNC Equipment

Laser routing can be an effective alternative to mechanical routing especially for flexible circuit board materials. Laser cutting is very accurate, allowing for the profiling of very small parts. There are several types of lasers in use, and some equipment uses more than one type in a single piece of equipment.

Some laser types include the following:

- Nd:YAG (neodymium-doped yttrium aluminium garnet;  $\text{Nd:Y}_3\text{Al}_5\text{O}_{12}$ ), a crystal that is used as a lasing medium for solid-state lasers
- $\text{CO}_2$  cuts using heat only
- UV cuts using both thermal and chemical reaction

It is important to match your application and material with the laser type. Using the wrong application can result in burned material.

### 35.4.6 Tooling

To simplify tooling and expedite loading and unloading operations, effective hold-down and chop-removal systems should be provided as part of the machine design. Various methods may then be devised to mount the boards to the machine table while properly registering them to facilitate routing the outline. Some machine designs have shuttle tables available so that loading and unloading may be accomplished while the machine is cutting. Others will utilize quick-change secondary tooling pallets or subplots that allow rapid exchange of bench loaded pallets with only a few seconds between boards.

**35.4.6.1 Tooling Plates.** Tooling plates utilize bushings and a slot on the centerline of the active pattern under each spindle. They are doweled to the machine table (Fig. 35.10). The plates may be made by normal machine shop practice, or the router may be used to register and drill its own tooling plate. Mounting pins in the tooling plate should be light slip fit.

**35.4.6.2 Subplates.** Subplates should be made of Benelax, linen phenolic, or other similar material. The pattern to be routed should be cut into the subplates' surfaces. The patterns act

**FIGURE 35.10** Typical tooling of numerically controlled routing.

FIGURE 35.11 Tooling schematic for numerically controlled routing.

as vacuum paths and aid in chip removal. Part-holding pins should be an interface fit in sub-plates and snug to loose-fit in the part, depending on cutting technique used (Fig. 35.11).

It is recommended that the programmer generate the tooling and hold-down pinholes in addition to the routing program. That will provide absolute registration between the tooling holes and the routing program.

### 35.4.7 Cutting and Holding Techniques

Since the precision required for cutting board outlines, as well as the placement of tooling holes for registering boards, will vary, a number of different cutting and holding methods may be used. Three basic methods are illustrated here.

FIGURE 35.12 No-internal-pin method. Step 1: Cut three sides (a). Step 2: Apply masking tape (b). Step 3: Cut parts away.

Experimentation will determine which method or combination of methods is most applicable to a particular job. With all methods, the minimum dimension for board separation with a 0.125 in. cutter is 0.150 in.

- No-internal-pin method** If no internal tooling pins are used, the procedure of Fig. 35.12 may be employed, but it is normally used only when no other method is possible. Characteristics of this method are as follows: accuracy,  $\pm 0.005$  in.; speed, slow (best used with many small parts on a panel); load, one panel high for each station.
- Single-pin method** The single-pin method is illustrated in Fig. 35.13. Characteristics of this method are as follows: accuracy,  $\pm 0.005$  in.; speed, fast (quick load and unload); load, multiple stacks.
- Double-pin method** In the two-pin method, there is a double pass of cutter offset; see Fig. 35.14. Make two complete passes around each board, the first pass at a recommended feed rate and the second at 200 in./min. Remove scrap after the first pass. Characteristics of this method are as follows: accuracy,  $\pm 0.002$  in.; speed, fast (highest-accuracy system—loads and unloads slower than single-pin method due to tight pins); load, multiple stacks.

FIGURE 35.13 Single-pin method.

FIGURE 35.14 Double-pin method.

## 35.5 SCORING

Scoring is a circuit board fabrication method used to make long, straight cuts quickly, and therefore is often used to create rectangular profile board shapes. More commonly, however, it is used in concert with CNC routing for complex shapes, enabling each tool to be used to its unique advantage. When used with routing, scoring has a much wider application and can provide simple breakaway for complex profiles (Fig. 35.15).

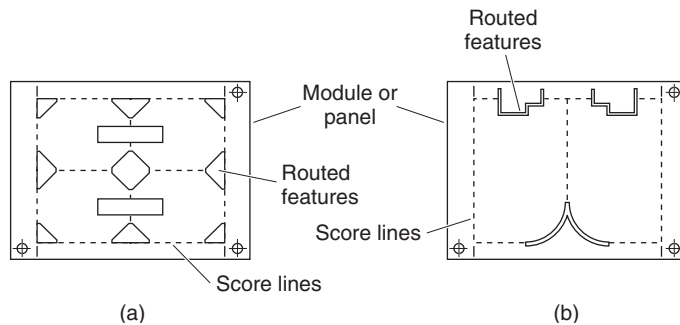

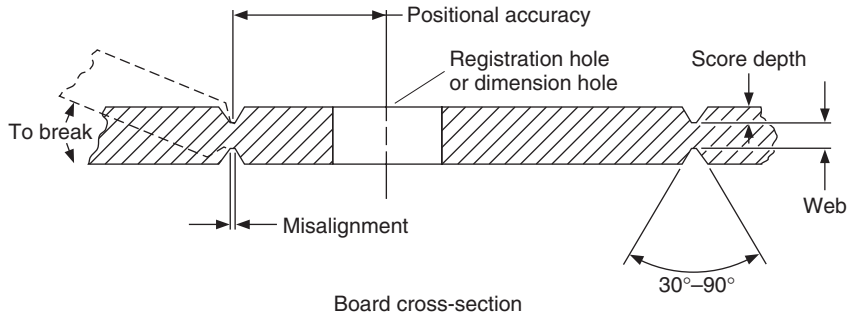

FIGURE 35.15 Scoring processes: (a) module or panel with typical scoring lines and routed corners; (b) scoring lines and routed complex features.

### 35.5.1 Scoring Application

Scoring is accomplished by machining a shallow, precise V-groove into the top and bottom surfaces of the laminate, generally with the use of CNC equipment. The two most significant elements of the score line are as follows:

- The positional accuracy from the reference feature (usually the registration hole)
- The depth of the score, which determines the web thickness

The final edges of a scored circuit board are yielded by breaking the panel, or border, at the score line (Fig. 35.16). The angle of the cutting tool is reflected in the V-groove geometry, and limiting this angle to  $30^\circ$  to  $90^\circ$  will minimize the score line intrusion into traces near the edges of the circuit board. The score line exposes the laminate glass fibers and resin. Measurements from these surfaces will vary greatly, even though the score line is precisely machined

**FIGURE 35.16** Cross section of board, showing finished V-groove and break.

(Fig. 35.13). These irregular surfaces will be noticed as dimensional growth and should be considered in design or planning when designated as a scored edge.

Positional accuracy Board cross-section Registration hole or dimension hole Misalignment Web Score depth To break 30°-90°

The dimensional accuracy of the final board is determined by the degree of precision with which the following are performed:

- Misalignment within  $\pm 0.003$  in. of the score line from the desired location
- Web thickness within  $\pm 0.006$  in. of the designated dimension

Typically, a nominal web thickness is 0.020 in. for 0.060 in. thick FR-4 boards and 0.014 in. for 0.030 in. thick FR-4 laminate. For CEM-1 or CEM-3 materials, 0.040 in. and 0.024 in. nominal web thickness values apply, respectively. These web thickness values enable sufficient module strength to avoid accidental or premature score separation while providing simple breaking efforts without excessive edge roughness or growth.

## 35.5.2 Operation

Two major types of panel scoring systems are available:

- Dedicated CNC scoring machines utilizing high-speed carbide or diamond-embedded cutter blades, operating as a pair, one on each side of the board. This generates the V-groove on each side simultaneously
- Drills or driller/routers equipped with scoring software and spade type carbide bits, generating score lines on one side of the panel at a time (Fig. 35.14)

**35.5.2.1 Dedicated Scoring Equipment.** The dedicated CNC scoring machines are high-production, precision computer-driven machines. With an exception or two, they utilize blade type cutting tools of all-carbide or with carbide inserts, as well as diamond-embedded varieties, and are designed to self-center the panel.

The panel feed rate is high due to the blade's ability to operate at high-surface-foot cutting rates. Scoring both sides simultaneously with one pass contributes greatly to elevated production processing. This equipment utilizes pin or edge registration, with positioning of score lines and steps by programmed instructions. The vertical adjustment of the cutter blades permits variation in V-groove depth, and on many models jump scoring is available. The ability to do jump scoring, or score/no-score segments along a simple line at desired points, is programmable.

**35.5.2.2 Multiple-Role Machines.** Scoring with CNC drillers or driller/router machines equipped with scoring software produces score lines only on one side of the panel per machine cycle, although each spindle can be used. The panel and program data must be flipped to score the second side. The panel registration method is similar to that of routing, using existing tooling holes to pin the panel to the machined tooling plates. The tooling plates must be machined flat to ensure uniformity of score depth. Brush-type spindle pressure foot inserts should be used to apply downward pressure during score line cutting. Spade-type carbide tools of various angles and configurations are used in the spindles. Typically, multiple passes (two or three) may be required to produce a clean, uniform score line.

## **35.6 ACKNOWLEDGMENT**

---

### 36.1 INTRODUCTION

---

Advances in packaging technology resulting in finer board geometry, including the various forms of high-density interconnection (HDI), have combined with increasing data rates to put significant pressure on the electrical test area. Fixture construction is more expensive and requires improved process control. Advanced test methods, such as radio frequency (RF) impedance testing, are more often required. Global price competition demands reduced costs. Meanwhile, original equipment manufacturers (OEMs) demand that board manufacturers accept increased liability for defective product—thereby demanding improved fault coverage. This chapter is devoted to the why, what, where, when, and how of current electrical test methods useful in meeting these requirements.

---

### 36.2 THE IMPACT OF HDI

---

Test engineers are currently confronting significant changes in test requirements that derive from changes in the product itself. Notable among these changes are those driven by the growth of various HDI technologies. Examples of common HDI applications are direct chip attach (DCA), high-density ball grid array (BGA), and variants of these often referred to as chip scale packaging (CSP). In addition, higher-density input/output (I/O) connectors are commonly applied. In addition to the changes in physical geometry, HDI also implies increasingly high data rates and clock speeds. Advanced means are being applied that verify not only the ability of the product to interconnect electronic components, but to do so in a manner that guarantees signal fidelity.

An analogy is possible comparing the impact of HDI on board technology with the impact of the sound barrier on aerodynamic flight. This analogy is readily applied to final electrical testing. It was popularly imagined that the sound barrier was impassible, or could be passed only by Buck Rogers in his silver rocket—that beyond the speed of sound was no place for an airplane to go. As it turned out, passing the sound barrier *was* difficult, and required rethinking many aerodynamic principles. But the resulting vehicles are still recognizable as aircraft. They have wings, they burn fuel. They meet all of the objectives of earlier craft, and do so in a superior manner. The test processes that are resulting from the impacts of HDI upon final

electrical testing are similarly recognizable evolutions of previous methods, employing familiar base technologies, but in new combinations and with added features that actually improve test coverage rather than diminishing it.

Proposals have circulated for radical new measurement approaches to electrical testing. These have included the use of electron beams, laser-stimulated photoelectric effects, and gas plasma techniques in configurations similar to existing flying probers. In each case, the board is scanned without use of a custom test fixture. To date, all of these methods involve compromise of fault coverage, or add little or no fine-pitch performance beyond conventional methods. Relaxation of test criteria is not a relief available to most users. HDI product types demand increased fine-pitch capability. These finer trace and via geometries increase the risk of latent defects and increase interest in measurement methods most sensitive to precursor symptoms of such defects. As a result, none of these approaches has seen widespread adoption.

Rather than witnessing radical breakthroughs, the market has seen a steady improvement in the availability of software and hardware tools that provide for the effective combination of the best features of conventional test systems and increased availability of test systems dedicated to specialty markets, in particular the small-format laminated chip carrier product type.

### 36.3 WHY TEST?

Why pay for testing? Why do we need to test? The answer has several components. The primary assumption is that not all boards produced are good. If we could look at the yields through the history of the industry in printed wiring boards using similar technology, we would see exponential reductions in the percentage of bad boards produced. Process improvements and a wide variety of quality improvement programs continue to make a difference. In spite of these improvements, the need for electrical testing remains.

#### 36.3.1 The Rule of 10s

One reason to test is to block the addition of further value to defective product. Consider the printed wiring board as a component of a completed assembly. A commonly accepted relative measure of the cost of faults in a completed electronic assembly can be expressed by the rule of 10s (see Fig. 36.1). The idea is that the earlier a fault is caught, the less it will cost. An example might be an open in a bare board that is not found at bare board test. The faulty bare board is now loaded with the components, soldered, and tested. If the fault is found at the loaded board level, repair or scrapping of the assembled board is much more expensive than repair or scrapping at the bare board level. There are situations where the assembler of the board charges back to the manufacturer of the bare board some portion of the cost of the scrapped components, assembly labor, and/or production cost. This is increasingly true with the high-cost and high-capability integrated circuits (ICs) present in so many designs. A fault that passes a system-level test and makes it to the end user entails even higher cost. Some of these costs are very tangible in the form of field service labor, downtime, parts, and labor. Other costs are counted in lost business and reputation.

FIGURE 36.1 Rule of 10s: cost of a found fault.

#### 36.3.2 Satisfying Customer Requirements

Where the rule of 10s is a logical big-picture approach to the necessity of testing, requirement from a customer is quite the opposite. The board user has already determined that electrical

testing is appropriate and necessary and has made it a requirement as part of supplying the board. It is the obligation and responsibility of the bare board manufacturer to meet this requirement of purchase contracts. In practice, we find such customer requirements stated in various ways.

**36.3.2.1 Generic or 100 Percent Board Test.** Unfortunately, this requirement may be nothing more than the words “100 percent electrical test” appearing somewhere in a purchase order or a larger package of documentation. Not only is such a specification relatively meaningless, but the issuer of such a requirement is led to believe that the boards will be tested to the most stringent requirements—that it will not be possible for a single bad board to be delivered. Nothing could be further from the truth. Such a specification fails to define what a 100 percent test consists of. The purchaser of the bare board will certainly be dissatisfied when he or she receives a bad board. Although the specific fault on the bare board in question may have a perfectly viable explanation (might not be detected electrically, or may be undetectable by the specific methods employed), the 100 percent test specification implies that no explanation is acceptable. In many cases, application of this general sort of specification is combined with a customer-imposed limitation on test cost, which in turn requires cost-driven limits on the thoroughness of electrical testing performed by the board manufacturer.

**36.3.2.2 Written Test Specification.** It is the responsibility of both the bare board manufacturer and the bare board purchaser to agree upon a test specification that is specific in terms of test thresholds and method of testing while keeping in mind the appropriateness to the application for the bare board design. Some limits on test thresholds and test methodology may be due to equipment and capabilities of the manufacturer. It is the responsibility of the bare board manufacturer to educate the end user as to the implications of test specifications in thoroughness and cost of testing. A matrix of test options, fault detection capabilities, escape risks, and associated costs should be presented to the end user. It is the responsibility of the end user to work with the bare board manufacturer to develop specifications appropriate to the bare board being produced and to accept and plan for any testing compromises imposed by cost or specification limits. Areas that should be covered in the specification are:

- Data-driven testing, source of data, format, and integrity
- Test thresholds: maximum allowable for continuity verification
- Test thresholds: minimum allowable threshold and applied voltage for isolation verification
- Test fixture methods: single fixture with simultaneous access of all test points versus split-net fixtures versus flying probe
- Test point optimization
- Board marking indicating electrical test satisfaction
- Resolution of discrepancies in process (contacts and procedures)
- Requirements for special test methods (time domain reflectometry [TDR], embedded passives, etc.)
- Resolution of escapes

Such agreements make for good communication, clear understanding, happy customers, good reputation, and good business.

**36.3.2.3 Using Available Standards.** Industry standards or guideline documents such as IPC-9252, “Guidelines and Requirements for Electrical Testing of Unpopulated Printed Boards” (which replaces IPC-ET-652), are useful in developing agreed-upon written specifications for a particular product.

Standards documents must be applied in consideration of the target application. An excessively rigorous specification would result in unacceptable test cost with little quality improvement.

Arbitrarily high isolation voltages or continuity test currents can actually lead to product damage. Conversely, relaxing isolation resistance specifications on boards containing sensitive amplifiers would be inappropriate. These are but a few examples. In IPC-9252, the IPC has made efforts to distinguish between general classes of board applications, suggesting specific electrical test requirements that attempt to recognize different levels of criticality in testing.

Final determination of the suitability of a given set of requirements must be made in cooperation with technical representatives of the bare board purchaser.

### 36.3.3 Electrical Testing as a Process Monitor

A third benefit of testing is the improvement of processes and the resultant reduction in costs. To raise yields, reduce scrap, or generally improve quality, there must be a system of measurements able to express results of changes. One of the best areas to collect data is electrical testing. This usually requires an integration of testing and repair data. While the test system can identify a bad board and the location of a fault, a repair operator can further classify the fault to associate it with a specific process (imaging, plating, etching, solder masking, etc.).

These data can be quantified and analyzed in a variety of ways, and corrective action may then be directed to one or more of the following levels.

**36.3.3.1 *Faults Specific to the Operation.*** Fault types may be detected that are not typical of the industry or competition. It can be difficult to assess this type of situation accurately because data commonly available from the customer, alternative vendor, or competitor are likely to be narrow or biased. It may be better to analyze fault types specific to an operation in terms of cost or profitability. Are certain product types profitable to manufacture? What would be the cost to make them profitable?

**36.3.3.2 *Faults Specific to the Process.*** An analysis of fault data may lead to a specific process that regularly induces faults in a wide variety of part numbers, or in a variety of part numbers sharing key characteristics. This may point to requirements for new settings, procedures, materials, training, personnel, equipment, etc.

**36.3.3.3 *Faults Specific to a Part Number.*** Fault data on a specific part number are useful in correcting and optimizing processes for future runs of the same part number, and often for similar future part numbers. It may be possible to feed back electrical test data in real time using software systems, depending upon lot size, factory flow, and the type of test and repair analysis equipment available for use. In this situation, results from electrical testing may help drive some adjustments or quick changes in the process that will immediately improve the yield and reduce scrapping, repair, and retesting costs.

### 36.3.4 Quality System Improvement

Quality control analysis of fault data is only a piece of what needs to be in place already, that is, a quality control system or process. The value of electrical test (or other process) data for process monitoring is only as great as the quality control framework making use of it. It is possible for electrical test results to become a vehicle for improvements to a board manufacturer's quality system.

## 36.4 CIRCUIT BOARD FAULTS

---

For electrical test purposes, faults may be defined as test system measurement results other than those programmed to be representative of a good board. The faults detected may or may not impact the functionality of the circuit board, though in most cases they will. Some guidelines

may prove useful when more specific guidance from the original specifier or designer is lacking. Obviously, gross shorts and opens in a circuit are likely to cause problems. Will an electrical test system find all the faults? No. The definition of “all the faults” is too subjective.

The electrical test system will not detect all faults related to aesthetics, annular rings, layer-to-layer registration, etc., unless they present an effect measurable by the test system. Further, the electrical measurement employed, type of test fixture, test program generation method, and end-use requirements vary too widely to state broadly that electrical testing will find all the faults.

For purposes of the following discussion, it is worthwhile to clarify the distinction between a defect and a fault. A fault is a test system designation for an item that does not meet the expected criteria. A defect refers specifically to the board and a defect in its design, fabrication, appearance, etc. Not all defects can be detected by the test system.

### 36.4.1 Fault Types

Table 36.1 presents common fault types. For those fault types that are commonly detected, it is valuable to distinguish types of tests from types of faults. It may be preferable to refer to isolation testing or continuity testing rather than to shorts or opens testing, as the latter meaning is often confused. Shorts and opens are results, not test types. Test methods themselves are discussed in detail elsewhere in this chapter.

**TABLE 36.1** Test and Fault Types

Test type	Fault type identified by test
Continuity	Open
Isolation	Short and/or leakage
TDR or network analysis	RF impedance fault
Hi-pot	Voltage breakdown

**36.4.1.1 Shorts.** Shorts, hard shorts, or short circuits are defined here as erroneous (undesired and unexpected) low-resistance connections between two or more networks or isolated points, typically exhibiting a fairly low electrical resistance value. Shorts are reported as failures of the isolation test of the product. Shorts are produced in a variety of ways, including exposure problems, underetching, contaminated phototools, poor alignment of layers, defective raw material, and improper solder leveling.

**36.4.1.2 Opens.** Opens represent an absence of expected circuit continuity, or in other words, a missing connection. This divides a circuit network such that the network is split or divided into two or more pieces. Opens are reported as failures of the continuity testing of the product. Opens are produced in a variety of ways, including overetching, underplating, contaminated phototools, contaminated raw material, layer registration errors, and mechanical damage. A common problem during electrical testing is “false open” errors, typically the result of localized contamination on the product or test probe that prevents proper connection to the test system. Of particular concern in testing substrates employing microvias are latent defects (those which may appear after test during subsequent substrate assembly processing). Examples are improperly formed conductors at stress points where cracks may form during thermal or mechanical stresses of assembly. Small HDI features are less tolerant of such defects. These may be completely undetectable at the time of test, or limited examples may be detected by especially sensitive ohmic measurements able to detect a limited conductor cross section where a future open circuit may occur. Frequent observation of such defects indicates the need for process changes if field failures are to be avoided.

**36.4.1.3 Leakage.** A leak or “leaking network” is essentially a type of short. Leaks are also referred to as high-resistance shorts, and differ from hard shorts in that they exhibit a higher resistance value. The precise division between the two types of error reports varies according to the type of equipment used, and some equipment does not attempt to distinguish them in fault reports. As in the case of hard shorts, leakage is a failure of the isolation testing of the product.

Common leakage causes are moisture, chemicals, or debris. Contamination can occur during innerlayer fabrication, lamination, plating, solder masking, or any stage due to handling. Chemical contaminants are often deposits of metal salts left as artifacts of the chemical processes used to manufacture the product. With sensitive test methods, even fingerprints can result in detectable leakage between networks. Such contaminants are often spread over an area of the board such that several networks become interconnected. Consideration of the potential for multiple network involvement is useful in selecting the particular isolation test algorithm or test method, as these methods differ in their sensitivity to this situation. Isolation test methods are discussed elsewhere in the chapter. Some circuits are not sensitive to the high-resistance loads immediately presented by such contaminants. But it is important to note that, in the presence of time, electric fields, and moisture, it is possible for the resistance of a high-impedance short to decrease greatly. Contamination sites may facilitate the growth of metallic crystals that reach out as thin metal threads between networks, forming hard shorts.

Thus an area of the product exhibiting unusual leakage may, at some future time, exhibit hard shorts between networks. This amplifies the need for effective high-impedance testing of high-reliability product types as a means of preventing latent field failures. Note that the nature of board materials is such that they can absorb moisture relatively easily, and they do so over time. Thus even a fairly “dry” contamination providing a very weak electrical path may eventually result in sufficient metal migration during product operation to cause a serious field failure.

**36.4.1.4 RF Impedance Fault.** Many circuits produced today are required to operate at very wide bandwidths. Examples include fast microprocessors, fast general digital circuits, RF amplifiers in wireless devices, etc. Just as we must use a proper type of cable to connect a television antenna to a TV receiver, it is important for specific RF characteristics to be maintained in interconnections between components of fast electronic circuits on printed wiring boards. One parameter commonly specified and measured is the RF transmission line impedance of the signal traces. This parameter is strongly affected by the materials used in fabricating the board, the trace thickness and width, and the spacing from ground planes and adjacent signals. A common method of measuring RF impedance is to employ TDR.

The TDR measurement provides a statement of RF impedance as a function of distance along the trace. (Distance and time are related here, as the electric signal flows through the board at velocities approaching the speed of light.) TDR testing is often performed on a test coupon attached to the product during manufacture and subsequently disconnected. TDR testing on actual product traces is also done on selected traces, but is complicated by the need for a trace length of several inches, uninterrupted by branches or other constructions. Common values for RF impedance on circuit boards range from the low tens of ohms to several hundred ohms.

RF impedance should not be confused with ordinary direct current (DC) resistance and cannot be measured with common ohmmeters, even though the same unit of measure—the ohm—is used.

RF parameters of interconnections can also be characterized in the frequency domain using instruments referred to as network analyzers, but this method is not common in bare board testing. Requirements for RF impedance testing are more commonly applied as signal frequencies exceed 100 MHz.

**36.4.1.5 Hi-Pot Faults.** Hi-pot or high-potential voltage breakdown testing is often confused with isolation testing. The tests are very similar, and, to the extent that high voltage is

employed in an isolation test, they might achieve a similar result. But isolation testing of bare boards commonly occurs with 250 volts or less applied between networks, and hi-pot testing is often performed at values from 500 volts to several kilovolts. Hi-pot testing attempts to verify the strength of the insulating material between networks by subjecting it to so high a voltage that a catastrophic or avalanche-type voltage breakdown will occur if the insulator is subpar. In contrast, isolation testing on bare boards attempts to detect the small current flowing through contamination (or, for that matter, a hard short) before voltage breakdown occurs. Of course, if the insulator is very weak, then avalanche failures can occur at almost any voltage. Hi-pot testers tend to be benchtop devices with a pair of test leads and no switch matrix, and hi-pot test requirements usually specify that the voltage be applied for a sustained period of time.

Hi-pot testing is valuable for inspection of very thin insulating core material, before circuits are etched. This can serve to detect z-axis faults or contamination in the material before value is added in subsequent processes. It can be impractical to perform hi-pot tests between all conductors of finished fine-pitch boards, as the atmospheric environment (air) between conductors will break down before high voltage is reached. The slow speed at very-high-voltage hi-pot testing and the costs of suitable fixtures and electronics present problems. For final product inspection, it is arguable that a very-high-impedance isolation test provides the superior solution.

# BARE BOARD TEST METHODS

---

**David J. Wilkie**

*Everett Charles Technologies, Pomona, California*

---

## **37.1 INTRODUCTION**

Although the main bare board testing technology is electrical, it is important to consider that nonelectrical methods are also important in the acceptance or rejection of bare printed wiring boards (PWBs). This chapter therefore includes detailed descriptions of both electrical and nonelectrical testing methods.

---

## **37.2 NONELECTRICAL TESTING METHODS**

There are two nonelectrical acceptance/rejection methods, both based on inspection processes:

- Visual inspection
- Automatic optical inspection

### **37.2.1 Visual Inspection**

Visual inspection is a very manual approach in that it makes use of people, good lighting, some type of training defining what is acceptable and what is not, and good operator judgment.

Usually a comparison to a known good product or the artwork is made. If the operator has seen the board often, he or she becomes more skilled at finding faults and looking for faults in likely locations. As product complexity has increased, we find that many modern products are not suited to this method. Many innerlayer defects are completely undetectable, and even the external layer complexity is visually overwhelming. Visual inspection often remains appropriate for detecting cosmetic defects, such as poor solder masking or physical damage. Such defects generally fall outside the realm of electrical testing as they are not detected by electrical means.

### **37.2.2 Automatic Optical Inspection**

There are computer-based visual inspection methods, referred to as automatic optical inspection (AOI). AOI equipment compares the board or its innerlayers to expected data and/or design rules that have been programmed into the controlling computer. These can be generally

accepted parameters or design-rule-based parameters, or windows of acceptable dimensions for each specific feature on the board. As with manual visual inspection, faults found with this method can imply that there may be an impact on the board's functionality, but the board's functionality and interconnect are not directly tested. Distinctions between the aesthetics of the board's features and its fitness for use are difficult to differentiate, and may result in false failures. Rather than being used in final testing, AOI is used for inspection of innerlayers prior to lamination, with the goal of increasing final yield by weeding out the majority of defective layers prior to the addition of further value. As such, AOI can achieve significant financial benefit. AOI can detect some defect types not readily detected by electrical means, particularly "mouse bites" (brief narrowing of the conductor cross section). AOI may also be used to inspect the outside layers after lamination, but is not generally accepted as a quality assurance substitute for final electrical testing.

### 37.3 BASIC ELECTRICAL TESTING METHODS

Electrical testing is the final test method frequently used to determine whether a board should be shipped. Electrical testing emulates the intended function of the board conductor and insulator patterns by passing currents through conductors and applying voltages across insulators. Such direct electrical measurement requires that the board come into physical contact with a measurement system. Two test types are almost universally performed: continuity and isolation testing. Some other tests may be applied selectively, depending upon the product and customer requirements.

Test order is usually such that the continuity test is performed first. This verifies that each network is intact within itself, and that contact is established between any test fixture and the product. The isolation test can then be performed using only a single test point per network. Some test methods attempt indirect inference of continuity and isolation without making direct current (DC) measurements. These methods are commonly employed in flying probe systems.

#### 37.3.1 DC Continuity Test Method

Continuity testing checks for the expected continuous path within each electrical network. This is done in a series of point-to-point measurements within each network. The resistance found in each measurement is compared to the selected continuity resistance threshold. If the measured value is higher than this threshold, then a fault report is generated. For complex networks, multiple measurements are required in order to ensure that all extremities of the network are interconnected. For example, the network with test points labeled A through D, shown in Fig. 37.1, could be tested in the sequence illustrated in Fig. 37.2. For a network with four test points, the minimum number of tests would be three to determine whether all points are connected. If a board contains a total of  $N$  isolated networks, and contains a total of  $X$  test points, we may calculate the number of continuity measurements  $C$  as  $C = X - N$ . In assigning test points, the software system often is programmed to delete those that are unnecessary. This is referred to as test point optimization. In Fig. 37.1, a test point located along the path between D and the branch to C would not be useful. Various optimization rules may be applied, but should be applied with care to ensure that adequate test coverage remains in place.

FIGURE 37.1 Sample network.

**37.3.1.1 Continuity Test: Two-Wire versus Four-Wire Switching.** Switch matrixes are constructed using either two-wire or four-wire circuits. A diagram

comparing a single continuity measurement being performed on both two-wire and four-wire matrixes is shown in Fig. 37.3.

Grid test systems use solid-state switches to connect appropriate test points to an internal measurement system (which is effectively an ohmmeter). Current  $I$  is driven from the upper test point through the product network and returned to the measurement system through the lower test point. The resultant voltage  $V$  across the network is measured. The continuity resistance  $R$  is then determined using the relationship  $R = V/I$ .

**37.3.1.2 Two-Wire Switch Matrix Construction.** The simplest, most affordable, and most common construction of the switch matrix is to have a pair of switches for each test point that can connect the test point to either the high side or low side of the ohmmeter. This technique is illustrated on the right side of Fig. 37.3. However, as the solid-state switches exhibit a certain amount of on-resistance, they contribute error to the measurement. The resistance of the switches is added to the resistance we measure, increasing the likelihood of failing the test. These errors can be reduced in various ways:

- Use switches with low on-state resistance (and thus a small amount of variation in on-resistance). This means using physically larger transistor dies. Such devices are not expensive, but are harder to integrate into integrated circuits. Thus, most two-wire designs rely upon discrete output transistors as switch elements.
- Use software to subtract the estimated typical on-resistance. As switch resistance effects vary from device to device, and change with temperature, some error remains.
- Make multiple measurements for each continuity to be inspected, and mathematically subtract most of the switch resistance. However, this slows the measurement process somewhat by requiring extra measurements and requires high-quality fixture construction such that contact resistances do not vary during the required multimeasurement sequence.

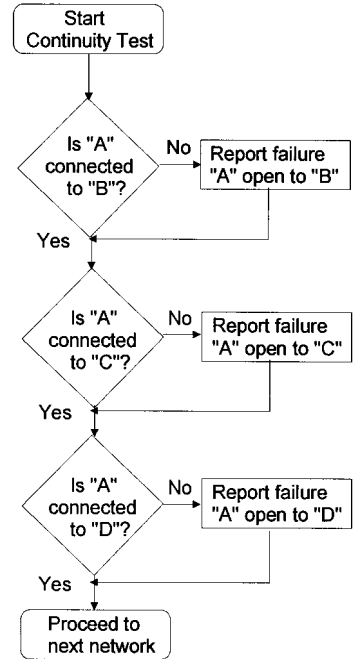

FIGURE 37.2 Continuity test algorithm.

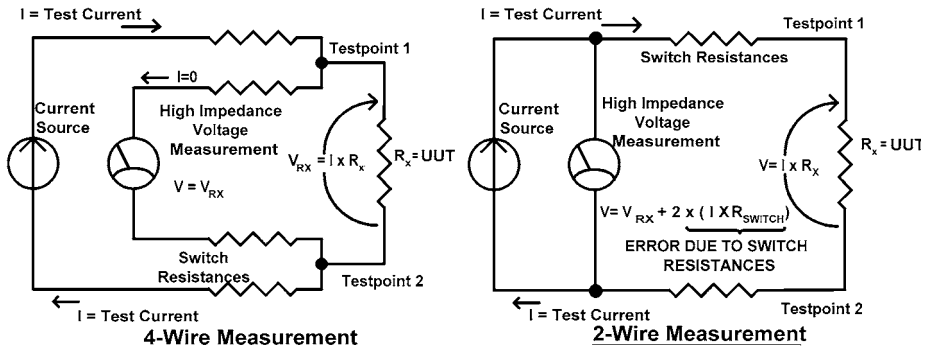

FIGURE 37.3 Continuity measurement circuits.

- Attempt to learn the resistance of each switch. Some systems require the operator to install a shorting plate over all test points, and the system then learns the sum of the switch resistances plus contact resistances to this plate. Note that this technique can actually add error if a high contact resistance value is learned for a particular test point, perhaps due to dirt on a probe. The excessive resistance value learned is subtracted from all subsequent measurements made with that probe, masking some high product resistances. The net result is a slightly increased possibility of passing a board that should be failed.

**37.3.1.3 Four-Wire Switch Matrix Construction.** The left side of Fig. 37.3 represents a Kelvin or four-wire switch matrix construction. Notice that each test point will require four switches, so that any test point can be connected to the high-side current drive, high-side voltage sensor, low-side voltage sensor, or low-side current return via separate paths. Because the voltage-sensing portion of the measurement system has an extremely high input resistance, almost zero current flows through the extra pair of switches that connect the test points to this circuit. The result is that there is zero voltage drop across these sense switches, and the measurement unit sees exactly the voltage across the unknown load. Because the measurement system knows exactly the current flowing through the load, and exactly the voltage across it, it can calculate the load resistance accurately. The dominant error term in this situation is generally the contact resistances in the fixture and fixture-product interface. Also, the smaller transistors leak less current in the off state, thereby permitting isolation testing at higher thresholds with smaller errors. The continuity accuracy benefit of this technique is realized only if high-quality fixtures with low contact resistance are employed.

**37.3.1.4 Continuity Threshold.** The continuity resistance threshold parameter is usually specified in the range from a few ohms to 1,000. Several standards useful in suggesting continuity thresholds are summarized in Table 37.1. IPC-9252 has actually weakened the recommendations of IPC-ET-652, which it replaces. As discussed earlier in the chapter, these must be applied with judgment. Generally, a lower continuity threshold provides a more stringent test of the board. Networks with resistances of 5, 10, or 25, although rare when using copper traces of moderate length, can significantly impact the functionality of precision measurement instruments or high-speed computer products. At the same time, it should be noted that there are practical and economic considerations in determining how low the continuity test threshold should be set. Part of the limitation comes from the test system's measurement and switch matrix capabilities and, to a greater part, from the type of test fixture used. At the time of this publication, a 10-continuity resistance test threshold is a common lower limit for production testing with good-quality systems and fixtures.

**TABLE 37.1** Examples of Continuity Resistance Test Threshold Standards

IPC Board Class	IPC-9252	IPC-ET-652 (obsolete)	MIL-55110D (obsolete)
Class 1: General Electronic	< 50–100 Ohms	< 50 Ohms	< 10 Ohms
Class 2: Dedicated Service	< 50 Ohms	< 20 Ohms	< 10 Ohms
Class 3: High Reliability	< 50 Ohms	< 20 Ohms	< 10 Ohms

**37.3.1.5 Continuity Test Current.** Continuity test current is not addressed in IPC-9252 or in most other publications. Use of high current has been proposed as a means of burning out weak traces or mouse bites. But such currents may also damage good traces. If this occurs after the test system has already determined that there is a good connection, the result is a board that once tested as good but is now bad. It is preferred that the continuity test not be invasive or destructive. Typical test currents today are in the range of 5 to 50 mA.

**37.3.1.6 Continuity Test False Opens.** A common problem with continuity testing is a high incidence of false failures due to fixture and product contamination, poor product registration, or fixture damage. Dramatic improvement is often possible with the addition of product and fixture cleaning methods. Separation of the board-testing environment from such dust-producing processes as drilling/routing can be invaluable in increasing throughput. High-voltage pulses are sometimes used to overcome thin-film contaminants or oxides coating the surface of the board and preventing good contact with the test probe. As no current is initially flowing through the oxide, some test systems offer a feature delivering a high-voltage pulse of strictly limited current and duration, and therefore limited total energy. While brief, the energy level is higher than for a normal continuity test and a small risk of damage at defect sites remains. Adding test time for automatic or manual retesting of the product yields additional boards, but this common approach becomes expensive when large numbers of false opens occur. It may be advisable to correct the root cause.

### 37.3.2 DC Isolation Test Method

Isolation testing verifies the presence of adequate electrical isolation between networks that are not intended to be connected to one another. Typically a resistance measurement is made from a given network to another net (or group of nets). If the measured value exceeds the specified isolation resistance threshold while the specified voltage is applied, then the measurement is considered to have passed. Otherwise, a fault report is generated. So long as contact with the net has been ensured (during the continuity test), only a single test point per network is required to perform the isolation test. The actual number of isolation measurements required to test a given board can vary substantially with details of the algorithm employed, with subtle impacts upon fault coverage. These issues are discussed in a separate section.

**37.3.2.1 Isolation Resistance and Voltage.** As isolation testing is a means of evaluating the ability of product insulation to withstand voltage and prevent current flow, it is common for the isolation test specification to include not only a statement of minimum resistance, but also an applied voltage. This is the voltage that the insulator must withstand while exhibiting at least the minimum isolation resistance. Given the relationship  $R = E/I$ , increasing the applied voltage is also a means of increasing the measurement current level up out of the noise floor internal to the test system. Thus, high-voltage-capable bare board test systems usually are able to verify isolation at higher resistance levels and do so at reasonable speed. Typical values for isolation resistance can range widely, from as little as 1 k. to as much as 1000 M. Values of 2 to 10 M are common, but higher values are useful in detecting trace contamination. Excessive humidity in the test area may preclude the use of very high thresholds and may affect accuracy at lower thresholds. Values below 50 to 55 percent relative humidity are desirable. Common isolation test standards (see Table 37.2) have not always kept pace with the capabilities of new equipment to test at elevated and sensitive thresholds. In any event, assignment of specific test thresholds would ideally be based upon a competent analysis of the intended application of the specific circuits on the product to be tested.

There is somewhat less emphasis on test voltage than was true previously, probably as a result of increasingly fine geometry in the product. Older or simpler test systems may be limited to 10 to 40 volts, but most are able to apply 100 to 250 volts during the isolation test.

**TABLE 37.2** Examples of Isolation Resistance Test Threshold Standards

IPC Board Class	IPC-9252	IPC-ET-652 (obsolete)	MIL-55110D (obsolete)
Class 1: General Electronic	> 500 K Ohms	> 500K Ohms	> 2 M Ohms
Class 2: Dedicated Service	> 2 M Ohms	> 2 M Ohms	> 2 M Ohms
Class 3: High Reliability	> 10 M Ohms	> 2 M Ohms	> 2 M Ohms

**TABLE 37.3** Examples of Isolation Test Voltage Standards

	IPC-9252	IPC-ET-652 (obsolete)	MIL-55110D (obsolete)
Minimum isolation test voltage	High enough to provide sufficient current, but avoid arcover	High enough to provide sufficient current, but avoid arcover	All least 40 volts, or twice the rated voltage of the board, whichever is greater

A higher voltage increases the test current, providing a better signal-to-noise ratio and generally improving test speed at higher isolation thresholds. Excessive voltage is inappropriate for very fine-pitch substrates and may result in damage from arcing in normal environments (see Table 37.3). The insulating properties typical of modern board material suggest that it may be of little value in specifying elevated voltages while using low (relaxed) threshold resistances. Raise the resistance threshold first, then use enough voltage to get adequate speed and accuracy.

**37.3.2.2 True Isolation Test Method.** Several different algorithms have been developed for sequencing the switching state during the isolation test, and the choice may affect test coverage. In the most rigorous method, each network is individually tested to determine the total parallel leakage resistance to all other networks on the product. This requires one measurement per network, as illustrated in Fig. 37.4 for a board with three networks. Each network is, in turn, given a chance to charge to an elevated voltage. All other networks are connected together and to 0 volts at this same moment. Notice that only one test point is needed per network.

**Test 1: Raise net AB positive while nets CD, E are Grounded.**

**Test 2: Raise net CD positive while nets AB, E are Grounded.**

**Test 3: Raise net E positive while nets CD, AB are Grounded.**

**FIGURE 37.4** True isolation test of three-network board.

If the network under test is shorted or leaking to any of the other networks, or to any combination of them, it will fail to charge adequately and the test will fail. The pattern continues until each network has been tested.

Figure 37.5 illustrates the status of the measurement system during the three tests. Notice that test points A and C are used to access their respective networks, and that test points B and D are not needed for the isolation test. These test point switches remain open through all measurements.

A key feature of this method is the ability to answer the rigorous question: “How well isolated is this network from the rest of the board?” Consider the example illustrated in Fig. 37.6.

FIGURE 37.5 Measurement sequence for three isolations.

FIGURE 37.6 Parallel leakage detection.

Here the isolation threshold is 100 M. Four leakage paths exit network A, one each to networks B, C, D, and E. Each path, measured separately, is well above the 100-M. pass/fail threshold. But electrically we can only guarantee that network A is isolated by the parallel combination of these four resistances, given by:

$$R_A = \frac{1}{(1/R_{AB})+(1/R_{AC})+(1/R_{AD})+(1/R_{AE})} = 68 \text{ Mohms}$$

Thus, the true isolation test method will correctly fail this measurement. A not unlikely real-world situation would be a smear of contamination that touched A, B, and C.

**37.3.2.3 Log of (N) Isolation Test Method.** Table 37.4 illustrates the log of N isolation test method, and compares it to the true isolation method described earlier. The log method offers the powerful advantage that only a small number of measurements are required to test a complex board. That number is given by log<sub>2</sub>(N) rounded up to the next whole number, where N is the number of networks.

Thus, for a board with eight networks, we need only three measurements. The gain is even greater for large boards. For a realistic board with 4,000 networks, only 12 measurements would be needed.

This method involves a compromise of fault coverage for parallel leakage detection. Consider the example shown in Table 37.4. The top half of the table considers a very simple board with eight networks and illustrates the pattern of measurements required by the log method.

**TABLE 37.4** Isolation Methods Compared

Measurement number	Network name							
	A	B	C	D	E	F	G	H
<u>Log method</u>								
1	+	+	+	+	-	-	-	-
2	+	+	-	-	+	+	-	-
3	+	-	+	-	+	-	+	-
<u>True method</u>								
1	+	-	-	-	-	-	-	-
2	-	+	-	-	-	-	-	-
3	-	-	+	-	-	-	-	-
4	-	-	-	+	-	-	-	-
5	-	-	-	-	+	-	-	-
6	-	-	-	-	-	+	-	-
7	-	-	-	-	-	-	+	-
8	-	-	-	-	-	-	-	+

Networks noted with a + in a given measurement are connected to the upper side of the measurement system. Networks with a - are connected to the lower side. Notice that in each measurement, about half the networks are positive and half are negative.

A hard short between any two networks in Table 37.4 will be detected by either method. In at least one measurement, a + will be at one end of the short, and a - at the other. Both methods work well for hard shorts, and parallel resistance effects play no significant role. But consider the effect of two 15-M. leaks, one from network A to network B and the other from network A to network C. If the threshold is 10 M., this fault will not be detected by the log method, but the true

method will fail test measurement #1. The log method is ineffective because there is no one measurement that has the + end of the measurement system on network A while the—end is connected to networks B and C simultaneously. (Were the A–B resistor moved to A–D, then we would detect an error on measurement #2 of the log method.)

The log method may fail to detect certain combinations of high parallel leakage. For product types where a low isolation resistance threshold is acceptable, this may not be a significant issue. Note that this risk may be reduced by substantially increasing the test threshold, such that a larger proportion of individual leaks are likely to trigger a fault report.

**37.3.2.4 Isolation Failures: Distinguishing Shorts and Leaks.** Earlier discussion made a distinction between hard shorts and leakage failures, although both reports result from the isolation test. Consideration of either the true isolation test method or the  $\log(N)$  method shows us that neither method immediately tells us the opposite end of the short or leak (refer again to Table 37.4). In the true isolation method, we know that the network under test is leaking or shorted to some other network, but we don't know which one. Initially the  $\log(N)$  method tells us slightly less: We know only that the short is between that half of the networks switched positive and the half switched negative (or ground). Upon fault detection, either method must call a subroutine to search all network pairs systematically to localize the fault. Searching all networks in pairs for leakage can be slow as well as ambiguous. Therefore, some test systems allow the user to disable searching for leakage.

In the case of distributed leaks, a clear answer may be impractical because searching pairs of networks never connects all of the leakage paths in parallel. The effort to localize a high-resistance leakage may report the entire problem, part of the problem, or none of the problem. The exact result depends upon the actual leakage resistances present, the pattern of networks involved, and the isolation resistance threshold. Note that a flying probe system seeking to “verify” defects may be unable to detect some or all leakage for the same reason. It may be advisable to return such boards to a grid (or other fixtured tester) for final pass/fail.

## 37.4 SPECIALIZED ELECTRICAL TESTING METHODS

---

Certain special testing methods have evolved to provide for detection of defects more subtle than simple shorts, opens, or leaks. Additional methods have evolved as suitable to specific types of test equipment, notably the flying prober. These are discussed in the following text.

### 37.4.1 Hi-Pot Testing

Hi-pot or high-potential testing is very similar to isolation testing, but is commonly distinguished by the magnitude of the applied voltage and, to some extent, by the expected behavior of the detected failure. In the context of bare printed circuit boards, hi-pot testing usually refers to voltages over 250 volts, often 500 to 3,000 volts. The objective is to locate faults in the dielectric (insulating) layers of the board that may result in subsequent field failures at lower voltages.

When the dielectric is subjected to a voltage substantially in excess of the expected working voltage, certain types of material defects can result in an “avalanche” mode of failure of the insulation. Ionization of the intervening material or atmosphere occurs, resulting in a sudden increase in current flow to some relatively large value. Visible arcing and/or burning may result at the failure site. This contrasts somewhat with the isolation test, where a very subtle leakage current flow is usually detected using a somewhat lower voltage. Most often, the isolation test is less destructive as the total energy delivered is less. However, depending upon product conditions, arcing can occur at many voltages and in such cases an ordinary isolation test is essentially the same as a hi-pot test.

It is often impractical to perform hi-pot tests on finished products, except at limited numbers of test points. Equipment limitations are one factor, it being expensive to construct test equipment and fixtures capable of routing such high-voltage signals to a large number of test points. However, the product itself is often a poor target for such tests when evaluated in finished form. Modern products are often constructed with relatively fine spaces between conductors.

On the surface layers of the board, the exposed component connection sites are usually too close together to withstand very high voltage stress without surface arcing. Such arcing is destructive to perfectly good product. The voltage at which such arcing will occur is a function of product geometry and atmospheric conditions.

In consideration of this, the most common practical application of hi-pot testing is to inspect raw material for defects before etching. For example, a thin FR-4 core, clad with copper on both sides, might be evaluated by placing a high voltage across the opposing sides. Any crack or other defect in the insulating material may ionize, resulting in a large current flow. Thus the defective material is rejected before substantial value is added in subsequent processing.

### 37.4.2 Embedded Component Tests

Methods of embedding certain electronic components *within* the board have been developed. The most common example is the embedded or “buried” resistor. Such resistors are constructed by embedding a layer of partially conductive material within the board. By selectively removing (or adding) material, the resistance value is adjusted. Accuracy ranging from a few percent to many tens of percentage points is realized. Typical resistance values range from a few ohms to thousands of ohms. The most common use of this technology is within high-speed digital circuit designs to replace large numbers of termination resistors with a resistance of 200 ohms and lower. Measuring these values accurately is challenging, requiring good fixture construction and cleanliness. Another difficulty with testing of buried resistors is obtaining usable expected value data for the resistors. At the board shop, most resistors are specified as a shape and a type/thickness of resistance material rather than as a specific resistance value and tolerance.

It may be necessary to analyze the circuit pattern and compute the net resistance of series and parallel combinations, arriving at a measurable final resistance value for the tester.

Embedded capacitors may also be present. All boards exhibit capacitance between various traces, and especially between planes. The amount of capacitance is determined by the parallel surface area of the conductors, the thickness of the insulator between them, and the dielectric constant of the insulating material. Some product designs seek to maximize the desirable noise suppression benefits of capacitance between power and ground planes by making the intervening insulator thin. Some go further and use special insulating cores for these layers.

This is the common form of buried capacitance. Most bare board test systems are not well suited to measuring capacitance values, particularly small ones. In some cases, no measurement is specified and it is only important that the test system tolerate the presence of the capacitance. When measurements are specified, it is usually true that few test points are involved. It may be expedient to use benchtop equipment.

### 37.4.3 Time Domain Reflectometry

Time domain reflectometry (TDR) is a measurement method often used to verify the radio frequency (RF) impedance of a signal conductor on a circuit board. The RF impedance is important to the proper function of high-speed digital or RF applications. Examples include computer products, cellular telephones, radios, etc. The RF impedance of a signal path should not be confused with the DC resistance, as verified during the continuity test. It is common for

a trace with seriously errant RF impedance to demonstrate a very solid DC connection (i.e., low DC resistance). The RF impedance of the trace is most strongly affected by the trace's width, thickness, z-axis spacing from the ground plane, the location of adjacent traces, and the relative dielectric constant of the type of insulating core used to build the board. These parameters are usually rather constant within a particular panel, justifying use of coupons as a means of monitoring the delivered product. Standard bare board testing systems (other than flying probes) do not incorporate TDR capability, as the signal paths through the fixture will not pass the fast-risetime TDR signal. TDR is commonly conducted on a test bench manually.

TDR test systems inject a very fast-risetime voltage step into one end of the conductor. Discontinuities in the RF impedance level along the conductor result in reflected voltage waves being returned to the driving point, where they are collected by the same probe that injected the signal. The result is usually presented as a graph of RF impedance versus distance from the point of injection. Because of reflections and disturbance occurring at the point of injection, a minimum trace length is needed to get a meaningful measurement. Extremely short networks are not ideal candidates for TDR measurement. A trace 2 in. or more in length is generally required to obtain a useful reading. Longer traces may provide improved accuracy of the result. A branch-off to a second signal path along the measured length will disturb measurement badly; thus an undisturbed signal path provides the best measurement target.

A typical TDR result graph is illustrated in Fig. 37.7. This illustrates a region of approximately 50 ohms RF impedance, rising toward infinity as the trace ends in an open circuit at the right, but falling between the upper and lower pass/fail bounds in the region of interest.

Sample testing using handheld probes is popular and practical, but the influence of hand and body position on the measurement can be significant, reducing the repeatability of the result. Several vendors offer flying probe solutions dedicated to TDR test. While requiring some additional setup they are faster at higher volumes and greatly improve repeatability.

FIGURE 37.7 Typical TDR measurement.

### 37.4.4 Test Methods Unique to Flying Probe Systems

Because flying probe systems contact pairs (or other limited numbers) of points at any one time, they cannot directly perform precisely the same isolation measurements as can universal grid (and other fixtured) systems. DC isolation is performed between pairs of networks, with the number of measurements reduced by determining which networks are adjacent to the network being tested and therefore likely to cause isolation problems. Otherwise, flying probes are capable of ordinary DC continuity and isolation measurement, as discussed earlier. In addition, most flying probe vendors have developed alternative measurement methods that reduce the number of measurements and therefore reduce time lost to mechanical motion. These methods are discussed in the following text.

**37.4.4.1 Indirect Measurement of Isolation or Continuity.** Different vendors have developed various implementations of indirect measurement, but in general these methods share a general assumption that a given product network will display a certain amount of capacitive or other electromagnetic coupling to neighboring planes or traces. The amount of coupling is affected by the geometry of the traces involved. If a trace is broken, the remnant will display reduced coupling. Similarly, if a trace is shorted to another trace, the amount of coupling will increase substantially. If the test system measures the amount of coupling from each trace to a ground plane (or other electrical environment), a degree of confidence can be obtained that all traces are intact. No direct measurement of isolation or continuity is necessarily made.

Instead, the coupling signature is used to imply the correctness of the configuration. As no direct measurement of isolation or continuity is made, we refer to these methods as indirect measurements.

Typically these methods are highly reliable in detecting hard shorts and opens, but may be less effective in detecting distributed contamination or high-resistance connections of several meg ohms or more. Specific methods include constant-current capacitance measurement (charging or discharging variations), voltage-source measurement of Resistance-Capacitance (RC) time constant, alternating current (AC) capacitance measurement, and measurement of the electromagnetic coupling of an AC signal between adjacent networks.

The capacitive techniques using constant currents are generally based upon the approximation:

$$C = i \frac{dt}{dv} \text{ or, } C = i \frac{\Delta t}{\Delta v}$$

where  $C$  is the network capacitance,  $i$  is the charge or discharge current, and  $v$  is the change in voltage that occurs during the measurement time  $t$ . Related, though more complex, behaviors occur for RC time constant and AC coupling measurements.

Using the preceding example, note that if two networks are shorted, the resulting capacitance is the sum of their individual capacitances. The larger capacitance causes a slower charge rate than is expected for either net individually. The system may note that these two networks are adjacent and displaying suspiciously similar charge time behavior. The system tags the networks as suspicious, and either fails them or verifies the presence of a short with a DC measurement. Networks containing an open will have reduced capacitance and will charge or discharge too quickly. These conditions are illustrated in Fig. 37.8.

To use these indirect methods, most systems require testing of a first article board using standard direct measurement methods for both continuity and isolation. Once the board is known to be good, the signal-coupling behavior is learned for each network on this board. The learned values are saved and compared to measured results from subsequent boards as described previously. Tremendous speed increases are obtained by eliminating repetitive probing of each network at multiple locations, particularly in the case of isolation testing. Some users combine a traditional DC continuity measurement with the indirect method as a substitute for isolation.

FIGURE 37.8 Indirect measurement: constant-current discharge.

**37.4.4.2 Adjacency Analysis: Isolation Testing on Flying Probe Systems.** Adjacency analysis simplifies isolation testing on flying probers by reducing the number of measurements, even for direct measurement methods. In adjacency analysis, a database is prepared listing each network and all traces found to be immediately adjacent to that network according to a set of geometric criteria. Such locations are assumed to represent the sole opportunities for shorts and leaks. Isolation testing is then performed only between adjacent pairs, this measurement being well suited to the nature of the flying prober. It is important that attention be paid to whether such analysis is three-dimensional. Networks may cross over a network horizontally, but on a different layer of the board. A hole or defect in the intervening insulating layer may allow a short or leakage to occur.

In the example illustrated in Fig. 37.9, network A would probably be judged adjacent to B, but not to C. B would be considered adjacent to A and D. Assuming that the qualifying dimension was a bit smaller than the distance from E to either B or D, E might not be judged adjacent to either.

FIGURE 37.9 Network adjacency.

## 37.5 DATA AND FIXTURE PREPARATION

An essential element in any test operation is the means of generating test programs, and, in the case of fixtured tests, the design of an appropriate test fixture. There are several methods for deriving this program and fixture information.

These methods vary from simple to complex and from escape-prone to very sound. The most common terms used in the language of bare board testing for the test program development are self-learning and netlist testing. *Netlist testing* is a misnomer that confuses computer-aided design (CAD) output with test inputs and implies that there is not much in between. In this discussion, we will use the term *data-driven test program* to indicate the program to be loaded into the test system is derived from the board's design data (which may be provided in any of several different forms). On the other hand, a self-learned program is derived by placing an assumed good board on the test system and causing the test system's internal computer to create a

program automatically that can be used to compare other boards to the detected pattern. It is worth noting that the description “known good” is often used to describe this first board, when in fact our knowledge of its quality is often imperfect.

Flying probe test systems generally require no fixturing, except sometimes a frame to hold thin boards or to load multiple small boards simultaneously. Flying probers still require test program generation and optimization. Instead of a fixture, the product program contains probe position information for planned test. Data preparation processes are therefore similar to those of fixtured tests, but only test program data are output.

Note that the extractions of program and fixture information are quite naturally linked. In fact, the final test program cannot be created until the fixture is defined. The fixture determines how the individual test points of the test system are connected to specific product locations.

Knowledge of how the fixture has taken hold of the product is essential to determining which system test points to employ in performing specific measurements. Thus, the same software system generally outputs both the final test program and the fixture drilling/loading information.

### 37.5.1 Self-Learning

Self-learning has increasingly limited application and is subject to certain escape risks derived from assuming that the original circuit board is good. The self-learning method requires that a fixture be already available, as well as a known good board (preferably). A shorting plate is placed on the fixture in place of the product, and the test system uses this to identify which test points are employed in the test fixture. (All test points found shorted to the plate are considered active. This eliminates test points of no interest, shortening the test program and saving considerable execution time during both learning and testing operations. This set of active points is sometimes referred to as a mask.) The known good board is then substituted for the shorting plate, and the pattern of product interconnections is learned and saved as a test program.

A few boards are tested, and, if results appear reasonable, the program is considered valid. The key drawback of the method is that self-learned test programs determine that all the boards are the same, not that they are good. Moreover, for economic fabrication of the test fixture, it is necessary to process product data anyway; thus we may as well have output a data-driven test program. With virtually 100 percent of board designs being CAD-driven, there is little motivation to use self-learning today.

### 37.5.2 Data-Driven Testing

The preferred method of deriving program and/or fixture data is data-driven programming (DDP), sometimes referred to as netlist testing. The basic idea of data-driven test programming is to test the board using the same database used to specify its manufacture—in other words, the original design database. The fixture and DDP development process can be divided into two stages:

- Input/extraction, the preparation and processing of the various possible input sources into a format usable by the second stage
- Fixture data, test program, and repair file output, and subsequent application of the data.

Factors such as data quality and completeness, the format of data available, and fixture design can significantly reduce or extend software processing and engineering time. Board technology, size, and complexity tend to increase time requirements. While software tools are

not always the most immediately visible tools in the testing department, the completeness and automation of software tools can have a large impact upon whether you are able to set up and test boards quickly and efficiently rather than struggling to build fixtures quickly—while testing very few boards.

Ideal fixture software readily accepts the product data, analyzes the data, recommends an optimal fixture design including all fabrication details, and outputs computerized numerical control (CNC) files for fixture fabrication, material requirements, special procedures required, and a test program in the proper format for the selected test system(s).

**37.5.2.1 Selecting Fixture Software.** A complication arises due to the mechanical incompatibility of many types of test systems. If the available equipment includes something of a grab bag of different equipment types, the test manager's task is made considerably more difficult in several ways. Aside from the obvious problems of manufacturing different fixture types, the manager is also faced with difficult load-leveling tasks. In such circumstances, the test manager may be forced to select general-purpose fixture software packages. By virtue of offering many configuration options, these require additional operator training and present increased opportunity for error. If the testing equipment uses a shared fixture type, it becomes possible to standardize the software process (and raw material). Optimized configurations may be locked into the software, minimizing error opportunities.

**37.5.2.2 Test Data Extraction Methods for Fixtures and Programs.** The initial stages of processing include the acceptance and inspection of the input data to ensure that they have been presented in a valid format. These data are then scanned to determine which sites on the board deserve test points, and what measurements are required among these test points in order to ensure proper continuity and isolation of the product. There are a variety of input sources, summarized in subsequent sections.

A usual goal of the extraction process is to eliminate unnecessary test points. According to predefined rules, the software identifies those end points of each network segment where test pins can and should be placed. For example, a T-shaped network probably requires three test points, located at the extreme extensions of each arm of the T. This provides sufficient connectivity to the product to permit a complete continuity test. One point per network is the minimum needed to attempt isolation testing, and two points per network make the isolation test more robust by permitting the tester to ensure that these points are in proper contact with the product.

The following is a generic description of the software process, where CAD or photoplot information is available.

- **Data orientation** The toughest side of the board in terms of test centers is usually oriented face down. It is often easier to manage a heavier, more complex fixture on the bottom side of the test system. This may require flipping or inverting the data.
- **Test site identification and optimization** Depending upon customer preference, it is often true that some test points can be deleted from the program. Figure 37.10 shows a network with a midpoint B that does not need to have a test point on it. The test points at A and C are all that are necessary to determine whether this network is isolated and contains no opens. Test point optimization can reduce the number of points in a fixture by 10 to 50 percent, thereby reducing the cost of the fixture and the time needed to test the board.

**FIGURE 37.10** Optimizing a network.

Although optimization provides some economic and minor throughput benefits, this must be offset by any impact upon the repair process and by any fault coverage risk. Midpoints can provide failure data that help the repair station more easily pinpoint the actual fault site. Where an operator is required, or when flaws appear in the algorithm, the deletion of test

points can add to the risk of test escape. Optimization is sometimes not performed, speeding data preparation and reducing escape risk but adding cost to the fixture.

- **Pin type assignment** Once the test sites have been identified, test pins can be assigned to the features to be tested. Different pin types may be required for different features. For example, a through hole might require a large head or larger-diameter pin than a surface-mount technology (SMT) pad on 0.025 in. centers. The software usually includes a table relating feature types to pin types.
- **Test system type identification** Mechanical details of the fixture must suit the target test system. The fixture in a universal grid system requires assignment to a grid of uniform centers. A more detailed description of fixture and system types is included elsewhere in this chapter, but obviously the fixture must be built in the correct size and grid density to match the specific test system to be employed. Figure 37.11 shows three of the most common grid configurations available. Single density (100 points per sq. in., or a 0.100 in. grid) is the most common, with double-density systems being added as product technology demands.

Of course, a few systems still use wired fixtures, and here the output will be a set of drill files, a wire list, and the test program. The balance of this discussion focuses on tilt pin translator–equipped grid systems:

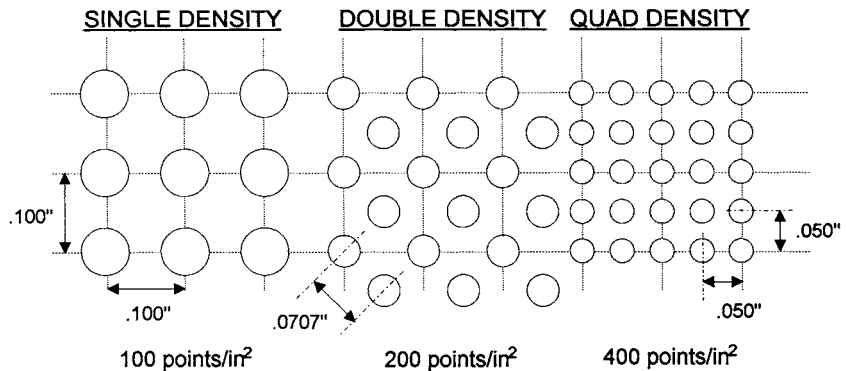

FIGURE 37.11 Single-, double-, and quad-density universal grid patterns.

- **Grid pin mapping** The fixture software determines which system grid location will be mapped to each of the previously determined on-product test targets. Several factors are considered:
  - No two targets can be assigned to the same grid location.
  - No assignments can allow the pins to touch each other as they tilt through the fixture (cross pins).
  - Drilled holes in fixture plates cannot break out into adjacent holes (adequate spacing on all plates).
  - No assignment can require a pin to tilt beyond the predetermined deflection limit (determined by the fixture and pin design).
  - Test sites that are very close together may require that on-product targets be staggered such that the test pins are more widely separated. (See Fig. 37.12.)

- Hole diameter and placement relative to the pin diameter and pin deflection must be optimized. A nearly vertical pin might be assigned a hole diameter just slightly greater than its shaft diameter. This clearance balances avoidance of friction against pointing accuracy during testing. Other pins of the same diameter that are highly tilted will require a slightly larger hole to avoid binding. The fixture adjusts drill sizes for each hole, depending on the amount the pin is deflected. This maintains pointing accuracy while eliminating pin binding. Hole locations may also be shifted slightly to compensate for the fact that the pin is pointed at an angle and that the point of contact will not be at the center of the hole. The result is a more reliable test fixture.

FIGURE 37.12 Test point staggering.

- **Test program output** With all pins fully mapped to grid locations, the test program file can now be constructed and saved.
- **Tooling** The last step in data preparation requires the marrying of the job being processed with the tooling. The tooling includes tooling to the test system and tooling for the specific fixture design utilized.
- **Fixture file outputs** The completed CNC files for fixture drilling and fabrication can now be created and the test fixture prepared.

### 37.5.3 Data Formats

Modern circuit boards are designed using CAD systems. These systems output data files used by the board shop to generate phototools, drill files, routing patterns, and other tools used to fabricate the boards. While several standards have been developed for data outputs from this process that can provide useful data input to the final test process, adoption has not been universal. As a result, test engineers and software providers have developed means of hijacking and converting the photoplot data stream, and can use this to drive the test process with certain compromises and a degree of inconvenience. Both approaches are discussed in the following text.

**37.5.3.1 Gerber Format Data Extraction.** The primary example of “hijacked” photoplot data arrives in Gerber photoplotter format. Even here a standard was eventually developed. RS-274X is a standard that affords a degree of consistency to the photoplotter files. This data stream is a series of drawing commands that direct the photoplotter in drawing the copper patterns for each layer of the board. The drawing is made with a selection of “apertures” that define different pen tip shapes and dimensions. Thus a fine line is drawn by choosing a small aperture, issuing a light-on command, and directing a move. These data are contained in a very large set of files, containing a picture of each layer of the board. Combined with a drill file and aperture definitions, the appropriate information for generation of fixture and test program files is present, but a considerable amount of processing is necessary to develop understanding of layer-to-layer connectivity and finally identify test targets.

Although the standardization of Gerber data has been improved with efforts such as RS-274X, it remains a data format originally optimized for the purpose of photoplotting and not for testing. CAD system developers and board designers have a great degree of freedom in how they design board features and in how these features are represented in Gerber. As a child will readily demonstrate, many different sequences can be used to draw even simple shapes. A rectangle might be created by “flashing” a square pattern, or might be created by an elaborate spiral using a much finer aperture, a zigzag pattern, or a sequence of overlapping flashes. This variety leads to occasional errors, because it is difficult for any Gerber extraction routine to be capable of handling all possible permutations. The software system must successfully interpret any of these examples (and many others) as defining the same intact square area of copper conductor pattern on the final product. Some methods result in huge file sizes.

Despite these problems, this method is far superior to self-learning, digitizing, or drill file extraction, and remains in common use in a variety of software packages. The data requirements to start from this format include:

- Photoplot files for each layer, solder mask layers, etc.
- Photoplot files for silk screen legend(s) (required for computer-aided repair)
- Aperture file
- Drill file
- Board outline

**37.5.3.2 CAD/CAM Data Extraction Method.** Recognizing the problems inherent in photoplot extraction, system vendors have agreed to add support for test-oriented output formats, in particular IPC-D-356 and 356A. These formats provide data in a much more readily digested format, and eliminate most ambiguities in processing the data. These formats include the following data:

- Signal ID, network name, and/or network number
- Reference designator or PIN number (e.g., U14, 12, R11) for the related component on board
- X-y coordinate of pad center (minimum data set requirement if grouped as connected)
- Pad dimensions relative to the center, and size of the hole (if any)
- Resistor or other component values (if appropriate and not usual)
- Board side (top or bottom)
- Mid-network flag suggesting that test point placement may not be required.

Often this data set is converted to a standard such as IPC-D-356 from the CAD/CAM system's internal data formats by means of an intermediate converter. These software converters, although simple, are usually customized for each individual CAD system. A converter must be updated or modified with any output changes made by a CAD vendor due to a CAD system software update or new product introduction. The number of converters required by an independent PWB manufacturer could be quite high, as data will likely be received from many different CAD system types. Fortunately, many of the CAD vendors now include direct output of IPC-D-356 data or readily provide converters. Acceptance of these standards is now such that in many cases even Gerber input data are first converted into IPC-D356 format prior to final processing.

#### 37.5.4 Outputs from Data Extraction

Once all the preparation steps and processes have been performed, there are several outputs generated by the fixture software.

- **Test file** A data-driven test program is outputted in a format compatible with the test system type. This file informs the test system of the measurements expected and of pass/fail criteria. Some test system formats permit the data-driven test program to support a graphical representation of the fixture and/or board on the test system monitor, provided that sufficient data are included in the test program file. This graphical presentation is useful in fixture and/or program debugging.
- **Fixture fabrication files** Probably the most significant output—the drill files, one for each plate or pass required by the fixture design—is needed in drilling to start building the fixture. (In the case of wired fixtures, a wiring list is also required.)

- **Repair/verification files** Files can also be outputted that support the repair or verification function. These relate the graphical image of the board to the assigned test point locations in the program. Preparation often relies on inclusion of Gerber data in the input data stream to the software system. Extensions to IPC data formats are planned to better support the repair function without this recourse to photoplot data. Some test systems may carry trace image information in the test program file as well, for enhanced debugging support on the test system.

### 37.5.5 Setting Up a Fixture

With the fixture assembled and CAD data–derived program prepared, the next step is to set up the fixture on the test system and validate the fixture and program. Details vary with the fixture and system used, but in general the following steps are taken:

- Program data are loaded into the test machine from the disk or network.
- Test thresholds are set to the desired continuity and isolation values.
- Compression settings on the test system are adjusted to the proper values for the fixture type. In some cases, these values may already be included in the test program file.
- The new (or recalled to duty) fixture is compressed with a nonconductive material of similar thickness to the board being tested.
- An all-isolations version of the test program is executed to verify that the fixture does not contain any internal shorts.
- The fixture is then compressed again with a conductive plate in place of the product, intentionally shorting all fixture test points together. Often this plate is a simple piece of copper-clad G-10. Copper oxidation can prevent reliable contact, and users sometimes wrap the plate in fresh aluminum foil or use a flash-gold-covered plate. In this step, an all-shorts version of the test program verifies that all expected test points are continuous through the fixture, up to the shorting plate. The intent is to verify that the number of test points is correct and that, under multiple compressions or closures, all points are present and remain in contact with the shorting plate.
- Assuming proper alignment and cleanliness, the product can then be tested with the final test program. If certain errors immediately repeat on all boards, then it is reasonable to suspect a pin-loading error or other error in the fixture, and investigation is warranted.

The basic techniques just described are generally applicable to all fixture types, whether tilt pin, wired-dedicated, or other specialized types.

Do not underestimate the value of removing dust and debris from the product and fixture, both during setup and occasionally during operation. Target sizes on modern products are not tolerant of debris, and false open circuit reports are an immediate result. Tacky roller-type cleaning systems may be helpful in periodically removing debris from test fixtures, system grids, and the products themselves. Follow the test equipment manufacturer's recommendation regarding the use of electrostatic discharge (ESD)-safe cleaning materials near the test system.

Adjustment of fixture compression is also important, especially on press-type systems where the amount of compression stroke is controllable. (In vacuum fixtures, the dimensions of various fixture plates and components usually fix the amount of compression.) Undercompression usually leads to poor contact and false open results. Overcompression can cause excessive marking of the product by probe tips, probe damage, and fixture damage.

Overcompression is a very common problem, and, unfortunately, so is product damage in the form of excess probe marking. It seems intuitive to just press harder when you experience contact problems, and this is often the first step taken. But the actual change in force per spring probe is very small as it travels further, until the spring probe hits bottom—and at that point you begin damaging the product almost immediately. A typical spring probe in a grid system

presents about 139 g of force when compressed 0.167 in. (two-thirds of travel). At zero travel (uncompressed), the spring inside is already preloaded to about 55 g. The force increases at a spring rate of 503 g/in. Just before bottoming, the spring force peaks at about 180 g. Thus, there is only modest force gain possible before serious danger of bottoming the probe occurs. Consult the spring probe manufacturer for details, but most probes function well at about two-thirds of full travel. If contact problems remain at this level of compression, leave further compression adjustment as a last resort and look elsewhere. Generally, you should never cause the probes to hit bottom. (Some older vacuum fixture probes are a notable exception.)

## **37.6 COMBINED TESTING METHODS**

---

As product density and geometry become more challenging, the cost of fixture construction increases. In a large number of cases, the most challenging test sites occur at only a few areas of the product. It is possible to combine test techniques such that less expensive means are used to test the majority of product features, while more advanced and costly techniques are reserved for the most challenging test sites. Some examples follow.

### **37.6.1 Split Net Testing**

This is perhaps the oldest and most primitive example of a sequential or combinational test. When the product complexity exceeds the capacity of a fixture design to solve the test requirement with a single fixture, it is possible to divide the test responsibility among multiple fixtures. The flip test method of dual-side access described earlier is one example of this. More typically, the test department has dual-side-access equipment, but the density of test sites exceeds the capability of the fixture and/or test system.

One way to split the responsibilities is to divide continuity and isolation between fixtures. For example, one fixture could be limited to two test points per network. These two would be checked for continuity with each other (to verify that there are no open pins in the fixture) and would then be used to perform a 100 percent isolation test of the product. A second fixture would complete the continuity test. In very difficult cases, multiple fixtures can be used.

Handling boards in this scenario is complicated. Boards that pass the first fixture must be stacked and prepared to run on the second fixture. But boards that fail the first fixture must be tagged with failures, and in many cases must be run through the repair process, retested, and combined with the boards being sent to fixture 2. Such failed boards must not be confused with any failed boards from fixture 2, which have already completed the first phase of testing.

Unless there is a large continuous flow of boards with two different test systems/fixtures set up, it is also likely that the two fixtures will have to be installed/removed from the test system a number of times.

### **37.6.2 Manual Combination of Methods**

It is also possible to divide the test burden by testing the majority of ordinary test sites with a test fixture, followed by a flying probe system to test strictly limited portions of the product. Without special software, one has the same handling problems as in the split net case. But it is possible to automate the data handling between the two test systems using network resources, such that a single error tag results from both tests. All boards then flow through both test systems, and any rejects flow to repair. This flow is very similar to that of ordinary testing, resulting in less confusion. An interesting additional benefit of this combination is that the flying prober not only can test those sites that you wish to avoid fixturing, but can also retest any of the failures noted by the universal grid. This can eliminate the majority of false open reports caused by stuck pins and contamination, improving the total first-pass yield.

# CHAPTER 38

---

# BARE BOARD TEST EQUIPMENT

---

**David J. Wilkie**

*Everett Charles Technologies, Pomona, California*

---

## 38.1 INTRODUCTION

---

The largest volumes of bare boards are tested on fixtured systems. However, for smaller volumes or special purposes, “flying probe” systems may be preferable. This chapter discusses them both to enable the user to make the most effective decision based on testing objectives and volumes.

---

## 38.2 SYSTEM ALTERNATIVES

---

### 38.2.1 Fixtured Systems

Each dedicated, or hard-wired, test system presents some sort of standardized interface pattern of test points. This may consist of a universal grid’s continuous array of points (bed of nails) or may be a connector pattern of some type. In the most primitive systems, a simple cable connector may be presented. Each of these types of equipment uses one or more types of customized test fixtures to connect this standard electrical interface pattern to the unique contact pattern of a particular product to be tested.

Each fixtured system includes a measurement unit that can be connected to any of some thousands of test points by a solid-state switching matrix. A central computer controls the measurement unit and switching matrix. This computer also controls the press (or vacuum mechanism), which can compress the product against spring-loaded test points presented to the product by a customized test fixture.

To imagine the system’s operation, first consider the measurement unit to be an ohmmeter. The computer commands the switch matrix to connect the red lead of the meter to, say, test point 17. It then connects the black lead of the meter to test point 1027. The measurement system can then be commanded to measure the resistance of the product under test between test points 17 and 1027. The test program dictates a long series of such measurements organized to test the product completely. Because the switching and measuring occur at the high speeds possible with modern electronics, a complex board can be tested in seconds.

### 38.2.2 Dedicated (Hard-Wired) Fixture Systems

Originally the most popular system type, dedicated systems are generally being displaced by systems employing less expensive and more accurate fixturing methods. The word “dedicated”

refers to the fact that it is generally impossible to salvage very much material from these fixtures for reuse in other fixtures. The cost of these fixtures derives from this fact, and from the high labor and material costs involved in the original construction.

**38.2.2.1 Advantages of Dedicated Fixture Systems.** A primary advantage of these systems is that, because each test point is routed within the fixture by a flexible wire, it is possible to position any test point at just about any location. If your product requires 8,000 active test points, then you need no more points than this in the test system. One hundred percent utilization of available test points is possible. This contrasts with the universal grid approach discussed later, wherein points can be shifted only a small distance from the original location on the grid. In that case, you must have enough electronic test points to cover the entire surface of the product at some constant density, and any given fixture will generally use only a portion of these points. Thus, the capital equipment cost of a dedicated system may be lower, but the ongoing fixture costs may be much higher. Dedicated systems are generally built with no more than about 10,000 test points, with smaller numbers common.

**38.2.2.2 Construction of Dedicated Fixtures.** The test fixture for such systems generally consists of a rigid box structure with one side facing the product to be tested and some other side or surface presented to the interface pattern of the test system. The side facing the product includes the probe plate. This plate of insulating material is drilled to mount an array of spring-loaded pins able to make electrical contact with the product. The reverse side of these pins is connected within the box by physical wires to the system interface connector on the opposite side of the fixture.

Fabrication of the fixture involves the usual data-processing steps, followed by spring probe type selection, drilling of the probe plate, installation of spring probes, drilling of the interface plate, and installation of system mating contacts or connectors. Many spring probe tip styles are available to suit different diameters of target pads and holes (see Fig. 38.1).

**FIGURE 38.1** A variety of spring probes and receptacles.  
(Courtesy of Everett Charles Technologies.)

FIGURE 38.2 Vacuum versus pneumatic compression.

In most cases, the probe plate actually carries a socket or receptacle into which a replaceable spring probe is inserted, simplifying service. The underside of the receptacle protrudes into the fixture box and carries a wire-wrap tail. Each of these receptacle tails must be wired to an individual system interface contact on the bottom of the fixture.

Compression of the product onto the fixture spring probes may be accomplished with electric drives, pneumatic air cylinders, or vacuum (see Fig. 38.2). Vacuum compression can result in the lowest system cost, but adds cost to the fixture and limits the total number of probes that can be compressed.

Many forms of fixture interfaces have been provided, with many appearing as small universal grid patterns. Some very simple test systems have been constructed with a large number of ribbon (or other) cable connectors presented as the only connection to the fixture. The matching wired fixture may be troublesome to connect (because of the large number of cables), but is left connected for days or weeks at a time to a single fixture type due to the quantities of boards being tested.

### 38.2.3 Flying Probe-Type Test Systems

Smaller volumes and specialty parts are tested on flying probe-type test systems. These consist of a small number of robotic probes with independent measurement abilities. These are moved among the various product test target locations, and a sequence of measurements is made. Such systems offer the powerful advantage that no fixture preparation is required (although data must still be processed to prepare the test program). The best of these systems are also able to provide extremely high probe placement accuracy, generally exceeding that of fixtured systems. The primary drawback of such systems is low throughput, as a result of the need to reposition the probes mechanically between measurements.

## 38.3 UNIVERSAL GRID SYSTEMS

The most flexible and widely used electrical test solution is the universal grid test system (see Fig. 38.3). Most systems now include upper and lower grids, permitting simultaneous dual-side access for test of surface-mount technology (SMT)-type products. Grids offer very high test speeds, and moderate the cost of test fixtures by permitting the reuse of many fixture components. Thus, today, the majority of product is tested on universal grid systems and fixtures.

**FIGURE 38.3** Universal grid test system. (Courtesy of Everett Charles Technologies.)

### 38.3.1 Universal Grid Test System Design

The universal grid test system presents a rectangular array of equally spaced test points. Generally this is chosen to be large enough to cover the test area of the largest product type to be tested (see Fig. 38.4). It is common to speak of the density of test points presented.

**FIGURE 38.4** Universal grid testable area.

A single-density system presents points spaced at 0.100 in. (10 per in.). Thus, there are 100 points per sq. in. Similarly, a double-density system has test points spaced at 0.0707 in. and provides 200 points per sq. in., and quad-density spacing is 0.050 in. for a density of 400 points per sq. in. As grid cost is largely a function of the number of test points, larger sizes and/or higher-density configurations become expensive. With modern grid designs, the test system grid size can be upgraded in the field by addition of electronic modules. With older designs that use wire between the grid and the electronics, upgrades may be less practical.

### 38.3.2 Exclusion Mask Fixtures for Universal Grid Systems

Occasionally, some applications involve product whose test-point spacing exactly matches the grid pattern. This situation may permit use of a very simple fixture referred to as an *exclusion mask*. This is composed of a thin glass-epoxy sheet, perhaps 0.030 in. thick, drilled at those locations where test probes are desired to pass through from the grid to make contact with the product. The exclusion mask (see Fig. 38.5) prevents unused grid probes from contacting the product unnecessarily, preventing erratic contacts and marking of the product. To use such a mask, it is necessary that the grid be constructed with a pointed or chisel-tip probe. Unfortunately, few products exist that are so simple to test.

FIGURE 38.5 Exclusion mask fixture.

### 38.3.3 Pin Translator Fixtures for Universal Grid Systems

Most boards manufactured today are tested on universal grids through the use of pin translator fixtures. These fixtures are rapidly designed and produced using available software systems, and the most expensive material components (the contact pins and plate spacers) are generally reusable. These fixtures are also referred to as *tilt-pin fixtures* or *grid fixtures*. Grid fixtures and related software remain the fastest-evolving area in electrical testing. Particular fabrication details will not remain current for long. Therefore, this discussion employs current practice only as means of illustrating key issues such as density and registration.

In a tilt-pin fixture, a rigid pin serves the dual roles of providing an electrical contact path from a grid test point to the product and translating the grid test-point location a small distance horizontally (in x- and y-coordinates) such that contact is made to the desired target on the product surface. Because the product targets are unlikely to be perfectly centered above grid test point locations, these pins are usually somewhat tilted from vertical. The amount of tilt or displacement varies according to the amount of x-y shift required. Several lightweight plates of plastic material support these pins. The individual hole locations in each plate are offset the amount required to achieve the desired pin tilt and spaced apart the required distances (see Fig. 38.6). These pins are variously referred to as *tilt pins*, *translator pins*, or *fixture pins*.

To enable grid test points to be translated to exactly the correct target location on the product, it is important that each translator pin fall into the correct sequence of holes while the fixture is being assembled. If sufficient intermediate guide plates are employed, then the geometry of drilled holes can be so arranged that a virtual tunnel is created for each

FIGURE 38.6 Single-side multiplate tilt-pin translator fixture.

translator pin. It becomes impossible for a pin to fall into an incorrect sequence of holes. More plates are required when the maximum degree of pin tilt is increased. Calculation of plate count, position, and drill hole locations is a key function of the data extraction and fixture software, whose process is described elsewhere in this chapter.

**38.3.3.1 Test Pins for Pin Translator Fixtures.** A wide variety of pins are available for use with different system types and for different applications (see Fig. 38.7). These vary in length, tip style, material, cost, and thickness. For a given angle of tilt, a longer pin is generally able to

FIGURE 38.7 Examples of translator pins. (Courtesy of Giese International.)

translate the test point a larger horizontal distance (larger pin displacement). Pins with enlarged heads of various shapes are useful for probing large-diameter holes. Aggressive shapes such as chisels provide the pin with enhanced abilities for cutting through product contaminants, but may be unsuited to closely spaced test applications. At present, the vast majority of pins are headless music wire pins with lengths ranging from 2.5 to 3.75 in. When probing a large-diameter through hole, common practice now is to probe the annular ring around the hole rather than pay the penalty for an odd-headed pin type.

**38.3.3.2 Pin Displacement in Grid Fixtures.** Pin displacement capability is one of the more significant performance measurements of a pin-fixture design combination. A larger displacement ability provides greater freedom in allocating test points, resulting in improved ability to fixture complex products on a test system of given density. With an arbitrary fixed rule of thumb of  $10^\circ$  maximum tilt, we can see from Fig. 38.8 that the longer the pin, the further the pin can be displaced from its on-grid location to its on-product target location. The maximum pin displacement that can actually be obtained is a function not only of pin length, but also of fixture design and the resultant maximum tilt angle that can be tolerated in the design. The fixture software usually seeks to arrange pins such that the maximum tilt in the fixture is minimized. This decreases the number of guide plates required, minimizes the number of different hole sizes required in the plates, and tends to reduce friction and binding. Nonetheless, a design that permits a maximum tilt capability ultimately provides the greatest flexibility in assigning test points and generally permits the solving of denser products on grids of a given density.

FIGURE 38.8 Approximate pin displacement as a function of pin length.

**38.3.3.3 Pin Binding and Friction in Grid Fixtures.** As noted, the grid fixture pins must lean some distance to connect the grid to the on-product target location. Thus, the relationship between the plate thickness, hole diameter, and angle of displacement is critical. If the plates

**FIGURE 38.9** Pin binding in multiplate tilt-pin fixture.

capture the pin too tightly, binding and friction can result. A pin that is held down below other pins in the fixture by binding will fail to make contact with the product (see Fig. 38.9).

The spring force of the spring probe in the universal grid is intended to supply the pressure that presses the tilt pin against the product. Every bit of friction in the tilt-pin motion subtracts some of this force. If the friction is great, not only may the pin fail to contact, but if the pin is stuck high (toward the product surface), the product may press on it with undue force in shoving it back into the fixture, resulting in excess product marking. Binding can be caused within a single plate by hole diameters that are too small for the degree of pin tilt. Binding can result between plates if the plates are offset from one another, forcing the pin to bend as it snakes its way through the various plates. Binding can also result if the plate spacing is incorrect as compared to the design values.

**38.3.3.4 Calculations for Tilt-Pin Fixtures.** Modern fixture construction software should perform all of the necessary calculations automatically. Yet it is valuable to understand the basic decision processes.

**38.3.3.4.1 Minimum Hole Diameter Calculation.** The relationships between pin displacement, pin diameter, plate thickness, and drilled hole diameters are trigonometric. We calculate Eq. 38.1:

$$A = \sin^{-1} (PD/PL) \text{ and} \quad (38.1)$$

$$HS_{\min} = [SD/\cos(A)] + [PT \times \tan(A)] + HT$$

- where
- $HS_{\min}$  = minimum hole size in a particular fixture plate
  - $PT$  = fixture plate thickness
  - $SD$  = pin shaft diameter as it passes through the plate
  - $PL$  = overall pin length
  - $PD$  = horizontal displacement distance of the pin tail relative to the pin head location
  - $A$  = angle of pin tilt expressed as degrees from vertical. (i.e., a vertical pin has a tilt of  $0^\circ$ )
  - $HT$  = minimum acceptable tolerance to ensure that the pin slides freely in the hole

The first term in the equation derives from the effective increase in shaft diameter in the horizontal plane as the pin tilts (see Fig. 38.10). The second term derives from the horizontal

**FIGURE 38.10** Illustration of hole diameter calculations for a tilt-pin fixture.

distance that the center line of the pin travels as it passes through the plate thickness. The third term, as mentioned earlier, is to provide a minimal clearance.

For angles of tilt below  $15^\circ$ , the value of the cosine is close to 1 (over 0.96), and for rough calculations the term may be omitted. (For a 20 mil diameter pin, the contribution of pin tilt to effective shaft diameter is less than 0.7 mil). Similarly, for the same small angles, the calculation of the tangent can be simplified to  $\tan(A) \approx PD/PL$ . The error incurred increases as the plate thickness increases. For a 0.1 in. thick plate, the error at  $15^\circ$  will again amount to something less than a 1 mil hole diameter.

With these simplifications, for low tilt angles and thin plates, the formula may be reduced to that shown in Eq. 38.2, with an extra mil or two added to the clearance.

$$HS_{\min} \approx SD + [PT \times (PD/PL)] + HT \quad (38.2)$$

For the highest-accuracy applications, use the exact calculation.

**38.3.3.4.2 Drill Bit Size Selection.** Note that the minimum hole size calculated previously is often not the ideal drill size. The most common material used for grid fixtures is polycarbonate.

Polycarbonate tends to have a finished hole size that is about 0.001 in. smaller than the drill size for plate thicknesses typically employed in fixtures. Therefore, 0.001 in. should be included in the tolerance figure  $HT$  to permit accurate drill bit selection.

**38.3.3.4.3 Pin Lean and Pointing Accuracy.** *Pointing accuracy* is defined as the pin's ability to hit an intended target, usually described as a radial dimension (the distance from the intended target to the actual contact location). Because the pin is typically not perfectly vertical, there are several possible sources of error, depending upon the type of pin employed.

With the older headed pin types, the head sat above the top plate of the fixture. With modern headless approaches, the pin tip is usually flush with the upper surface of the top plate while in contact with the product. As the pin tip projects less (nearly zero) above the top plate surface, its tip position in x-y coordinates is better controlled by the hole in the top plate. For this reason, most modern fixture designs operate with the probe tips arriving flush with the top plate surface while the product and fixture are compressed.

It is also preferable that the pins remain approximately flush when compression is released. If they project above the top plate surface, the tip moves out of position in x-y coordinates, as illustrated in Fig. 38.11. When a product is placed on such a pin, the tip initially contacts an incorrect target location. During compression, the pin must drag across the product surface as the pin retracts into the flush position. Thus some spring mechanism, which supports the fixture and pins above the array of grid spring probes, is commonly employed. The fixture may rest on a spring-loaded stripper plate over the grid of spring pins, or the fixture may be designed with spring feet on its underside. In some designs, the fixture kit itself is compressed.

**FIGURE 38.11** Pointing accuracy.

Some fixture designs have used bent or curved test pins. In such cases, the pin is bent by including additional fixture plates such that the tip of the pin as it comes through the top plate is perpendicular to the test pad. This allows the top plate holes to remain on the product and mirror the board under test and thus eliminates concerns about the effects of pin contact at an angle. Common examples of such fixtures were built as spring boxes, such that the overall thickness of the fixture decreases during compression. This eliminates the need for spring feet or a stripper plate, but complicates friction and binding issues as the entire array of test pins must bend and flex during every compression. Contact reliability, product marking, and ease of pin loading all suffer.

**38.3.3.4.4 Offset Error Compensation.** Figure 38.12 represents the problem associated with the deflection of a pin retained in the top plate and its ability to hit the center of the pad or target. As described earlier, the hole diameter must be sufficiently oversized to allow the pin to pass through the hole at its angle of deflection without binding. Vertical force on the pin from the product above tends to press the pin against one side of the hole, as illustrated. (This has the curious effect that tilted pins can display more consistent targeting performance than do perfectly vertical pins.) As the pin tilts, the center line of the pin becomes substantially shifted from the center line of the hole (note the offset distance *OS* in the illustration). Finally, the conical tip associated with most modern pins has a certain finite radius—the pin is not infinitely sharp. Thus, in the illustration, the product will not contact the pin on its center line. As illustrated, contact will come at the highest point of the tip radius, slightly to the right of the

**FIGURE 38.12** Pin tip offset error.

center line. Thus, the theoretical contact point will be at neither the center line of the pin nor the center line of the hole. Probing targets only a few mil wide with probes two or three times as wide requires high-quality probes displaying consistent tip geometry, and software able to calculate the actual point of contact carefully.

**38.3.3.4.5 Countersink Drilling of Top Plate.** The calculations and considerations just discussed illustrate that thicker plates and higher pin tilt present some interesting problems when combined. A highly tilted pin in a thick plate requires a substantially oversized hole if binding is to be prevented. Looking through the hole at a viewing angle equivalent to the tilt of the pin, the hole will appear to be oval, with the narrow axis considerably shorter than the drill bit diameter. Of course, the pin is thereby allowed somewhat more freedom of movement along the major axis of the oval. This bit of looseness can be a problem with very fine-pitch products.

A better solution is to use a very thin plate for the upper fixture plate, backed up by a thicker plate drilled oversize. Alternately, a single plate can be countersunk. The effect is the same, as illustrated in Fig. 38.13.

**FIGURE 38.13** Countersink drilling of top plate to avoid binding or oversize holes.

**38.3.3.5 Retaining Fixture Pins.** It is necessary to retain the pins in a translator fixture such that they do not fall out of the fixture during ordinary use and handling. Older headed pin types were often used in single-sided fixtures. The oversized head protruded above the top fixture plate, and therefore the pin was unable to fall out the bottom of the fixture (although they fell out all too easily if one accidentally inverted the fixture). Early top-side fixtures attempted to duplicate this method for the upper fixture by employing a different pin in the upper fixture half, using an oversized “tail” on the fixture. However, the oversized geometry of the heads is inappropriate for fine-pitch testing, and therefore the use of such pins has fallen out of favor.

The desire to use thin, headless music wire pins necessitated the invention of new means of pin retention (see Fig. 38.14). These have included:

**FIGURE 38.14** Alternative pin retention methods. (a) (b) (c) (d)

- a.** Crimping a wide flat into the pin, and trapping the oversize flat between two plates
- b.** Trapping the pin in a sheet of foam rubber such that friction retains the pins
- c.** Passing the pin through a sheet of spandex cloth that grips the pin
- d.** Passing the pin through a sheet of drilled latex rubber that grips the pin with flexible flaps

**38.3.3.6 Examples of Real-World Fixture Designs.** While many combinations of fixture techniques have been employed, it is worthwhile to compare several popular examples. No substantial discussion of older headed rigid pin types is included here, as their use is largely disappearing. Most fixtures today are built with headless pins that compress flush into the fixture without bottoming on the spring probe below, such that the contact force is entirely controlled by the spring (excluding friction or binding effects).

Figure 38.14a represents a common bent or curved pin design using 3.75 in. music wire pins. The upper and lower fixture plates are held apart by a spring mounting, and the entire fixture compresses during actuation. The pins hit the intended target perpendicularly, because they bend toward vertical as they reach the product area. But extra force is required, increasing pad marking. Hole diameter in the top plate can be tightened to improve pointing accuracy because all pins pass through perpendicularly, and a fairly thick top plate is possible. For a given pin length, the maximum possible horizontal displacement is more limited than in straight pin designs, because all displacement must occur in the lower portion of the pin length. The hanging middle plates do not contribute to torsional stability of the fixture design, increasing distortion under compression. This in turn can increase pin binding as the pins try to bend and slide through the compressing fixture envelope. The pins usually used have a flattened crimp trapped between the upper two plates and must be loaded or serviced with the upper plate removed. Pin loading is therefore difficult. The increased diameter in the crimp region limits close spacing of the probe. Finally, the crimp cannot be employed on very fine-diameter pins, as they would weaken excessively.

Figure 38.14b illustrates a significant evolution from Fig. 38.14a. Here the pins are not bent or curved. Shorter pins (3 in.) are sometimes used, providing about the same horizontal translation as in Fig. 38.14a. Deleting the bend significantly reduces pin binding. A retention crimp similar to the previous example is used, relocated toward the bottom of the fixture where the pins are more widely spaced. Pins are loaded from the bottom side, with the lower plate removed. This design still requires disassembly of plates for pin servicing, but the bottom plate is somewhat easier to reinstall due to the possibility of larger hole sizes. Fixtures are usually rigid as opposed to spring-loaded, reducing friction effects during compression.

Variations of the fixtures illustrated in Figs. 38.14a and 38.14b are produced using a foam-rubber pin retention method. In these versions, the crimp on the pin is deleted and a sheet of foam rubber material is sandwiched between the two lower plates. During loading, pins are forced through this foam, and friction holds them in place. This provides the important advantage that individual pins can be replaced without fixture disassembly. Unfortunately, high-density zones incorporating many pins stretch the foam rubber material. The stretched foam holds adjacent pins so tightly that a group of pins becomes reluctant to move except as an almost solid block. The resulting pin binding effect causes contact reliability and product marking problems. Also, the foam tends to deteriorate with time and/or heavy use. As densities have increased, this fixture has become difficult to use.

Figure 38.14c illustrates a retention technique employing a very thin sheet of drilled Mylar combined with a unique feature on the pin. The Mylar sheet is sandwiched between standard polycarbonate plates. The pins employed begin as straight-sided music wire pins 3 in. long. A grinding operation reduces the pin diameter in a short region (about 0.2 in.) of the pin length. The Mylar retaining sheet is drilled with a hole diameter that is slightly smaller than the original pin diameter. As the pin is inserted, it is forced through this undersized hole until the reduced-diameter zone reaches the Mylar sheet. At that point, the pin can slide freely over the 0.2 in. narrowed length. Only in this region are the pins able to move quite freely up and down. The height of the Mylar plate in the fixture is matched to the reduced-diameter portion of the pin, such that the pin is free to move a short distance up and down from its nominal position without falling out of the fixture. Pins are generally specified with the grinding operation performed at locations near both ends of the pin, such that the pin is symmetrical and can be loaded without regard to orientation. This pin demonstrates low friction and good contact, but a few problems remain. The Mylar sheet is thin and fairly brittle. It is not uncommon for a particular hole to fracture when extracting or reinserting a pin, such that the damaged hole can no longer retain a pin. Replacing the Mylar sheet requires unloading all pins and removing one or more plates. Pins for this fixture are expensive, as the grinding operation is difficult. The requirement to grind the pin undersize along a portion of its length limits the minimum pin diameter which may be used without causing the pin to become excessively weak at the narrowed section. As product pitch and density demands have increased further, these issues have become significant limiting factors.

Figure 38.14d represents techniques employed in more recently developed fixtures. These fixtures include nonoriented, nonfeatured pin designs, usually 3.75 in. long. A key feature is retention via drilled latex rubber or undrilled spandex cloth. The drilled latex is not sandwiched but rather floats in a gap between two plates, amounting to 0.1 in. or so. Drilling tends to cut or tear a slit in the rubber rather than to cut a round hole. The result upon pin insertion is that the pin is gripped by a pair of tiny rubber flaps, allowing short motions of the pin to occur without actually rubbing the pin against the rubber. (The flaps are able to move short z-axis distances with the pin.) This provides essentially frictionless pin motion over the short range of travel needed to conform to surface irregularities on the product. Properly sized to match pin diameter, the presence of the holes or slits tends to relieve any accumulation of stress in the rubber sheet in high-density areas, providing good contact reliability under such conditions. The lack of motion against the rubber sheet also promotes long life of the fixture. The presence of the hole or slit provides stress relief in the rubber in high-density situations. Molded one-piece plate spacers speed assembly and disassembly, lower cost, and provide

accurate z-axis position control of the plates. Use of the longer 3.75 in. pin provides maximum pin displacement.

The featureless music wire pin is economical and widely available. A countersunk top plate hole or two-ply top plate is generally used for high-performance applications. Notice that no disassembly is required to service a pin.

A variation of this fixture employs a stretchable fabric web in place of the latex, generally referred to as *spandex*. Under close examination, this material appears as a very fine, stretchable net. The stretchable net requires no drilling operation—pins are just pressed through during the pin-loading operation. However, some stress accumulation is observed in very dense areas.

**38.3.3.7 Intermediate Guide Plates in Fixtures.** Early pin translator fixtures were constructed with only two plates, top and bottom. Modern fixtures add intermediate plates to speed fixture building, produce a more reliable fixture, and make the fixture determined. Determined fixtures ensure that a pin started into a fixture hole during pin loading is able to follow one and only one path through the fixture (without bending). This is required if data-driven test programs are to be used because the test program assumes a specific mapping of grid test points to product targets. The determined pin load must remain constant if the fixture is taken apart and later reloaded; otherwise, the test program will become invalid.

Intermediate plates simplify and shorten the pin-loading process because each pin must fall into the intended track. Assemblers do not have to pick between several possible holes or spend time checking for misloads and/or short circuits. Determined pin loads permit the fixture software to calculate the side loads imposed on fixture plates by the combination of tilted probes in each region of the fixture, adjusting the pin-loading plan until these side loads are balanced. This prevents the fixture from collapsing sideways under compression. The intermediate plates also support finer-diameter pins, ensuring that they do not buckle under load.

As density increases, holes in the various plates become more closely spaced. At some point, for a given plate stack-up, there is the risk that some pair of holes on the next plate will become close enough that a pin being loaded might fall into the wrong hole. At that density, the fixture software must add an additional intermediate plate to the design. Thus, denser fixtures generally require more plates. Fixture software should analyze the requirements of each fixture and delete unneeded plates.

**38.3.3.8 Fixture Plate Spacing Techniques.** Errors in the vertical (z-axis) position of fixture plates can result in pin binding. As a tilted pin travels through the plate stack-up, the hole position in each plate shifts slightly in the x and y directions, according to the amount and direction of tilt. If a plate were to be mounted either too high or too low in the plate stack-up, the drilled hole would no longer be at the correct x-y position, forcing the pin to bend in order to pass through the hole. Pins would become difficult or impossible to load; binding and friction would occur during operation. Sensitivity to this problem increases as the amount of tilt increases.

Early multiplate fixtures used a plate-spacing technique referred to as *post and doughnut*, which had mediocre control of z-axis plate position. A long screw passed through a stack consisting of the fixture plates and thick plastic washers. The washers were drilled in the center, and the plates were drilled with corresponding mounting holes. The screw passed through all of these in turn. The thickness of a given washer determined the space between two plates. The problem was that the errors in washer and plate thickness accumulated through the stack-up. At greater pin tilts, the result was binding. It turned out that the thickness of inexpensive fixture plate material was not terribly precise.

Alternative means of plate spacing have been devised in which a single molded (or machined) part is responsible for the entire fixture stack-up, and which eliminate intermediate plate thickness as an error contribution. One method is illustrated in Fig. 38.15.

**FIGURE 38.15** Molded spacer prevents pin binding.

This molded spacer provides a series of flat surfaces upon which individual plates sit. In a top view, the shape of each surface is modified such that plates slip easily over the top of the spacer, but are locked into position when the spacer is rotated 90°. As long as the spacer is accurately molded, no cumulative plate spacing error results. For midfixture plate supports, a similar part of smaller diameter is used. Short screws at the top and bottom plate secure the support in place. Alternative methods use machined bars around the periphery of the fixture. Either method results in accurate fixtures, reduced parts count, and ease of assembly.

**38.3.3.9 Headed Music Wire Pins.** For very large through-holes, the preferred probing method is to probe the annular ring of the plated through-hole. If, however, this ring is insufficient, a headed pin may be required. Such pins are manufactured with a machined tip attached to a standard music wire pin. Various head shapes are available. These headed music wire pins work in the fixture design much the same as the headless pin, that is, flush in the top plate (see Fig. 38.16), with the exception that the headed pin must be loaded from the top individually.

FIGURE 38.16 Headed pin in a tilt-pin fixture.

### 38.3.4 Dual-Side Testing Considerations

Modern SMT boards often have networks that terminate at component locations on both sides of the board. Continuity testing of such networks requires that the top and bottom terminations of such networks be probed simultaneously. There are three ways to test boards that require dual-side access:

- Flip test
- Clamshell upper fixture
- Dual-side universal grid fixture

These methods vary in terms of test coverage, fixture cost, labor cost, risk of test escape, and required infrastructure. Each method is discussed in the following subsections.

**38.3.4.1 Flip Testing.** Flip testing is a last-resort method employed where up-to-date dual-side equipment is not available and compromising in test coverage is acceptable. The flip test method requires building either two fixtures, one with the top-side image and one with the bottom-side image, or one fixture with both images on it. The board is then tested one side at a time. Although this does provide partial fault coverage, it does not test those plated holes that link the top-side half of a network to the half on the bottom of the board. This poses a significant risk that bad boards will escape the test process. The problem only becomes worse if these interconnecting vias are tented (that is, if they have solder mask over them), preventing probing. In this case, the traces that run from the tented via to the first pad on the network that can be probed are also untested at both sides of the board.

Flip testing is expensive. Not only are two fixtures built, but also many test points are duplicated between the fixtures. Much additional board handling and potential for confusion are involved. The cost and risk incurred would likely justify an equipment upgrade to dual-side test capability.

**38.3.4.2 Clamshell Upper Fixture.** Clamshell testing is another compromise method employed where dual-side equipment is not available. This method provides top-side access through the use of a wired (dedicated) top-side fixture. The method is superior to flip testing in that it can provide complete simultaneous access and full test coverage. However, fixture costs are quite high, especially for top-side test points. In this scenario, a more-or-less normal pin translator grid fixture is built for the bottom side of the board. The board should be oriented such that the busy side of the board faces down, as this minimizes the costly top-side fixture (see Fig. 38.17). Additional test points (called *transfer points*) are added outside the product area on both the top and bottom fixtures, conducting test points from the lower fixture and grid to the upper fixture assembly. Normal wired fixture construction methods are used within the upper fixture to relocate these points to desired top-side product target positions.

FIGURE 38.17 Transfer point clamshell fixture for dual-side access.

To use this method, it is necessary that the lower grid be larger than the product under test such that a number of transfer test points adequate to provide for the upper fixture can be placed outside the product area. Again, the cost of the extra contact points, spring probes, wiring, and other special material and labor processes associated with the topside fixture may well justify an equipment upgrade.

**38.3.4.3 Dual-Side Access Universal Grid.** The third and most widely accepted method of providing for volume testing of dual-side product is the double-sided universal grid. Such systems provide electronics and grid probe fields on both the top and bottom sides. Upper and lower translator fixtures are built for dual-side products using the standard techniques discussed earlier, providing economical fixtures, reusable pins and hardware, full fault coverage, excellent throughput, reliable contact, and accurate targeting.

### 38.3.5 Press Units

The major mechanical component of the grid is a press unit. The three major compression methods used to compress the product onto the fixture are hydraulic, pneumatic, and electric. The total force requirement can be quite large. The spring probes employed in grids usually require a force in the range of 4 to 10 oz. each. A large, complex board may have 20,000 active points per side. This amounts to 5,000 to 12,500 lb. of force, depending upon the probes used.

Hydraulic drive is probably the least used compression method. Although it provides tremendous power, it is difficult to maintain and fluid leakage is a problem. Pneumatic and electric compression are popular and successful. Electric drives are easy to control, but become expensive and/or slow when larger forces are required (as in the case of larger grids). Pneumatic systems are fast and powerful, but require a good supply of clean, dry, compressed air. With any method, accurate compression control is critical to reliable fixture performance.

As noted, universal grids present the test points as an array of spring-loaded contacts. A variety of contact tip shapes have been used, but most contacts used today offer waffle tips.

Waffle tips are nominally flat, but with an *H*-shaped pattern of grooves cut into the surface to provide a somewhat aggressive contact surface. Such a surface is better able to cut through thin contaminants on any surface it contacts.

## 38.4 FLYING-PROBE/MOVING-PROBE TEST SYSTEMS

---

Moving probe, flying probe, and x-y prober are all names for test systems that make use of two or more test points that can be accurately positioned anywhere on the board surface by means of a computer-controlled motion system (see Fig. 38.18). Probe tips can be retracted in a z-axis direction away from the board surface, then moved in the x and y directions to a new board

**FIGURE 38.18** Flying-probe test system. (Courtesy of atg Test Systems GmbH.)

**FIGURE 38.19** Two probe tips contacting board. (Courtesy of Probe Inc.)

location and extended again to make contact. Figure 38.19 shows two probe tips contacting board. Dual-side systems generally provide a minimum of two independently moving probes per side for a minimum total of four heads.

#### 38.4.1 Advantages of Flying-Probe Systems

The major advantage of these systems is elimination test fixtures, making these systems ideal for small-to-moderate volume production. Advanced flying-probe systems provide highly accurate probe placement, and contact the board with minimal force, leaving no discernable witness marks on most surfaces. They are very well suited to testing the finest pad sizes. Although not subject to limitations due to test-point density, these systems do slow down as additional test points are added.

Direct current (DC) continuity test measurements are accomplished by placing one probe tip at each end of the continuity to be verified and performing a measurement. The probes then retract, move to the next measurement site of interest, make contact, and make the next measurement. Similarly, it is possible to perform DC isolation testing of a network by placing one probe (probe A) on the network, while another (probe B) checks all other networks in sequence for the presence of a short or leak. Probe A can then be stepped to the next network to be tested and the process repeated. This continues until each network has been checked against all others.

This requires a huge number of measurements. For a board with  $N$  networks, the total number of measurements  $M$  required would be:

$$M = (N^2 - N)/2$$

For example, a fairly ordinary board with 1,000 networks would require 499,500 measurements. Fortunately, several means of reducing the measurement burden have been developed.

The program preparation software can analyze the conductor pattern on the board and, noting that short circuits should occur only between physically adjacent conductors, reduce the number of measurements required. This is termed *adjacency analysis*. To achieve further time savings, the testing department might use an indirect measurement method. Please refer to Sec. 38.4.4.

Some indirect methods require only a single probing action of each net, combining continuity and isolation testing with some extra probing to verify any suspect results. Theoretically, our example board with 1,000 networks might have isolation verified with only 1,000 probe placements.

### 38.4.2 Economics of Flying-Probe Systems

The primary limitation of flying-probe test systems is throughput. Although systems with up to 16 test heads are commonly available, these systems still lose a substantial fraction of the operating time due to mechanical positioning of the heads. Yet the cost savings derived from elimination of direct fixture costs, fixture support infrastructure, fixture debugging, and so on, are substantial.

Accurate comparison of the costs associated with grid and prober methods requires inclusion of all the costs associated with each approach. Common omissions include:

- Labor overhead
- Floor space allocated to fixture storage, materials, and assembly
- Costs outside the test department (such as drilling)
- Stranded investment in completed fixtures, pins, other fixture materials
- Stranded investment in drills and other equipment
- Lost throughput of test systems due to maintenance
- Lost throughput of fixtured systems during fixture setup, debugging, and maintenance
- Peak throughput demand

It is quite possible that, depending upon product mix, a testing department would be made more efficient with a larger investment in capital equipment (in the form of flying probe systems) and a smaller investment in fixtures. With smaller runs and/or smaller lots necessitating frequent fixture teardown/bring-up, this becomes more likely.

### 38.4.3 Flying-Probe Throughput Enhancement Systems

The tremendous advantages of flying probers for advanced substrates (such as the ability to hit the smallest targets even on large panels, the lack of fixture cost, witness mark reduction or elimination, and fractional ohm measurement) have traditionally been offset by the relatively slow speed of test compared to universal grid methods. As products have included increased amounts of high-density features, test managers find that flying probers are the solution that can reliably contact the smaller features without damaging them. This has provided tremendous motivation for flying-probe manufacturers to find ways to increase throughput.

Recognizing that many of the test targets are easily measured (only a fraction of the sites on most boards presents the majority of the challenge), one new approach uses an extra piece of equipment to prescreen the boards before they are placed on the flying prober, eliminating many of the measurements from the flying prober's task list. This approach is described in this section, with each of the two commercially available models summarized.

In the first case, a row of thousands of regularly spaced sliding contacts moves relative to the board surface, scanning the surface electrically as a row of scan lines. The contacts are designed to be individually flexible and to apply minimum force, eliminating witness mark concerns for most surfaces. Adjacent to the row of contacts is a planar section of a pliant conductive surface. This surface electrically grounds all exposed conductors on the board that lie beneath any part of the planar area. This conductive plane is fixed in position relative to the row of scanning contacts and extends to within a fraction of an in. of the row of scanning contacts. The relationship is illustrated in Fig. 38.20.

**FIGURE 38.20** Flying-probe throughput enhancement system. (Courtesy of Everett Charles Technologies.)

As relative motion of the board to the scanning contacts/pliant conductive plane occurs, a high-speed measurement apparatus constantly makes measurements among the scanning contacts and between the scanning contacts and the pliant conductor. For example, if a scanning contact is at one moment making electrical contact at one point end of a network so that another end of the same network is being grounded by the compliant planar surface, then current injected into the scanning contact will fail to increase the voltage of (that is, fail to charge)

the network. The pliant planar surface holds the network grounded. Similarly, if two adjacent networks are simultaneously contacted by different scanning contacts, and if at that moment no area of at least one of these networks is grounded by the compliant planar, then it will be observed that at least one of the two networks can be charged to a high voltage and that they must not be shorted together. Software in the prescreening system uses the real-time measurement results to “image” the board and constantly adapt to any shifts in geometry. Thus the system solution is useful for very-fine-pitch substrates appearing in large-panel form.

In a manner similar to the preceding examples, significant portions of most boards may be tested using this apparatus. Some portions of the board usually remain untested, and these measurements are reserved for the subsequent final test by the flying-probe test system. The flying prober also retests and verifies any failures reported by the prescreening system, effectively eliminating most false failures. The resultant speed increase of the combined systems is tremendous, so that true production volumes can be tested. It is important to note that no fixture is required and that both systems provide for true DC measurement of continuity and isolation. Moreover, because high-density interconnect (HDI) features that are too fine for the scanning contacts of the prescreener are simply passed on to the prober, this solution seems to be appropriate for very advanced substrates.

A second commercially available pre-screening system is very similar, but uses a capacitive measurement made at each time of the finely spaced row of scanning contacts. The overall function is very similar to that just described, except that the alternative of a true DC measurement of continuity and isolation is not provided. For those customers that do not perform such tests with their existing flying probers, this may not prove a significant limitation. For high reliability applications where DC continuity testing is required the utility of this method may be reduced.

### **38.5 VERIFICATION AND REPAIR**

---

The test system identifies faults on the board. Assuming that repaired boards are acceptable to the end user and that it makes economic sense to repair boards, a repair process normally follows testing. Because fixture problems, contamination problems, product registration problems, and other issues often result in false error reports, a verification process usually is added between testing and repair. During verification, a technician reads the fault data and makes confirming measurements to determine whether the reported faults are genuine.

If verification of the fault finds that the fault report is valid, the board proceeds through the repair function. If the fault report is not valid, the board may be either retested or directly shipped, depending on customer requirements, in-house policy, etc.

When deciding on a ship-from-verification policy, be mindful of the possibility of multiple defects masking one another (an open hiding a short) or appearing only under the pressure of the fixture. If possible, it may be preferable to perform a complete retest.

In some cases, simple tabletop meter equipment is used for verification, and verification may actually be done at the repair station by the repair technician. More commonly, some form of computer-assisted search-and-display tool is employed. The computer has information concerning the product and test program available, and searches the artwork pattern for areas likely to contain the fault being considered. The resulting risk area is displayed to the operator or superimposed as a visual projection onto the suspect board, simplifying the task of placing meter leads.

Automatic verification may be accomplished by a flying-probe-type system. The flying probe performs a similar analysis, but does the retesting itself and displays a final result. Video camera systems may provide image capture of suspected fault sites, storing the image for subsequent recall at the repair station. Advanced systems may even suggest the reparability of particular fault sites according to user-defined rules.

Figure 38.21 shows an example of a fully automatic verification system and Computer Aided Repair (CAR) station. At the repair station, a display computer similar to that

**FIGURE 38.21** Fully automatic verification system and CAR station. (Courtesy of Everett Charles Technologies.)

described for verification purposes is used to highlight the proposed repair site to the operator, who performs the appropriate cuts or welds.

## 38.6 TEST DEPARTMENT PLANNING AND MANAGEMENT

---

In most cases, a new manager inherits a selection of existing equipment, processes, and personnel. Nonetheless, over a period of time, the manager has the same opportunity to shape the test floor operation as does the unlikely individual starting from a clean sheet of paper. To the extent that the past suggests the future, the new manager may expect increased density, finer pitch, higher total test-point counts, decreased tolerance for test escapes, shorter product delivery times, shorter product lifetimes, and larger numbers of smaller batches of boards for just-in-time delivery.

### 38.6.1 Equipment Selection

Most equipment being purchased for general bare board testing consists of universal grids and flying probers. The increased capabilities of flying probers and increased demand for small lot and prototype testing have increased the number of probers selected. This trend seems likely to continue, but each shop must determine its appropriate solution individually.

A first consideration in selecting equipment lies in recognition of the type of business you anticipate. For very-high-volume production of a variety of part numbers, the universal grid is a likely participant. For medium volumes, considerable savings may result from the elimination of test fixturing costs and delays that can be achieved by combining flying-probe test systems with throughput enhancement systems, as described in Sec. 38.4.3. For prototype or small lot

production, a quantity of flying-probe systems may be the best alternative due to the elimination of fixture expense. Dedicated (wired) fixture-type equipment is rarely demanded due to fixture cost, excepting very simple systems that remain devoted to an extremely high-volume run of a single product type for extended periods of time.

A further important concern is the level of technology that you anticipate. Verify that it does not outrun the capabilities of the fixture or test system types that you plan to use. Plan for change, as the equipment that you purchase must last for several years. Also consider the level of support available from the equipment vendor, including ordinary maintenance service, emergency service, employee training support, and applications support.

For high-volume operations, you can achieve substantial throughput and consistency of operation by adding automatic handling systems to a universal grid system configuration. For prototypes and moderate production volumes, the ability to place a stack of boards on a flying probe system and walk away for an hour or so, rather than wait for a board to come out every three minutes, can result in huge labor savings. Note that some very large, very thin, or very small product types may not be well suited to automatic handling without the use of special carriers or adapters. It may be best to size the automation equipment to handle the major portion of production and leave unusual product configurations on manually loaded equipment.

An often overlooked but practical consideration is maintaining some degree of commonality in equipment and fixtures. It is not uncommon for fixture problems to lead a test engineer to change equipment types several times, resulting in a motley assortment of incompatible (but expensive) test systems but failing to resolve the fundamental underlying issue. With data-driven test processes and automated fault data management in the mainstream, the ability of equipment to share data, fixtures, and operating procedures will decrease cost, increase throughput, simplify training, and enhance opportunities for combinational test solutions. This is harder to achieve with a random mix of equipment. If this seems to state the obvious, try this experiment: Visit some shops, stopping in drill rooms and in the electrical testing area. Do you see a difference in the assortment of equipment? Department planning should include not only new equipment, but also an exit strategy for old and inefficient equipment that you wish to retire.

### 38.6.2 Fixtures: Build or Buy, and What Type?

If you plan to use fixtures, the selection of fixtures is probably more important than the choice of equipment on which you choose to run the fixtures. Certainly you must have equipment at least adequate to the fixture, and with sufficient test-point density for the product. This is where a careful evaluation of product technology is crucial.

If the product includes even fairly simple SMT boards, then you should plan immediately for a dual-side capability. If the product includes fine-pitch SMT, dense BGA patterns, and such, then you must consider higher-density universal grids and modern tilt-pin fixtures consistent with the test-site density on these products.

If you plan to build fixtures in-house, recognize that you are creating a complete manufacturing operation. Measurement of complete material, labor, inventory, and overhead costs as well as operating efficiency is critical to effective management of this operation. Don't just measure how fast you build a fixture, but include measurement of the time it takes to get it running. Consider whether you would be better served by outsourcing fixture fabrication.

Avoid manufacturing multiple styles of fixtures. Ensure that you have an inventory management process that does not run out of pins at midnight, but does not have half a million dollars tied up in obsolete pin inventory. Consider outsourcing at least the more difficult fixtures to specialists. You may save time, plus gain a partner who provides exposure to alternative techniques and materials.

### 38.6.3 Selecting Fixture Software

Today's tilt-pin translator fixture is largely a software product. It should be possible for you to establish a flow of information from your computer-aided manufacturing (CAM) department to the front-end fixture software that automates the design of fixtures and the creation of test programs. (The same goal holds true for processing data to create flying-probe test programs.) A premium tool will pay for itself many times over in reduced fixture scrap, reduced late deliveries, and elimination of test escapes. If you can select a tool that is also used by several fixture outsourcing vendors, you will have a backup supply of fixtures in the event of equipment problems, personnel problems, or workload peaks. If you have special and specific demands for the fixture design, verify that the proposed software package readily supports your requirements. And, as in the case of the test system, evaluate the software vendor's ability to sustain and support your operations.

---

## CHAPTER 39

---

# HDI BARE BOARD SPECIAL TESTING METHODS

---

**David J. Wilkie**

*Everett Charles Technologies, Pomona, California*

---

### 39.1 INTRODUCTION

---

Printed circuit technology is now being applied to high-density interconnection (HDI) applications that require consideration of new testing techniques. Notable examples include many types of advanced integrated circuit (IC) packaging introduced in recent years, such as area-array devices, ball grid arrays (BGAs), laminate chip carriers (LCCs), and circuit boards employing direct chip attach (DCA) or chip-scale packages (CSPs). In some of these cases, semiconductor dies are being directly attached to a printed circuit surface, and in the case of CSP, the package size is approximately the same as a raw die. Flip-chip die (or CSPs) may be attached to a circuit board by an array of solder balls. Other devices may attach with a peripheral array of wirebond pad sites just outboard of the die area. For high-pin-count devices, this last example can produce the finest side-to-side test-point pitch as efforts are made to squeeze a large number of contacts onto the limited periphery of the die. The flip-chip or CSP bump array attachment parts generally produce the highest test-point density per unit area. The flip-chip or CSP approaches allow the designer to distribute the solder ball contacts over the full surface area of the die or package. For fixtured test systems, the ability of the tester to provide a sufficient density of test points and the ability of the fixture to achieve the needed pitch and accuracy must be considered.

The general goal of electrical testing for HDI substrates remains about the same—detection of opens, shorts, and leakage, although often with increased concern for latent defects, whose appearance can be made more likely by the fine geometry employed in traces and microvias. The measurement electronics are often the same, and are not further discussed here except for special cases. For some applications, time domain reflectometry (TDR) or other radio frequency (RF) tests are desired, but are complicated by the short signal runs on some of these substrates.

Sensitivity to pad marking is increased as there is not much pad area to mark. Marking that penetrates the metallization layers on the board can affect the chemistry of the solder joint, adversely impacting reliability. It is quite challenging to prepare test fixtures able to test such products on universal grids given the need to minimize witness marks, meet

aggressive continuity test threshold expectations, and contact the finest geometries. When HDI parts are tested in panelized form, the very small target sizes combine with potential expansion/contraction issues in the panel construction to place a maximum demand upon test-point positional accuracy within the fixture. The ability of the latest camera-equipped flying-probe systems to locate these targets individually and probe them without marking combines with the fixture cost savings to make this method of test very attractive, especially as new techniques improve throughput (see Sec. 39.4.3). Because of the high costs associated with HDI fixtures, some fixtured solutions compromise test coverage such that the fixture can be simplified to a practical degree.

## 39.2 FINE-PITCH TILT-PIN FIXTURES

Many HDI structures can be tested with advanced examples of tilt-pin fixtures. Using such techniques as test pins that taper (see Fig. 39.1) to a very fine diameter at one end, fixtures have been built for devices with pitch down to about 0.010 in., with research and development (R&D) examples at about 0.008 in. These fixtures contain additional plates to support the very thin pins (so they do not buckle under pressure or short to adjacent pins). Those fixture plates very close to the product must be fairly thin, or the closely spaced holes will break out into one another. Such fixtures increase the demand for higher grid densities. These fixtures and pins are moderately more expensive to prepare than standard fixtures, but use similar technologies and processes. Excellent process control is important, as is excellent pin tip symmetry.

**FIGURE 39.1** Tapered pin for a fine-geometry fixture.

Areas of the product requiring large numbers of probes are subjected to considerable total force. If no equal and opposing force is applied on the opposite side of the product, bowing or “potato chipping” of the product will occur. Ultimately this can collapse the opposing test fixture, but long before this, the probing accuracy of a fine-pitch fixture will be affected because the product no longer lies in a flat horizontal plane. To avoid this, the fixture software can add support within the opposing fixture, directly opposite the densely probed site. This additional support can be accomplished with a spacer affixed between the top and bottom fixture plates or by using blind pins. Blind pins are ordinary test pins located in the opposing fixture at sites where the top (product side) plate of the probing fixture is not quite drilled all the way through. If a quantity of blind pins equal to the quantity of dense product site probes is employed, then the opposing forces are perfectly balanced in this region.

When dealing with fine-pitch fixtures, the problem of product and fixture registration must be considered. Even if the fixture is manufactured perfectly, the product may not align. Because the tooling features of the product (edge or tooling hole) are added in a process separate from the artwork production, the artwork and tooling features are usually misaligned.

With HDI substrates, it doesn't take much for this error to move pads completely away from the assigned test pins. To overcome this, a variety of test systems are available with optical and/or electrical means of sensing misregistration. Movable plates in the fixture are controlled by servomotors, which reposition the product through motion of the tooling pins. As the product grows in size, or as the manufacturing process deteriorates, the registration errors may not be sufficiently constant over the product area to permit the use of motorized alignment. In this case, none of the probe-per-pad fixtured approaches may be effective.

### **39.3 BENDING BEAM FIXTURES**

---

Bending beam fixtures are somewhat similar to tilt-pin fixtures, except that they use extremely thin test pins manufactured from a special alloy. As in the tapered pin fixture, a significant number of thin supports are required near the product, where the pin tends to be held fairly straight to avoid conflict with other nearby pins. These pins are not held rigid, but are expected to buckle under force. This buckling displaces the pin sideways. The buckled portion may be located at some distance from the product plane, where the probes can be more widely separated. Once the pin has buckled, the force applied to move through a substantial travel is constant. This is very different from the case for a spring probe, where the force increases at a constant rate determined by the spring constant. Bending beam fixtures provide good immunity to witness mark damage. The basic technique has been in use in specialty situations for many years.

At the interface side, these pins may mate to spring probes instead contacting a rigid contact surface. In some commercial examples, the pin continues away from the product as a piece of wire routed to widely spaced contacts on the interface portion of the fixture. These in turn interface with traditional spring probes. Within the fixture, the probe wire is bonded in place at some distance from the product, defining the separation between the probe and wiring portions of its overall length. Such fixtures are quite expensive, and replacing damaged probes can be challenging. Thus, this technique is usually restricted to small areas and limited test-point counts.

### **39.4 FLYING PROBE**

---

The more precise examples of flying-probe systems are very well suited to HDI testing. With on-head optical pattern recognition guiding the probe tips, they can contact extremely small targets—even in the presence of significant product registration problems. They can probe small features without marking or disturbing the surface. These systems can be equipped with true Kelvin contact tips supporting effective single-measurement fractional ohm testing, well suited to the sort of fractional ohm continuity test that may be desirable in efforts to detect precursor phenomena to latent defects caused by cracks or other geometry problems. The principle drawback is, of course, test speed. Used alone, these systems are ideal for prototype or small volume production applications where fixture production would be quite expensive. Used with throughput enhancement systems as described in Sec. 39.4.3, these systems can accommodate moderate production volumes.

### **39.5 COUPLED PLATE**

---

In a situation where most of the target product is relatively easy to fixture, but a DCA or CSP site is difficult, it may be possible to use coupled plate-type testing. A variety of proprietary

products are available, but the basic technique is fairly similar. The primary assumption is that each signal network arriving at the DCA or CSP site is accessible by a traditional probe at some other site on the board. These probe sites are used to perform a normal isolation test of the product. Continuity testing of most of the board is performed in the usual manner also.

To verify the continuity of the signals to the DCA or CSP site, a small metal plate or antenna is suspended just over the site, perhaps insulated from the site only by a thin dielectric. One at a time, the standard probe sites are used to inject some sort of alternating current (AC) signal or pulse into each network in turn. If the network is properly continuous to the DCA or CSP site, then a signal of appropriate amplitude is detected at the antenna. Substantial deviation from the proper amplitude means that something is wrong. The different methods vary in terms of the applied signal, antenna characteristics, and so on.

This method eliminates the need for super-fine-pitch probing at the DCA or CSP site and also avoids marking of the product at this site. However, the test does not perform a true DC test of continuity and may miss high-resistance connections, which would be detected by a low-threshold DC continuity measurement. Signals that loop from one DCA or CSP pin to another and go nowhere else may be untestable as there is no outboard probe site at which to inject the test signal.

### 39.6 SHORTING PLATE

---

This method is employed in circumstances similar to the coupling plate method just described. In this case, however, the plate must be movable during the test. Generally, a pencil-sized pneumatic actuator is mounted within the test fixture to accomplish this motion. The plate employed here is a small flat metal plate that is the size of the DCA or CSP site and covered with an electrically conductive rubber (see Fig. 39.2). When pressed against the product, it shorts together all of the pads at the DCA or CSP site. Continuity testing is performed in this condition by using the outboard probe sites to confirm that all of these (otherwise isolated) networks are shorted together via the path to the DCA or CSP site. All other networks are tested normally for continuity. Then the shorting plate is removed and a normal isolation test is performed. Key advantages of this method are the accomplishment of true DC measurements for both isolation and continuity and the use of standard bare board test systems.

In some applications, there is concern about any trace chemicals that may be left behind by the conductive rubber, although outright marking is minimal. Cleanliness of the product is

**FIGURE 39.2** Pneumatically actuated shorting plate.

critical, as the rubber or plate must be replaced when excessive dirt is embedded. As with the coupled plate, certain signal topologies are untestable or difficult to test. Signals that loop from one DCA or CSP pin to another and go nowhere else are untestable, as there is no external probe site with which to verify either continuity (to the DCA or CSP shorting pad) or isolation. Any signal that connects two DCA or CSP pads on the same package may be partially untestable, even if the signal continues to an external probe site. In this case, it is possible to verify that the external signal arrives at the device, and it is possible to verify isolation of this segment. But there is no simple way to discern whether the two device pads are joined to each other. (If they are already shorted together on the board and engaging, the conductive rubber has no effect.) This latter case may sometimes be mitigated by segmenting the shorting pad, such that each of the target device pads is in a separate segment. Then, if the connection on the board is good, the halves will be joined through the board.

### **39.7 CONDUCTIVE RUBBER FIXTURES**

---

Several designs for fixture systems employing conductive rubber as the basic probe element have been offered commercially. In some cases, the rubber is a specialized material in sheet form and is conductive only in the z-axis (through the thin sheet vertically, but not sideways across its surface). The fixture is itself made from a circuit board, with slightly raised pads to compress the rubber tightly against desired product sites. The fixture board connects to the grid electronics at its reverse side. Other designs have included various types of locally deposited rubber dots, usually of conductive rubber that is not sensitive to orientation. Again, a rubber probe is formed. Problems with cost, complex manufacturing, complex repair, dirt sensitivity, and suitability to very small pad areas (which limit contact quality to the rubber) seem to have prevented widespread adoption.

### **39.8 OPTICAL INSPECTION**

---

Optical inspection has been discussed elsewhere. It is generally applied early in the fabrication process as a yield improvement and data collection tool, not as a means of final product qualification. However, with improvements in resolution, the type of defect that may escape undetected becomes somewhat more limited, and optical inspection is argued as a possible means of final testing.

With complex multilayer product, optical inspection will not be able to identify assembly/contamination-induced defects internal to the board in any case, and may still be limited in cases of contaminants or very fine-geometry shorts and opens on external layers. The equipment is somewhat slower than universal grid test systems, particularly when run at very high resolution. For such reasons, it is still not common practice to employ optical inspection (by itself) as a substitute for electrical testing. This may be a method that develops further in the future or that finds acceptance in special circumstances.

### **39.9 NONCONTACT TEST METHODS**

---

Quite possibly the greatest daily irritant (and cost) in the operation of a typical test area today revolves around the cost of building test fixtures. Customers still hate to pay for them, and the creation of fixtures burdens the board shop with an entire manufacturing process that seems to add no value and that distracts from the main productive purpose of the factory. The only fully effective commercially available systems that require no test fixtures are flying-probe

test systems and the related throughput enhancement systems. In addition, extensive work has been done by several organizations to attempt to develop alternative noncontact means of fixtureless test. To date, no fully successful noncontact method has yet emerged with a capability for parametric measurement of the normal range of both continuity and isolation, yet some brief description of various techniques seems warranted.

### 39.9.1 Electron Beam Methods

When a test system contacts a product with an electromechanical contact, it uses this contact to inject or remove electrons. That is, current flows. The sort of electron beam common to the picture tube in a television might be used to do the same thing without contacting the product physically. Experimental systems have been built by several firms to date, but have shared some common problems. First and foremost, the amount of current delivered by the electron beam is so small that only a very poor continuity test is possible. Increased interest in fractional ohm and/or high-current testing to detect latent continuity defects runs counter to this limitation. Lab systems have been limited to continuity thresholds of 100,000 ohms or more, and this only very slowly. As most users wish to test at 10 to 100 ohms, this is a major compromise. (A smear of contaminant across an open circuit would appear to be a perfectly good conductor.)

Test speeds are affected by product capacitance, as a longer time is required for the limited current to achieve significant voltage effect in a highly capacitive environment. Also, such systems must operate in an extremely high vacuum of laboratory grade. Expensive pumping systems are required. Costly air-lock systems with multiple stages and robotic product handling are probably required to keep any reasonable flow of material through the system. (Staging product in and out through a series of chambers avoids the time delay of constantly pumping down the main chamber when loading new product.) At the present time, flying-probe systems seem to offer superior test and measurement coverage at more practical operating costs.

### 39.9.2 Photoelectric Methods

Subjecting a metal surface to an intense beam of light, such as that from a laser, can cause electrons to be ejected from the metal. As in the case of the electron beam, a very small current flow can be induced. Again a vacuum is required (so that the ejected electrons can be measured before they collide with air molecules), though the vacuum requirement is less stringent than that for the electron beam technique. The resistance at which continuity measurements can be made is quite limited, as in the case of the electron beam. (See discussion of electron beam method in Sec. 39.9.1.) Again, test speed suffers due to product capacitance. No practical system has resulted from investigative work.

### 39.9.3 Gas Plasma Methods

Fluorescent light bulbs emit light because a gas is subjected to an electric field, which adds energy to the electrons orbiting the gas molecules until some break free. As they attempt to reattach themselves to the gas molecules, they eject their excess energy as photons (light). The plasma consists of a mixture of gas molecules, ionized gas molecules (missing electrons), and free electrons. In this state, the gas can conduct an electric current. If a jet of plasma is directed from a small nozzle to the surface of a circuit board, the effect is that of building a "gas probe." In broad terms, the gas probe can be used just as any other probe or test is completely possible.

Generally a noble gas such as argon is used. The gas residue is nontoxic, only a tiny amount of gas is consumed, and substantial current can flow to the product. Several companies have developed experimental systems in the form of flying-probe systems.

Although gas probes offer the benefit of little or no product marking, it is difficult to achieve one that is as fine as the best mechanical probes. Adjacent jets tend to combine, producing a short circuit just as if two mechanical flying-probe tips shorted while testing. Thus, the commercial system offered to date includes completely traditional mechanical probes as well, using these to probe closely adjacent (i.e., HDI) sites. As a flying-probe mechanism is still used, there is little speed advantage to date. Eventually some benefit may be obtained due to the elimination of any wait time for z-axis travel of the prober head, although this is already the fastest motion axis of most flying-probe systems. The cost of this technique is modestly higher than that of an ordinary flying prober.

### **39.10 COMBINATIONAL TEST METHODS**

---

One technique that offers immediate practicality in resolving difficult testing situations for high-density product—often using existing equipment—is generally described as combinational testing or sequential testing. As the name implies, this is testing in one or more stages, using a combination of test techniques. Combining techniques inevitably adds complication. The simplest example is the use of a universal grid to test the majority of a product, followed by a flying probe system to test HDI features and reverify the failures reported by the grid. Software tools have simplified the process of combining test methods.

## 40.1 INTRODUCTION

---

The electronics “revolution” has been sustained through the development of products having increased miniaturization, enhanced functionality, improved reliability, and reduced costs of manufacturing. In fact, innovations in electronics assembly methodologies have kept manufacturing costs low with each new generation of product.

### 40.1.1 Feature Density

Product designers have been able to explore new packages, materials, etc., so as to increase functionality further while, at the same time, reducing the size and weight of both consumer as well as high-reliability military and space electronics. The result has been greater challenges for process engineers. For example, there is a continued trend of decreasing component sizes. Leadless ceramic chip capacitors having sizes of 0804, 0603, and 0402 are commonplace, whereas smaller 0201 devices are being introduced into product lines, particularly handheld products. Manufacturing resources are now developing the means to tool up for 01005-size components. Fine-pitch and area-array packages—ball grid array (BGA), chip-scale packages (CSP), and flip-chip (FC) or direct-chip attach (DCA)—provide the means to increase device functionality significantly. Input/output (I/O) interconnections that are reaching several thousands on BGA packages require stringent solder paste printing, part placement, and reflow processes controls to minimize defects. At the same time, the need for more complex, multi-layer substrates has also placed limitations on the process window so as to avoid damage to circuit board microvias and fine traces that are needed to support higher assembly densities. Lastly, these challenges are made more complicated by the use of Pb-free solders. Changing equipment parameters as well as alternative surface finishes impact solderability performance and thus process yields as well.

### 40.1.2 Printed Circuit Board Assembly Process

There are two basic steps in the assembly of a printed circuit board: (a) placement of the components (resistors, capacitors, etc.) on the substrate and (b) soldering those components into place. Although this is a fairly accurate description of a through-hole, hand-soldering operation,

nearly all electronics assembly operations are, in fact, considerably more complex. Multiple-step assembly processes provide the versatility to incorporate different component package types and a wide variety of substrate configurations and materials as well as to accommodate frequently changing production volumes in order to meet prescribed defect levels and reliability requirements. A more accurate, albeit still relatively general, listing of assembly process steps consists of the following:

1. Preparation of the component and substrate surfaces to be soldered
2. Application of the flux and solder
3. Melting of the solder to complete the joint
4. Post-process cleaning of the soldered assembly
5. Inspection and testing

Some of these steps may be either combined together or eliminated, depending on the particular product line.

It is important that the manufacturing engineer and operator understand the critical steps in the printed circuit board assembly process to ensure the manufacture of a cost-competitive, reliable product. That understanding includes both the general function of the equipment as well as the activity taking place *inside* the machines. The following sections of this chapter describe in detail the printed circuit board assembly processes.

### 40.1.3 Assembly Process Categories

Assembly processes can be placed into the following three categories, which are described by the types of circuit board components:

- Through-hole technology
- Surface-mount technology
- Mixed technology, which is a combination of through-hole and surface-mount components on the same circuit board

Within each of these assembly technologies are different levels of automation that equipment resources offer. The degree of automation will be optimized, depending on the product design, bill of materials, capital equipment expenditures, and actual manufacturing costs.

It is important to remember that through-hole printed circuit boards and their assembly processes remain a critical technology in the electronics industry, albeit clearly not at the same production volumes as experienced before the advent of surface-mount technology (SMT). Through-hole technology may be used because it is the only format available for some components, particularly large devices such as transformers, filters, and high-power components, all of which require additional mechanical support that is offered by through-hole interconnections. A second reason for using through-hole technology is economics. It may simply be more cost-effective to use through-hole components, together with manual assembly (i.e., no automation) to produce an electronics assembly. Of course, through-hole technology is not limited to manual assembly. There are varying degrees of automation that can be used to assemble a through-hole circuit board.

### 40.1.4 Pb-Free Technology

The introduction of Pb-free technology has not changed, per se, available electronics assembly processes (reflow, wave, hand soldering, etc.). However, it has caused manufacturing engineers to reassess the parameters used in those processes because of two factors: (1) higher process

temperatures required by Pb-free solders, and (2) the poorer solderability of these alloys (owing largely to the absence of Pb). With respect to the five general process steps noted previously, the use of Pb-free solders primarily affects steps 3, 4, and 5.

The need for higher processing temperatures limits the assembly “process window” of Pb-free solders. A higher *nominal* temperature is needed to accommodate the temperature variation at components across a circuit board to ensure melting of the solder and adequate wetting and spreading at each interconnection. On the other hand, the maximum temperature must be limited to prevent thermal damage to heat-sensitive devices and the circuit board.

The poorer solderability of the Pb-free solders presents several challenges as well. Although the longer time needed to heat the component lead or termination and circuit board is often cited as the underlying source of poor solderability for Pb-free solders, it is primarily the higher surface tension of the Sn-based alloys (in the absence of Pb) that restricts wetting and spreading behavior. The need for longer heatup times is a particular issue with “faster” assembly processes such as wave soldering and hand soldering. However, the intrinsically poorer solderability impacts all assembly processes because it can degrade the quality of hole fill and fillet development for both short and relatively long (e.g., reflow) assembly processes.

The intrinsic solderability performance of Pb-free solders is being improved by two means. First, new flux formulations are available that more effectively reduce the surface tension of the solder. Second, alternative surface finishes can be specified for the component I/Os and/or circuit boards that improve wetting and spreading activity exhibited by the Pb-free alloys.

Strictly from an assembly process point of view, the mixing of Pb-free and traditional Sn-Pb solder can be beneficial. The Sn-Pb solder can improve the wetting and spreading performance of the Pb-free solder by two phenomena. First, Pb contamination lowers the molten solder surface tension of the solder. Second, the Pb contamination reduces the melting temperature of the Pb-free alloy. However, concerns are raised by the mixing of Sn-Pb and Pb-free solders and its effect on the long-term reliability of interconnections under thermal-mechanical fatigue environments.

Lastly, the use of Pb-free solders impacts the post-assembly cleaning step (step 4) and the inspection step (step 5). The higher process temperatures can produce more tenacious flux residues that require more aggressive cleaning steps to ensure their removal. Also, the more tenacious residues affect the ability of test probes to contact test site pads on the circuit board. Poor contact can be responsible for detecting false opens on the assembly.

## 40.2 THROUGH-HOLE TECHNOLOGY

---

Through-hole technology refers to assemblies having components with leads that are inserted into holes in the circuit board and soldered into place. This technology has been used since the early days of electronics (the 1920s). The leap in automation came in the early 1960s with the advent of wave soldering. The particular drawback of through-hole printed circuit boards, which led to the introduction of surface-mount technology (see the next subsection), was low assembly densities. The relatively large devices, and the circuit board real estate required for holes, limited the density of components, which in turn restricted product functionality and further miniaturization. A photograph of a through-hole circuit board is shown in Fig. 40.1 along with an optical micrograph that shows the through-hole solder joint of the component lead extending through the circuit board.

An advantage of through-hole technology is reduced cost in some applications. That cost benefit may be realized by lower labor costs in some parts of the world that support hand assembly, which is relatively easy with the larger components and products, and lower board densities. Even when fully automated—either by wave soldering, selective soldering, or paste-in-hole/reflow—the capital equipment and manufacturing costs can still be lower than those required for surface-mount assembly.

**FIGURE 40.1** (a) Photograph of a through-hole printed circuit board. (b) Optical micrograph of the component lead as it is soldered into the circuit board hole. (Courtesy of Sandia National Laboratories.)

### 40.2.1 Impact of Pb-Free Soldering on Through-Hole Technology

The change to Pb-free solders affects through-hole assembly technology. First, there is equipment selection. Manual assembly operations may require purchasing higher-temperature soldering irons. At the other end of the cost spectrum, there are the expenses to replace several hundreds of pounds of Sn-Pb solder with a Pb-free alternative in the pot of a wave-soldering machine. Alternatively, it may be advantageous simply to purchase an entirely new machine to avoid cross-contamination with legacy Sn-Pb operations and/or to have the latest technology that mitigates the higher erosion activity of Pb-free solders on machine components.

The use of Pb-free solders also requires a review of the process parameters. The specific aspects are the higher processing temperature required to use Pb-free alloys and the reduced solderability of these alloys. It has been fortuitous that Pb-free solders, when used in manual (soldering iron) and wave processes, have not required a very significant increase in soldering iron temperature as was first anticipated in the early stages of Pb-free technology development. The added temperature margin was of least concern with manual soldering processes because the localized heating limits thermal degradation to either the component or substrate. Some concern arose in the wave-soldering process because the substrate is exposed to the molten solder bath. On the other hand, paste-in-hole technology that uses a Pb-free reflow process subjects through-hole components and substrates to temperatures higher than those to which they are normally accustomed, thereby possibly degrading them.

The soldering of a through-hole interconnection is also susceptible to the intrinsically poorer solderability of Pb-free alloys. The higher surface tension of these solders results in a slower flow of molten alloy between the pin and barrel, thereby potentially requiring a longer soldering time. Also, the poorer solderability can result in reduced wetting of the pad and limited fillet formation, particularly on the opposite side of the circuit board to which the joint is being soldered. Some of these solderability issues can be mitigated by changing flux and/or the use of alternative surface finishes (e.g., Au solderable finishes). Both options can reduce the solder surface tension as well as enhance the base material metallurgical reaction, thereby improving solderability.

### 40.2.2 Design Considerations

The design of a through-hole printed circuit board must necessarily consider currently available equipment and assembly practices as well as the potential for advances in future machines and processes. It is important that circuit board designs comply, as much as possible, with recommendations provided by industry standards, such as those of the IPC Association

Connecting Electronics Industries (IPC) and the Joint Electron Device Engineering Council (JEDEC). These recommendations include hole diameters, trace dimensions, and feature spacing. The overriding document is the specific product drawing. Any design deviations from industry standards must be fully considered with regard to how such changes will affect the assembly (process).

The following are important design considerations regarding the assembly process for a through-hole printed circuit board products:

- Tooling requirements (holes, edge clearances, etc.)
- Registration holes (manual alignments or vision systems)
- Component lead-hole sizes
- Circuit board dimensions (length, width, and thickness)
- Size and density of components
- Pb-free solders

Three of these factors are discussed below because of their general role on all assembly processes.

**40.2.2.1 Component Lead and Circuit Board Hole Sizes.** Designing the correct component lead hole diameters begins by referring to the appropriated industry standard(s) (e.g., IPC, Electronic Industry Association [EIA], etc.). Hole tolerances must take into account run-out by the drill, etch-back, barrel-plating thicknesses, and the need for a nominal gap of 0.07 to 0.15 mm between the pin and hole to support the capillary flow of the molten solder. In addition, there are added tolerance considerations due to the variation in component lead diameters as well as the positioning accuracy of the equipment.

**40.2.2.2 Circuit Board Dimensions (Thickness).** The thickness of the circuit board is typically governed by the product design and the number of layers required for signal routing. Thickness has minimal direct impact on the ability of automated machines to accept a circuit board physically. (The same is true of hand soldering.) However, the board thickness affects the soldering process. As thickness increases, it becomes more difficult to supply a sufficient amount of heat to the joint area that allows the molten solder to fill the through-hole completely prior to solidification. Copper layers contained within the laminate, which are used for signal transmission, ground planes, radio frequency (RF) shielding, and power sources as well as layers for thermal management, act as additional heat sinks that can impede the flow of molten solder into the hole.

**40.2.2.3 Pb-Free Solders.** Design rules and industry standards that have been established are based primarily on experiences with eutectic Sn-Pb solder. Studies are investigating through-hole processes for Pb-free solders. Part insertion, equipment tooling considerations, even paste placement for paste-in-hole technology will be largely unaffected by the change of solder alloy. As noted previously, in spite of the higher liquidus temperature, hand-soldering iron tips and wave-soldering pots will use similar temperatures. The design engineer will have to address the generally poorer solderability of Pb-free alloys, which arises from the higher surface tension of the solder. Flux selection and alternative surface finishes can mitigate this discrepancy to some degree. Other measures may be necessary. For example, the designer may be required to increase the spacing between components in order to avoid solder bridges that cause short circuits during wave and selective soldering. The high Sn content of Pb-free solders results in a greater degree of erosion of the Cu features on the circuit board. This phenomenon is particularly severe at the knee of the through hole when the molten solder is highly agitated such as in a wave-soldering or selective soldering machine. Therefore, it may be necessary to reduce the time that the joint is exposed to the molten solder or to select an alternative Pb-free alloy (Sn-Ag-Ni or Sn-Ag-Ni-Ge) that is less prone to Cu erosion.

### 40.2.3 Assembly Process

The through-hole printed circuit board can be a cost-effective technology for many applications. One determining factor is the level of automation used to make the product, which can range from hand assembly to fully automated processes (inline or batch). The specific assembly steps include component insertion (also referred to as “board stuffing”), lead trimming, soldering, and post-assembly cleaning. Labor costs, capital expenditures, board design, and production volumes are contributing factors toward determining the details of these steps.

There are two general formats for assembly processes: the cell or batch process and the line process. Both methods are discussed in the following subsections.

**40.2.3.1 Cell (Batch) Process.** The cell process routes the circuit boards in batches between the different steps. The cells or workstations are not always in immediate proximity to each another and can be entirely manual, semiautomated, or fully automated in terms of the actual process step. For example, component placement may be fully automated, but require several machines for inserting the different component types. Circuit boards are typically loaded and unloaded by hand between machines. Table 40.1 lists the advantages and disadvantages of the cell process. The cell or batch process is best suited for a facility that assembles a high mix of low production volume products (e.g., prototype development or high-reliability circuit boards) where flexibility is necessary on the factory floor.

**TABLE 40.1** Advantages and Disadvantages of the Cell Process

Advantages	Disadvantages
<ul style="list-style-type: none"> <li>• Single machine outage does not immediately stop the entire process line.</li> <li>• Adds greater flexibility to the process by creating alternative workflow routes.</li> <li>• Attractive for high-mix, low volume applications that require frequent equipment change-outs and re-tooling.</li> </ul>	<ul style="list-style-type: none"> <li>• Higher product flow time due to the transfer of parts between cells is unattractive for high volume applications.</li> <li>• Part transfer between cells increases the likelihood of handling damage</li> <li>• Difficult to predict product line throughput in a multi-cell assembly process.</li> </ul>

**40.2.3.2 Line Process.** The second approach is the line process, where the different insertion machines, as well as the soldering process in some cases, are linked together with automatic board-handling equipment. Table 40.2 lists the advantages and disadvantages of the line process line. The line process is best suited for a factory floor where high production volumes (e.g., consumer electronics) and a low mix of product types are typical of the manufacturing operations. Less versatility is required by assembly processes, which justifies the capital equipment expense.

**TABLE 40.2** Advantages and Disadvantages of the Line Process Line

Advantages	Disadvantages
<ul style="list-style-type: none"> <li>• Improved manageability of material inventory, product flow, and operator resources is attractive for high volume, low mix applications.</li> <li>• Shorter process times by eliminating the transfer of parts between machines.</li> <li>• Reduce the likelihood of handling damage to the assembled product.</li> </ul>	<ul style="list-style-type: none"> <li>• Failure or maintenance outage of a single machine failure can potentially halt an entire assembly line.</li> <li>• Reduced equipment flexibility is unattractive for high mix assembly.</li> <li>• Capital equipment costs and fixed floor space requirements are critical considerations.</li> </ul>

The configurations of most through-hole components fall into one of three geometries: axial leaded, radial leaded, and dual in line pin (DIP) packages. These traditional configurations are used for resistors, capacitors, transistors, crystals, and, in the case of active devices, the DIP package. There are also odd-form packages for devices such as transformers, switches, and relays. New package configurations such as the pin grid array (PGA) are being developed to accommodate the increased functionality and further miniaturization of active devices. Besides the actual component body size, shape, and lead configuration, the other factor that can impact the through-hole assembly process is the lead finish. First of all, the finish can potentially add significantly to the diameter of the lead, which must be taken into account when considering the tolerance budget for the hole in the board design. Secondly, for hot solder dipped leads, the potential accumulation of solder at the end of the lead can interfere with part insertion.

The Pb-free alloys can impact the hand-soldering assembly process. First, the higher melting temperature of these alloys requires a slightly longer soldering time. In the case of hand soldering, tip temperatures designated for Sn-Pb process can be used for the Pb-free soldering of traditional through-hole designs. However, hotter tips and/or irons with a higher power rating may be required for “borderline” designs such as those having bigger component leads or thicker circuit boards. Secondly, the Pb-free solders have a higher surface tension that tends to slow wetting and spreading on surfaces as well as capillary flow into holes. For example, the Pb-free solder may not fully coat pad surfaces on the opposite side of the circuit board. Third, the high Sn content of the Pb-free solder increases the rate of erosion of the soldering iron tip, wave-soldering machine parts, and the Cu features on the circuit board.

#### 40.2.4 Hand-Soldering Process

The sequence of steps used to hand solder a through-hole circuit board varies somewhat between different applications. First, there is part insertion. If the insertion operation is fully manual, the parts will be “kitted” into specific groups: The first group is inserted and then soldered; the second group is inserted and soldered; and so on. The order of the groups is determined so as to maximize throughput as well as to take into account human factors in order to minimize part error, lead damage, and operator fatigue or inattention. In semiautomated processes, the operator may receive the circuit board for soldering that was partially or fully populated by machine.

Next, there is the soldering step. The location of the joint where soldering is performed depends on the architecture of the circuit board. For single-sided boards without a plated through-hole, soldering must be performed on the component side. On the other hand, in the case of double-sided and multi-layer circuit boards with plated-through holes, soldering is typically performed on the bottom side in order to avoid potential heat damage to components by the soldering iron, particularly on densely populated circuit boards.

The hand-soldering process proceeds as follows:

1. The operator applies flux to the joint.
2. The soldering iron tip is contacted to one side of the component lead (see Fig. 40.2). The tip should not contact the circuit board pad, if possible. It may be necessary to contact the pad of thicker circuit boards.

**FIGURE 40.2** Diagram showing placement of the soldering iron tip for heating the lead and placement of the solder wire to complete the joint.

3. The solder wire is brought into contact at the side of the lead opposite to the soldering iron tip. The solder wire should not contact the tip in order to melt it. Once melting, the solder is allowed to wet and spread over the surfaces as well as to flow through the hole. In the case of flux-cored wire, the flux application step is omitted. A properly designed process—that is, one having a soldering iron with adequate power as well as tip temperature and geometry—should complete the joint in approximately 3 to 7 sec.
4. Once the soldering process is completed, the circuit board is cleaned of flux residues when required by the flux type or the product's long-term reliability requirements.

Hand soldering may be achieved in an assembly (or “slide”) line process for larger volumes. In this case, each one of several operators solders only a few of the total components of the circuit board. In the case of single-person work cells, the operator may solder all of the components to the circuit board. Alternatively, the work cell may be used to add odd-form components as the final assembly step on a nearly complete circuit board.

### 40.2.5 Automated Soldering and Insertion Technology

In the case of automated assembly processes, the general sequence is part insertion followed by the soldering step. (Slightly different steps are used for the paste-in-hole process; that is, the paste may be applied before or after part insertion.)

**40.2.5.1 Components.** Part insertion is typically performed in the following order:

1. DIP package
2. Axial leaded components
3. Radial leaded components
4. Odd-form components

The following subsections provide a brief description of each of the component formats and the manner in which the insertion machine addresses those formats.

Choosing the appropriate insertion machine depends on production volume requirements and the mix of products (part density, board sizes, etc.) that must be assembled in the factory. These factors determine the machine's physical dimensions, placement speed, and part-handling (staging) features.

**40.2.5.1.1 Dual Inline Pin (DIP) Package.** The first auto-insertion process is placement of the DIP packages. The typical DIP package (see Fig. 40.3) is manufactured in one of two widths: 7.6 mm and 15.2 mm. Package lengths vary with the number of pins. For example, a 6-pin DIP package can have the same width and length of 7.6 mm. On the other hand, a 42-pin DIP package has a width of 15.2 mm and a length of 54.6 mm. The DIP packages are typically received in 61 cm length plastic tubes. The insertion machine carries these tubes vertically in magazines. The part shuttle selects the appropriate package and carries it to the center of the machine for insertion into the circuit board. Tooling on the shuttle head holds the package by the leads during the insertion process. The tooling is simply scaled for different DIP package dimensions.

**FIGURE 40.3** Dual inline package (DIP). (Courtesy of Sandia National Laboratories.)

Dual inline packages are either molded plastic (PDIP) or ceramic (CerDIP, or just CDIP). The surface finishes on PDIP packages are typically electroplated layers of Ni (solderable layer) and Sn-Pb (protective finish) over a Cu lead frame. The Sn-Pb finish is being replaced with 100 percent Sn layers to meet environmental requirements. The CDIP package has low-expansion Fe-based alloy leads that are either electroplated with Cu finish for solderability or the alternative lead finish of Ni (the solderable layer) followed by Au (the protective layer). Although the DIP package is rarely received from the manufacturer with a hot-solder-dipped coatings, these coatings may be applied, after-market, to prevent Sn whiskers with 100 percent Sn finishes (PDIP) or Au embrittlement with Au finishes (CDIP). Aside from potential hole interference with a hot-solder-dip coating, there is also the need to unpack and repackage the components, which can potentially damage the leads as well as add to the overall cost of the assembly process.

**40.2.5.1.2 Axial Leaded Components.** Following the DIP packages is insertion of the axial leaded components, which are taped together at the leads by the manufacturer to prevent damage. The taping of the leads conforms to EIA specification number 296-E. Examples of axial leaded devices are shown in Fig. 40.4. During the insertion process, the machine cuts the axial components from their tape to ready them for sequencing into the shuttle head. The leads on axial devices are typically copper or a Cu-clad, Fe-based alloy material. Electroplated Sn-Pb or 100 percent Sn coatings are used to preserve lead solderability. Hot-solder-dipped coatings (Sn-Pb or Pb-free) may be increasingly encountered as a replacement for 100 percent Sn coatings, especially for high-reliability applications. The coating thicknesses must be considered when determining the tolerance stack-up between the hole and pin. Also, hot-solder-dipped coatings often lack uniformity, increasing in thickness near the end of the lead where molten solder accumulated prior to solidification.

Choosing the appropriate insertion machine depends on production volume requirements and the mix of products (part density, board sizes, etc.) that must be assembled in the factory. These factors determine the machine's physical dimensions, placement speed, and part-handling (staging) features.

**FIGURE 40.4** Examples of axial leaded devices: (a) axial leaded components; (b) axial leaded components in reels and boxes. (Courtesy of Sandia National Laboratories.)

Axial leaded components are inserted before radial leaded components because, typically, axial components are smaller overall than radial components. Because the associated tooling size is also smaller, inserting axial components prior to the radial components facilitates the stuffing of higher-density circuit boards.

**40.2.5.1.3 Radial Leaded Components.** After DIP and axial leaded components, the radial components are inserted into the circuit board. Radial components can vary greatly in size, shape, height, and weight (see Fig. 40.5). The lead finishes—types and thicknesses—are identical to those of axial leaded components. The possible exceptions are hermetically sealed components, such as active Si chip devices in TO-5 cans, optoelectronic packages, and relays. Such devices typically have low-expansion, Fe-based alloy leads that allow for them to be sealed into the header with a glass-to-metal joint. Although some device manufacturers use a Sn-Pb or 100 percent Sn finish over an electroplated Ni (solderable) layer, other suppliers prefer an Au (protective) finish over the Ni (solderable) layer to provide adequate solderability. In such cases, the Au layer is removed by hot solder dipping in order to prevent Au embrittlement of the circuit board interconnection.

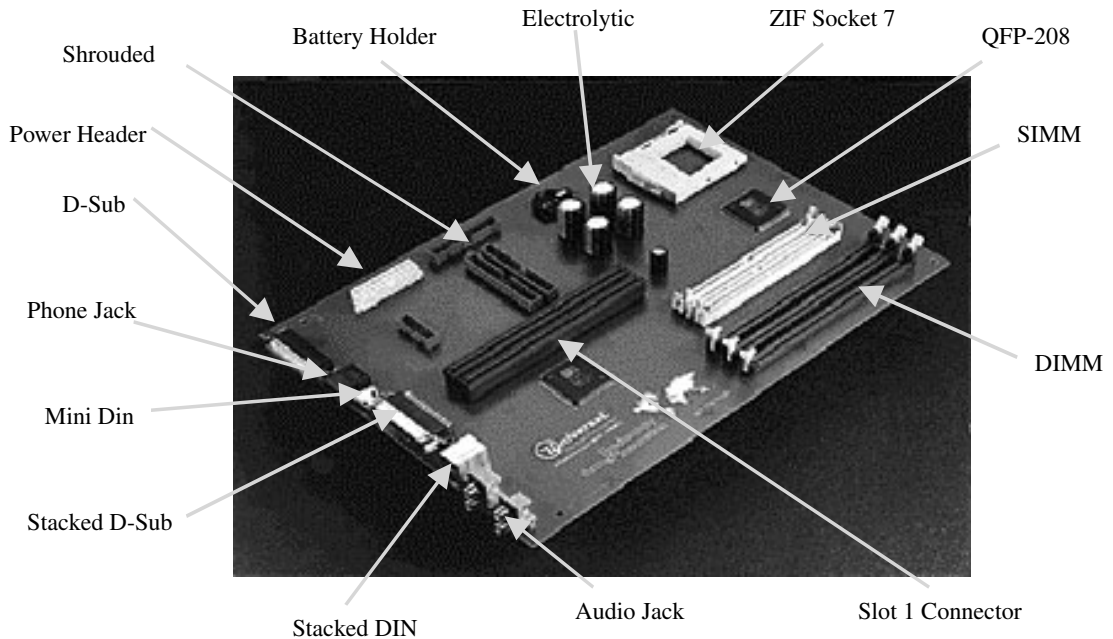

**FIGURE 40.5** Radial leaded components: (a) individually; (b) in taped reels. (Courtesy of Sandia National Laboratories and Universal Instruments.)

Radial leaded components are taped together at the leads. Radial insertion machines remove the components from the tape and insert them in sequence on to the printed circuit board using a shuttle system similar to that used for other components. The insertion machine tooling for radial components is designed to avoid previously inserted DIP and axial components.

**40.2.5.1.4 Odd-Form Components.** The odd-form components are the last devices to be assembled on the circuit board. Odd-form components, by definition, are those packages that are not readily addressed by automated assembly because (a) they are used at insufficient volumes on the product to justify machine “space” or (b) they are of a geometry (shape or size) that lacks the customer demand to justify the machine manufacturer to provide off-the-shelf tooling for them.

High-power applications often require a variety of odd-form components, including simply oversized DIP, axial leaded packages, or radial leaded packages. Also, odd-form components include transformers, switches, relays, and connectors. Several of these packages are shown in Fig. 40.6. Unusual package sizes and geometries are often accompanied by unusual lead configurations and materials. It is not uncommon to have Cu- and Ni-based alloy leads, or even leads made of refractory materials such as Mo and Ni. The leads may be round, square, or in the form of ribbons. Irrespective of the lead material or nontypical geometry (which must have the hole geometry addressed at the circuit board design step), it is *always* required that the leads have adequate solderability. Leads are typically plated with solderable layers (Cu or Ni) and

**FIGURE 40.6** Examples of odd-form, through-hole components and a circuit board assembly. (Courtesy of Universal Instruments.)

protective finishes (Au, Sn, Sn-Pb, etc.) very much like those used on traditional components to support the soldering process.

**40.2.5.2 Insertion Equipment.** Because the demand for through-hole circuit boards has remained strong, insertion equipment capabilities have steadily improved. Brushless servomotors and state-of-the-art motion controllers and sensors have replaced most pneumatic drive assemblies and bulky (and slow) mechanical switches and relays, respectively. Some equipment options include the capability to test parts electrically prior to insertion. At insertion rates of up to 40,000 components per hour (CPH), defect rates are a couple of hundred parts per million or lower for the common axial and radial leaded packages. Interchangeable tooling has allowed the automated insertion of many odd-form components, as well. The change to Pb-free solders does not have a direct impact on insertion equipment technology.

## 40.2.6 Automated Soldering and Wave Soldering

The most commonly used process for the soldering of through-hole and mixed (through-hole and surface-mount) circuit boards is *wave soldering*. The wave-soldering process is shown schematically in Fig. 40.7. The populated (or “stuffed”) circuit board is secured to a conveyor belt. The conveyor belt carries the board through the fluxer, then the preheat stage, and lastly on to the molten solder wave.

Interestingly, one of the most critical steps in the wave-soldering process is the application of the flux. Manual fluxing has given way to more precise, automated equipment in order to improve yields. The advantage is better control of the *quantity* of flux on the circuit board as it enters the wave because the flux controls both the entry and exit geometries of the molten solder wave, which in turn are instrumental toward minimizing skips, bridges, or icicle defects. Flux can be applied by spraying techniques or by passing the circuit board through the foam or “suds” of the flux. The latter technique is provided by the “foam fluxer.”

FIGURE 40.7 Schematic diagram showing the wave-soldering process.

FIGURE 14.8 Schematic diagram of the dual solder wave configuration.

FIGURE 40.9 Photograph of the dual-wave configuration. (Courtesy of Vitronics-Soltec.)

After the fluxing step, the circuit board passes through the preheat stage, which is comprised of a set of radiant heaters. As the circuit board is heated, this step evaporates volatiles from the flux coating (which if not adequately removed can lead to voids and blow holes) and activates the chemical reactions between the flux and oxides on the component lead or termination and the circuit board conductor.

The solder wave is created by pumping molten alloy upward through a nozzle, where it exits to a certain height and then falls back into the bath. The solder bath temperature is 260°C for eutectic Sn-Pb solder. The printed circuit board is carried by the conveyor so that it passes over the surface of the wave. The bottom side of the circuit board contacts the wave, allowing the molten solder to wet the exposed pads as well as to flow upward through the holes by capillary action. The speed of the conveyor and the take-off angle—that is, the angle at which the circuit board approaches the wave—are critical parameters for minimizing wave-soldering defects.

Another critical parameter of wave soldering is the wave geometry. The schematic diagram in Fig. 40.8 shows the commonly used dual wave. The first wave is turbulent so as to counteract the surface tension of the molten solder, thereby literally forcing the molten solder into confined geometries in order to initiate the wetting process. The second wave is smooth or laminar. The laminar wave is located at the exit point because its geometry reduces the propensity for bridges and icicle defects to form as the molten solder retracts itself from the circuit board. The photograph in Fig. 40.9 shows a circuit board entering the turbulent wave of a dual-wave soldering system.

A variation of wave soldering is the so-called selective soldering process. Instead of using a long wave to accommodate

the dimensions of an entire circuit board, a small fountain is created of molten solder. The reduced geometry allows for the soldering of individual components or several components on only selected areas of the circuit board. A manual operation is used to apply flux and preheat the circuit board prior to the actual soldering process.

The change to Pb-free solders has affected the wave-soldering process. Fortunately, the 260°C bath temperature used with eutectic Sn-Pb solder has proven to be adequate for most applications using the 99.3Sn-0.7Cu (wt. percent) and Sn-Ag-Cu alloys. Some users have preferred to raise the pot temperature to 260 to 270°C. The elements Ni and Ge have been added to the Pb-free solders in order to provide the shiny fillets that inspectors are accustomed to observing with Sn-Pb solders. The higher surface tension of the Sn-based, Pb-free solders increases the tendency for opens, bridges, and icicles to form as the circuit board exits the wave. A change of flux chemistry as well as adjustments to the take-off angle and conveyor speed have been used to minimize those defects. Lastly, a particular problem with Pb-free wave soldering is erosion of the machine parts by the high-Sn alloy compositions. Special coatings are put on the impeller, nozzles, baffles, and bath walls to mitigate the erosion process.

#### 40.2.7 Paste-in-Hole (Pin-in-Paste) Soldering

Very rapid production volumes are realized with inline surface-mount assembly processes. In general, the surface-mount assembly process consists of three basic steps: (a) screen printing of solder paste, (b) pick and place of components, and (c) reflow of the solder paste. To obtain similar throughputs for through-hole circuit boards, paste-in-hole soldering is being investigated as an alternative to wave soldering. Solder is provided to the joint in the form of a paste, using screen or stencil printing, or dispensed from a needle. The component is then inserted into the hole. In some applications, the parts are inserted into the circuit board and subsequently the solder is dispensed at the hole using a needle and pump. Then the assembly is sent through the reflow furnace. The primary hurdle with paste-in-hole soldering is supplying a quantity of paste that is sufficient not only to develop a fillet on that side of the joint, but also to fill the hole and, optimistically, create a fillet on the bottom side of two-sided and multilayer circuit boards.

A second concern for paste-in-hole soldering is the temperature sensitivity of the through-hole components. Recall that in wave, selective, or even hand soldering, the temperature rise is confined largely to the leads and circuit board. At worst, the component package materials experience only the preheat temperature environment. However, in paste-in-hole soldering, components must withstand the soldering temperatures within the reflow furnace. Therefore, a conversion to this solder process requires an in-depth review of the allowable temperature range for all of the components.

#### 40.2.8 Cleaning

The final step in the soldering process is the removal of flux residues from the completed circuit board. No-clean fluxes, as the name implies, produce residues that need not be removed from the assembly after soldering. The corrosive activators are locked up in a hard, polymerized residue. However, no-clean flux residues can potentially interfere with in-circuit testing (probes) and inspection, degrade cosmetic appearance, inhibit rework activities, and lessen the adhesion of conformal coatings. In the event that any one of these factors becomes critical, it is best to switch to a cleanable flux than to develop a cleaning process for a no-clean flux.

Low-solids fluxes (which are not to be confused with no-clean fluxes) are simply formulated with reduced solids content so that very little residue is left on the circuit board. Low-solids flux can be successfully used in wave-soldering and paste-in-hole processes, thereby eliminating the need for a cleaning step. However, they are somewhat more difficult to use in hand-soldering processes because the higher temperature of the soldering iron tip can cause premature loss of the activating agent, resulting in poor solderability.

The cleaning step can be performed in either a batch or inline machine. The optimum equipment is determined by production volumes, floor space, and capital expenditure costs. Smaller, batch cleaning (or “dishwasher”) machines are very cost-effective for overall batch-type processes (e.g., hand soldering) as well as for circuit boards assembled in low production volumes. Inline cleaning equipment is placed at the end of the soldering assembly line to accommodate high production volumes. Whether batch or inline equipment is used, an equally important consideration is selecting the type of cleaning solution. Solvent-based, aqueous, and semi-aqueous cleaning materials are commercially available that meet environmental regulations and provide adequate efficacy for the removal of flux residues.

The impact of Pb-free soldering on the cleaning step depends on the particular assembly process. By virtue that the same pot temperatures are used in Pb-free wave soldering as are specified for Sn-Pb solder, there is no added thermal degradation to the flux residues that would cause them to be more difficult to remove from the circuit board surfaces. Such degradation may be observed, albeit to a limited extent, with hand assembly due to slightly longer soldering times. Thermal effects are potentially most significant with paste-in-hole soldering because of the increased temperature settings of the reflow furnace required to melt Pb-free alloys.

### 40.3 SURFACE-MOUNT TECHNOLOGY

Surface-mount technology refers to assemblies that have components soldered to pads on the surfaces of the circuit board. Components may populate only one side (single-sided) or both sides (double-sided) of the circuit board. Surface-mount technology dates back to the 1960s, when it was developed for hybrid microcircuit (HMC) assemblies for which it was difficult to put holes into the ceramic substrates. The advent of surface-mount technology for laminate substrates, though, is relatively recent (c. 1980). The advantages of surface-mount technology include smaller components and greater board densities. The large holes have been replaced by small vias for signal conduction between sides and internal layers. Finer traces and reduced component heights also contribute to increased circuit board miniaturization and functionality. Surface-mount circuit boards are shown in Fig. 40.10.

**FIGURE 40.10** Surface-mount technology circuit boards showing the range of passive and active device sizes and geometries. (Courtesy of Sandia National Laboratories and American Competitiveness Institute.)

The trend in surface-mount technology is to use smaller passive devices such as capacitors, resistors, and inductors. Also, there is the use of embedded passive devices, that is, resistors and capacitors that are located within the circuit board laminate. Embedded passive devices free up additional surface area for larger, active components.

Active devices are experiencing two opposing trends. On the one hand, memory components (RAM, SDRAM, etc.) are becoming smaller as more transistors are being packed on to the silicon chip. On the other hand, microprocessors and application-specific integrated circuits (ASICs) are becoming larger because of increased functionality on larger chips. Both trends have seen a shift away from peripherally leaded packages to area-array packages. Area-array packages include BGAs and the smaller counterparts, those being CSPs and DCA/FC technology. Examples of peripherally leaded and area-array packages are shown in Fig. 40.11. The advantages of the area-array technology include a reduction of the component footprint by eliminating the leads that extend from the package. Also, fewer assembly defects result from damage to the fragile leads during packaging, transportation, and part placement on the circuit board.

**FIGURE 40.11** Photographs of (a) peripherally leaded and (b) area-array surface-mount packages. (Courtesy of Sandia National Laboratories.)

At the inception of area-array technology, the size and pitch of the I/Os were initially higher when compared to what was then 0.4 mm and 0.5 mm fine-pitch, peripherally leaded packages. However, as I/O counts have increased with the functionality of area-array packages, solder ball size and pitch have decreased significantly, particularly when taking into account DCA technology.

Increased device functionality and further miniaturization, which have resulted in higher board densities, are placing stricter requirements on circuit board technology. Increased internal conductor layer counts result in the need for thicker laminates. Whereas once the 1.58 mm board thickness was the norm, now 2.29 mm is commonplace, with many products requiring thicknesses greater than 2.54 mm. The internal conductor layers are being designed to carry not only the electrical signal, but also contribute to thermal management by removing excess heat from active devices. Similarly, the vias within the laminate are used to transmit signals between layers and the surfaces as well as remove excess heat from large active components (e.g., microprocessors, ASICs, etc.). Vias are reaching aspect ratios (length/diameter) of 8:1 to 10:1, which is nearing the fabrication as well as reliability limits for these structures.

A particular advantage of surface-mount technology is the lower manufacturing cost resulting from automated assembly processes. Solder paste, which is the combination of solder metal powder, flux, and thixotropic agents, is applied in highly controlled amounts (thickness and area) using screen or stencil printing as well as dispensing techniques. Pick-and-place machines handle even the smallest components, locating them precisely on the solder paste deposits (or “bricks”). The tacky nature of the flux component in the paste keeps the components in place. The assembled (or “stuffed”) printed circuit board then passes through the convection/radiation reflow furnace or vapor phase (or condensation) reflow oven to melt the solder. The machines responsible for the steps—paste printing, component placement, and reflow—are

connected by conveyor belts to create the inline process. In fact, the final step—cleaning the circuit board—may also be a part of the assembly process sequence.

Of course, various levels of automation may be considered, depending on production volumes and capital expenditure costs. However, with continued miniaturization of surface-mount products as well as the strict requirements for the repeatable placement of specific solder paste volumes and accurate placement of components, it will be a foregone necessity to assemble surface-mount technology with a fully automated assembly process.

Mixed technology refers to the combination of surface-mount and through-hole components on the same printed circuit board. The lack of components in a surface-mount package is nearly always the reason for using a through-hole counterpart. In general, the surface-mount devices are soldered first to the top side of the circuit board using a convection/radiation reflow furnace or vapor-phase soldering machine process. (Surface-mount is performed first because the through-hole components would interfere with solder paste printing and pick-and-place steps.) The through-hole components are then soldered to the board. The actual soldering process is performed at the bottom side. For larger numbers of through-hole components, the board is wave-soldered. If there are surface-mount components located on the bottom side, they can likewise be wave-soldered; however, those components must first be secured in place by an adhesive. Hand soldering may be preferred if there are relatively few through-hole devices or if bottomside surface-mount devices cannot be exposed to the solder wave.

### 40.3.1 Pb-Free Soldering

Pb-free soldering technology has affected surface-mount technology. Fortunately, the fallout has not included the need for new automation equipment. Lead-free solder paste behaves essentially the same as its Sn-Pb counterpart in the printing process. Slight modifications have been suggested for the screen and stencil apertures to accommodate the reduce solderability of Pb-free alloys once the paste enters the reflow furnace. Pick-and-place equipment can remain unchanged by a Pb-free soldering process. Reflow furnaces must be able to accommodate the higher process temperatures required by Pb-free solders. Vapor phase reflow machines are available with fluids that provide the higher process temperatures needed for Pb-free assembly. (As noted earlier, significant equipment costs are associated with altering a wave-soldering machine for the Pb-free assembly, which would pertain to mixed-technology printed circuit boards. Those costs include the replacement of the solder as well as the replacement of some components that are susceptible to erosion by the high-Sn alloys.)

The most significant impact of Pb-free technology is in reflow process parameters, specifically the time-temperature profile. Longer times at higher reflow temperatures increase the likelihood of thermal damage to components and substrate materials. Also, in seeking to reach higher reflow temperatures, one must also consider the sensitivity of the solder paste to the temperature ramp-up rate. An incompatibility between the paste and time-temperature profile can lead to increased levels of defects such as voids, solder balls, short-circuits due to paste slump, etc. Similarly, excessively fast cooldown rates from the higher reflow temperatures can result in board warpage and cracked passive devices. The greater need to control the Pb-free time-temperature profile favors greater control capabilities for the reflow furnace.

The Pb-free solders have intrinsically poorer solderability performance than their Sn-Pb counterparts. The slower rate of wetting and spreading is not as critical of a factor in reflow surface-mount assembly as it is the faster wave- and hand-soldering processes. However, the higher surface tension of Pb-free alloys may limit the extent of solder spreading on a pad, particularly with bare Cu, leaving the corners uncoated by soldre. The choice of flux and use of alternative surface finishes can mitigate this artifact in some cases. A high surface tension also increases the likelihood of *tombstoning* by passive devices particularly for the smaller chip resistors and capacitors. The degree of tombstoning can vary from the device having one termination just lifting from the pad to the component standing up completely on one end.

### 40.3.2 Design Considerations

The design of a surface-mount circuit board requires the consideration of three factors pertaining to the assembly process. First, there is a wide variety of solder-joint configurations for the different package types. Second, higher board densities can lead to upward of several tens of thousands of solder joints being fabricated at one time. Third, component miniaturization, as well as the unexposed solder joints of area-array packages, further diminishes the viability of performing repair or rework activities to correct solder-joint defects. A number of design rules are printed in documents (e.g., IPC SM-782 and D-330) that govern the size and location of bond pads. Surface-mount circuit boards are at least double-sided and, in most cases, multilayer, so that board design also must consider the interior of the laminate where vias are placed to conduct signals between the layers and surfaces.

Assembly requirements also place constraints on the circuit board layout. A very high part density requires a large number of apertures in the solder paste stencil, which can cause the stencil to become locally too flimsy to control the solder paste deposit. A surface-mount circuit board with a very wide range of component sizes and package configurations may require multi-thickness stencils to properly control the paste deposit. Solder paste printing quality is a determining factor in solder-joint defects observed after the reflow process.

The layout design of the surface-mount circuit board is a factor in the optimizing of the time-temperature profile used in the reflow process. Two important factors are overall thermal mass of the circuit board, determined primarily by the board thickness and number of internal layers as well as the variety package sizes and materials that can lead to temperature gradients as large as 20°C between the smallest passive devices and larger ball grid array packages over the board surface. Also, double-sided circuit boards require two reflow processes. Therefore, larger components should be placed on the side of the circuit board that is soldered last. If placed on the first side to be soldered, large packages may fall off of the board when the circuit board is upside down for the second side's soldering step, unless those devices are secured in place with an adhesive or "staking" compound.

The design of a printed circuit board for Pb-free assembly must consider the same points as are considered for Sn-Pb technology, but with a greater emphasis placed on the effects of higher process temperatures – e.g., temperature gradients between components across the circuit board. Foremost, there are the enhanced temperature gradients that may be created across a large circuit board having a high mixture of different component sizes and shapes. In the case of a mixed-technology product, there may be limitations placed on the maximum substrate thickness due to the less-solderable Pb-free alloys. It may also be necessary to limit via aspect ratios (typically remaining less than 10:1) to prevent immediate damage (defects) by the reflow process or a loss of long-term reliability.

### 40.3.3 Assembly Processes

The basic assembly process sequence for surface-mount technology is (1) solder paste printing, (2) pick and place of components, and (3) reflow of the solder. The assembly process is complicated when through-hole components are combined with surface-mount devices on the same circuit board; this is the previously mentioned mixed technology. In general, hand assembly of surface-mount boards is not always practical given the small size of passive devices and hidden solder joints of area-array packages. The use of hand soldering for repair and rework activities is limited by these same factors.

This section lists the sequence of process steps for the different circuit board categories. The term *top side* has typically referred to the side with the greatest density of components and/or where the larger, active device packages are clustered together. As the functionality of printed circuit board products increases, these physical distinctions between the two sides have become less obvious. Therefore, the circuit board sides are simply given a designation: A or B.

1. Single-sided (top side), surface-mount only:
  - a. Print paste
  - b. Place components
  - c. Reflow solder paste
2. Double-sided, surface-mount only:
  - a. Bottom side, print paste
  - b. Bottom side, dispense adhesive for larger components, if necessary
  - c. Bottom side, place components
  - d. Bottom side, reflow solder paste and cure adhesive

Flip the board over to the top side:

  - e. Top side, print paste
  - f. Top side, place components
  - g. Top side, reflow solder paste
3. Double-sided, mixed technology (with bottomside wave soldering):
  - a. Bottom side, dispense adhesive for surface-mount components
  - b. Bottom side, place surface-mount components
  - c. Bottom side, cure adhesive

Flip the board over to the top side:

  - d. Top side, print paste
  - f. Top side, place components
  - g. Top side, reflow solder paste
  - h. Top side, insert through-hole components

Keep the top side facing up:

  - i. Wave-solder the through-hole and the bottom-side surface-mount components

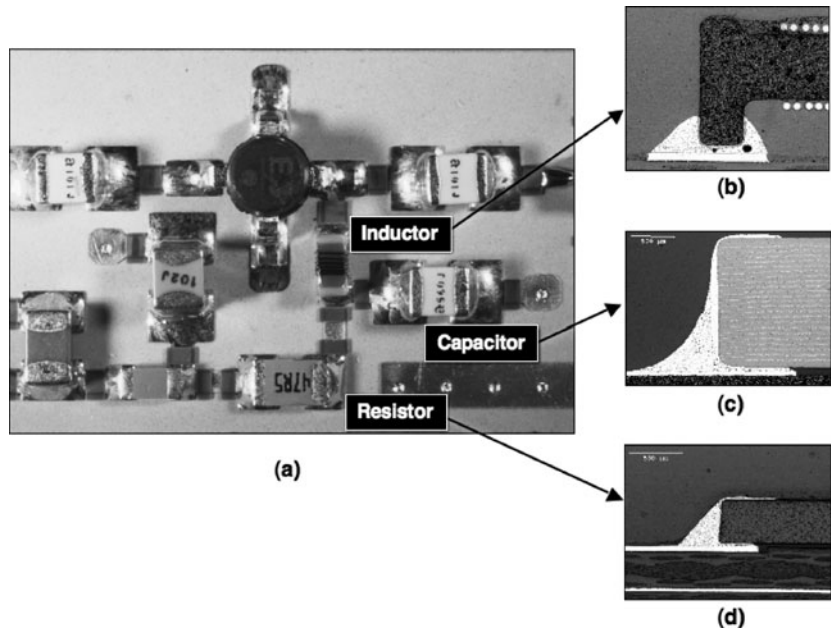

In case (3), for mixed-technology products, there is some flexibility regarding the sequence of staking (gluing) of bottomside components versus the topside soldering step, based largely upon the capabilities of the pick-and-place equipment.

In the case of area-array packaging technology having solder balls (BGA, CSP, and DCA), there is the option of *not* adding solder paste to the pads. Instead, only the flux is deposited on the pads, which serves to tack the package in place during transport of the board to the reflow oven. The solder balls provide the solder to complete the joint; however, the penalty is a reduced gap thickness that may affect self-alignment during soldering (as well as solder-joint reliability later on). Omitting the solder paste is most often considered for the DCA/FC assembly process because the solder balls, and the corresponding pads, are so small that it is not possible to print the acceptable quantity and dimensions of the paste consistently.

There is also the use of step-solder processes for double-sided, surface-mount-only circuit boards, that is, case (2). A high-temperature solder, often the 96.5 Sn-3.5 Ag (Sn-Ag) alloy ( $T_{\text{eutectic}} = 221^{\circ}\text{C}$ ), is used to attach the bottomside components. These solder joints do not remelt when the topside joints are made using the Sn-Pb solder ( $T_{\text{eutectic}} = 183^{\circ}\text{C}$ ). Somewhat tighter process control is required, since the  $221^{\circ}\text{C}$  Sn-Ag eutectic temperature is very near the optimum, peak process temperature for the Sn-Pb process ( $210\text{--}220^{\circ}\text{C}$ ). This approach provides the option of placing larger passive and active components on both sides of the circuit board without the need for an adhesive dispensing and curing step. Unfortunately, the use of the higher melting temperature, Pb-free Sn-Ag-Cu solders all but eliminates this step-soldering approach without identifying a higher melting temperature solder for the first step.

The following sections examine each of the steps in a surface-mount assembly process, beginning with an examination of component types. The different dispensing technologies are reviewed, including those for solder paste and adhesives. Component placement machines are examined, followed by a description of the use of the various heat sources such as convection/radiation reflow ovens, wave-soldering equipment, condensation reflow apparatus, hand soldering, and conduction soldering. Lastly, cleaning processes are described.

**40.3.3.1 Components.** A wide variety of components are available for surface-mount printed circuit boards. The form, size, and materials used for these components change constantly as new offerings are made by suppliers to meet miniaturization, functionality, and reliability requirements. The most common surface-mount components are the passive or “chip” devices—the resistors, capacitors, and inductors. Chip capacitors and resistors are often referred to by a four-digit number, such as 1825, 1210, or 0804. The first two digits refer to the component body length, which is the distance between the terminations, and are in hundredths-of-inches (0.xx). The second two digits refer to the body width in hundreds-of-inches (0.xx). (For passive devices, a similar numeric designation is given that is based upon the metric system [mm]. The actual values are very close to the English values and can be a source of confusion, especially when partnering with overseas companies.) Thus, an 1825 capacitor has a length of 0.18 in. and a width of 0.25 in. A stereo photograph appears in Fig. 40.12 that shows examples of passive components. Chip resistors tend to be very robust and thus relatively immune to damage during the assembly process. Multilayer chip capacitors are temperature-sensitive and therefore more prone to cracking during assembly, particularly under fast temperature ramp rates.

**FIGURE 40.12** (a) Stereo photograph showing surface-mount passive (chip) devices: inductor, capacitor, and resistor; (b–d) cross sections of their respective solder joints. (Courtesy of Sandia National Laboratories.)

The chip resistor is constructed of a piece of alumina ceramic on top of which is deposited a thin film that serves as the resistive element. Attached to the resistive element at the top, on the ends, and partially at the bottom are the termination structures to which the solder joint is made. The termination structures are comprised of a fired, Ag-based thick film; a Ni or Cu barrier layer; and lastly an electroplated finish of Sn, Sn-Pb, or Au.

Chip capacitors are constructed from a special oxide-based ceramic that is built up of alternating layers of ceramics and thin film layers that provide the device capacitance value. This capacitor is the multilayer thin film (MLTF) type. The second capacitor type has electrodes on the top and bottom surfaces of a homogenous “block” of ceramic. The ceramics used to make

chip capacitors tend to be more fragile than the alumina body of a chip resistor. The built-up layer structure of MLTF capacitors causes them to be particularly susceptible to both mechanical and thermal shock. Chip capacitors use similar metal layers to build up the terminations that are soldered to the circuit board pad as were described previously for resistors.

Chip inductors are of two types as well. Coil inductors are comprised of a fine Cu wire wound around the alumina body. The body size and number of windings determine the part inductance. The second type is the thin-film inductor. The winding is fabricated from a patterned thin film, which is deposited upon a piece of alumina. (Although the latter are considerably easier to fabricate, they have a limited range of inductance values.)

As much as 40 percent of passive components on a surface-mount product are chip capacitors. The miniaturization of these devices is critical for reducing the size and weight of electronic products. For handheld electronics (such as cell-phones, PDAs, and pagers), common capacitor sizes are from 0603 down to 0402 and 0201.

Some diodes and all active devices come in a wide variety of peripheral lead and area-array packages. The diodes and transistors are typically used in small-outline (SO) packages; they are the small-outline diode (SOD) and small-outline transistor (SOT) packages. The package body is a plastic overmolding compound. There are two leads for the SOD and three for the SOT. The leads are very robust, have a gull-wing shape, and are formed from Cu or an Fe-based alloy. Larger active devices require more I/Os. These devices use the small-outline integrated circuit (SOIC) package with gull-wing leads protruding from the two sides of the long dimension. The gull-wing leads are very robust with a pitch of 1.27 mm (50 mil) or 0.635 mm (20 mil). Pitch is the distance between the centerlines of two neighboring leads.

A further increase in the number of I/Os was realized by placing leads around all four sides of the package; the leads can have the gull-wing geometry or have the J-lead geometry. The J-configuration reduces the bond pad area by bending the lead inward, under the package. Like the gull-wing, the J-lead geometries are robust at 1.27 mm (50 mil) and 0.635 mm (20 mil) pitches.

Pitches below 0.635 mm, beginning with 0.5 mm and 0.4 mm pitches, are called fine-pitch (package) technology. The smaller leads are considerably more fragile, causing them to be more susceptible to damage during handling and pick-and-place activities. Also, the fine-pitch packages have a more stringent coplanarity requirement for the leads. Coplanarity specifies the degree to which the lead bottoms must be at the same level around the periphery of the package. A non-coplanar lead—one that is lifted high—is more likely to generate an open because of the reduced amount of solder used for these smaller I/Os. A lead that is too low will be damaged during package placement and also displace the solder paste deposit, causing a defective joint or short circuit to a neighboring lead after the assembly step.

A second type of peripheral I/O package is the leadless ceramic chip carrier (LCCC). This package is made of ceramic material; the I/Os are castellations on all four sides of the package. Solderability of the castellations is obtained by a Ni finish over which is deposited an Au layer. The Ni and Au layers extend down the castellation and under the frame to form a pad. This package can be used only on so-called matched or low-expansion substrates, that is, circuit board substrates with a thermal expansion coefficient that matches that of the ceramic package. Otherwise, the solder joints are quickly degraded by thermal mechanical fatigue (TMF) when exposed to even modest cyclic temperature environments.

Area-array packages include the BGA, CSP, the land grid array (LGA), DCA/FC, and the ceramic column grid array (CCGA). The common characteristic of these packages is that the solder joint is made to an array of solderable pads on the bottom side of the package rather than to peripheral leads or castellations. The difference between a BGA package and a CSP package is that the latter is stipulated to have molding compound dimensions that are less than 1.2 times the corresponding die dimension. There are no specified limits on a BGA package size.

The typical pitch size is 1.27 mm and 1.0 mm for BGA and CSP packages. Here, the pitch is the distance between the center points of any two balls or lands. Therefore, alignment requirements are not very stringent for these area-array packages. Also, there is a sufficient quantity of solder to allow self-alignment between the package and circuit board pads by the surface tension of the molten solder. However, as ball counts reach several thousands, reduced ball

sizes and pitches are required, which in turn necessitate closer tolerances on part placement. This is also the case of DCA, where the solder ball size and pitches tend to be as small as 0.10 mm and 0.25 mm, respectively.

The CCGA is a variant of the BGA in which the solder balls have been replaced with solder columns. The columns allow the ceramic package to be assembled to an organic laminate circuit board of considerably larger thermal expansion coefficient by absorbing the higher strains created by the larger thermal expansion mismatch between the two materials. The columns are created from one of the high-melting-temperature, Pb-based alloys (e.g., 95Pb-5Sn or 90Pb-10Sn) that will not melt during a eutectic Sn-Pb reflow process. The columns may also have a Cu spiral wound around them to enhance durability as those columns are susceptible to damage during handling and part placement.

The accelerated development of surface mount components has generated packages and I/O configurations that have not yet been standardized, resulting in odd-form devices. Examples of odd-form components include surface mount switches and connectors as well as a variety of inductors, (Fig. 40.13) LEDs, and transformers. Typically, so-called surface-mount connectors may actually be mixed technology with through holes providing the mechanical strength needed for cable insertion and removal activities and surface-mount leads establishing the electrical connection. (The through-hole interconnections can be made by paste-in-hole techniques or be soldered manually.)

**FIGURE 40.13** Odd-form components as exemplified by surface-mount inductors. (Courtesy of Sandia National Laboratories.)

A number of assembly-related issues must be addressed with odd-form components. First, it is necessary that correct pad dimensions be designed on the circuit board. Also, the stencil must have the correct aperture size to print an adequate quantity of solder paste. The pick-and-place machine may require custom tooling in order to handle these components. Lastly, odd-form parts are typically larger and heavier. Therefore, it is possible that they will not readily self-align while the solder is molten during the reflow process.

The conversion to Pb-free solders has significantly affected surface-mount components. In the case of leadless passive devices and peripherally leaded packages, the traditional electroplated Sn-Pb finish has been replaced with 100 percent Sn coatings. The Sn coatings have raised concerns regarding the development of Sn whiskers that can potentially short nearby conductors in service. The Sn-Pb solder balls of BGA, CSP, and DCA technologies, having a melting temperature of 183°C, are being replaced with Sn-Ag-Cu alloys with a melting temperature of 217°C. In the case of DCA/FC and CCGA applications, the high-Pb alloys used for the balls and columns, respectively, will not melt during a Sn-Ag-Cu solder process used to create the second-level interconnections.

**40.3.3.2 Dispensing.** In surface-mount technology, three classes of materials must be dispensed on to the circuit board: adhesives, fluxes, and solder pastes. Each of these three categories, which utilize very similar equipment options for the actual dispensing action, is discussed in the following subsections.

**40.3.3.2.1 Adhesives.** Adhesives are used to secure surface-mount devices to the circuit board. An adhesive may be required when, for example, exposing surface-mount components to a wave-soldering process used to assemble a mixed technology circuit board. Also, larger components on double-sided circuit boards may be adhesively bonded in place to prevent them from falling off when the board is turned upside down for the second reflow step. Under these circumstances, the package weight exceeds the surface tension force of the molten solder that keeps smaller components on the board. The adhesive must be able to withstand the temperature conditions of the wave or reflow soldering process as well as the chemical activity of the flux. Adhesives may also be required to anchor larger surface-mount devices to the circuit board. This additional strength is needed for service specifications that include mechanical shock and vibration environments.

(Adhesives are typically not used for through-hole components because clinching the leads provides a sufficient anchor to keep the component on to the board prior to and during the soldering process. After soldering, through-hole solder joints are sufficiently robust to withstand heavy shock and vibration environments. Nevertheless, in very severe environments, adhesives may be used to anchor through-hole components to the substrate.)

It is important to control the quantity of dispensed adhesive since there must be sufficient material to perform the attachment function. On the other hand, too much adhesive can cause run-out onto the solder pad or component I/O, resulting in poor solderability. Some adhesives are prone to run-out or “bleeding” caused by their separation into individual liquid components that together comprise the adhesive material. When bleeding by a component liquid occurs beyond of the adhesive deposit, that bleeding liquid can contaminate nearby solderable surfaces. In the case of very dense circuit boards, excessive migration of the whole adhesive migration, or the bleeding of one of its components, can contaminate the pads of other components, affecting their placement and solderability.

Although the function of the adhesive is to anchor components in place for the soldering process, the adhesive deposit remains as a part of the assembly after soldering, and as such must not interfere with next-assembly steps or negatively impact the long-term reliability of the circuit board. For example, some epoxies readily absorb moisture or other organic compounds. Those absorbed materials may outgas during subsequent temperature excursions that could contaminate critical surfaces (e.g., sensors) when the product is in service. Therefore, it is important to select only adhesive materials that are qualified for a particular application.

Adhesives materials that are used in electronics assembly processes are typically based upon epoxies or silicones. Adhesives can also be described by the following four functional/materials categories: thermosetting adhesives, thermoplastic adhesives, elastomer adhesives, and toughened alloy adhesives. Each group differs in its compositions, the type of curing cycle, and its pre- and post-cure material properties. The curing cycle, which typically requires an elevated temperature/time profile, must not degrade the components present on the board or the laminate itself. It is understood that the added step of a curing cycle slows the overall assembly process.

*Thermosetting adhesives* cure by heat or a catalytic reaction that cross-links the polymer chains. Once cured, these materials remain very strong and will not readily soften at elevated

temperatures. Epoxies are one group of thermosetting adhesives, which are used widely in electronics assembly because they do not weaken at the high temperatures of wave and reflow soldering environments. Also, epoxies are resistant to attack by solvents and aqueous-based cleaning solutions. Epoxies can be one-part, in which the curing agent and resin are already mixed together, or two-part, in which the two chemistries are combined prior to application. Although the one-part epoxies are convenient from the assembly standpoint, their storage and handling must be rigidly controlled to prevent curing prior to use. Both epoxies are cured by exposure to elevated temperatures, which can range from less than 100°C to as high as 125 to 150°C, for time periods of 1 to 4 hours, depending on the specific product recommendations. There is very little outgassing associated with the curing of thermosetting adhesives. Higher residual stresses can be generated by these materials due to their rigidity at elevated temperatures when there is a significant thermal expansion mismatch among the package, the epoxy, and the circuit board substrate. The “permanency” of thermosetting adhesives complicates repair or rework functions. The removal of these adhesives usually requires mechanical scraping and abrasion that can damage the component and circuit board.

*Thermoplastic adhesives* soften when exposed to elevated temperatures. These adhesives are weaker than thermosetting epoxies. However, when tolerances are less restrictive, these materials may be preferred for assembly applications, particularly when excessive residual stresses are of concern during the soldering process temperature cycle. Thermoplastic materials are less resistant to solvents and aqueous-based materials. These adhesives tend to absorb these liquids more readily, resulting in dimensional changes (swelling) and more outgassing than is observed with thermosetting adhesives.

Thermoplastic materials have curing temperatures that are lower and time durations that are shorter than thermosetting materials. Some compositions will cure at room temperature, making them suitable for temperature-sensitive components or when thermal expansion mismatch, residual stresses are of concern. Another advantage of thermoplastic adhesives is that because they readily soften at elevated temperatures, they can be easily removed to allow for the rework of components.

*Elastomeric adhesives* are a subset of thermoplastic adhesives. These materials tend to be very tough, yet have a higher degree of elasticity. The silicone (rubber) adhesives are examples of this category. The lack of rigidity limits the application of these adhesives in the soldering assembly process. Curing temperatures are relatively low, as some compositions cure at room temperature. However, the curing cycle of some silicone adhesives include considerable outgassing and, moreover, the outgassing of vapors that can be corrosive to metal surfaces (e.g., acetic acid).

*Toughened alloy adhesives* are blends (or alloys) of elastomeric materials and epoxy resins that together form this special class of thermosetting-like adhesives. These adhesives are engineered to provide both high structural strength and sufficient toughness (ductility) to resist damage due to either thermal or mechanical shock. Examples of this type of material include epoxy-nylon adhesives.

All of these materials have been engineered to have properties that can accommodate one or more of the various dispensing techniques used in printed circuit board assembly (which are discussed later in this chapter). However, these properties do not remain optimal indefinitely. There are two stages of degradation. The first stage is the shelf-life of the material, which is the time frame during which the adhesive keeps its properties while the container remains unopened. Manufacturers date-code specify shelf-life based on changes to the mechanical properties (strength, ductility, etc.) and physical properties (glass transition, density, liquid viscosity, etc.) that occur to the adhesive. Density and viscosity directly impact dispensability.

The second stage of degradation occurs when the adhesive is removed from the container, mixed if required, and is loaded into the dispensing equipment. Exposure to air, even under room temperature conditions, causes the adhesive to begin curing on the assembly floor. The curing can alter density and viscosity and thus the dispensing properties of the adhesive. Indications of a significantly cured adhesive include a clogged dispensing machine, run-out or bleeding of the deposit, and “stringers” of material created as the dispensing tool moves from one location to another spot.

**40.3.3.2.2 Fluxes.** The dispensing of fluxes has more limited applications in surface-mount technology (aside from mixed technology that includes a wave-soldering step). Flux dispensing is performed when solder is not simultaneously delivered to the joint—for example, the wave soldering of a mixed technology circuit board or the attachment of an area-array package for which the solder balls provide a sufficient quantity of alloy for the joint. In fact, flux dispensing is most widely used for DCA/FC applications. The DCA joints often require only a very small quantity of solder that would be difficult to control or to place accurately with typical printing equipment and stencils. Thus, the quantity of solder present in the ball forms the joint, and only flux must be added to the assembly.

Soldering fluxes are generally available only as a liquid for electronics applications. The low viscosity prevents the flux from being precisely located on the circuit board using stencil printing. Therefore, flux is usually dispensed by spraying techniques. However, once flux is sprayed on the surface, the circuit board must be soldered very quickly as volatiles and other components begin to evaporate from the flux coating.

In the case of DCA applications, the flux is applied directly to the component. The process is shown schematically in Fig. 40.14. The die is placed into a bath containing a very thin layer of flux. The thickness of the layer controls the quantity of flux taken by the die when it is withdrawn from the bath. The flux must be sufficiently tacky to anchor the die to the substrate for transport to the reflow step. Because of the large exposed surface area of the flux bath, the flux volatiles readily evaporate so that the bath must be replenished on a regular basis.

**FIGURE 40.14** Flux dispensed on the balls of a flip-chip component: (a, b) The solder balls are immersed into the flux reservoir; (c) the component is removed from the reservoir with the solder balls coated with flux; (d) the component is placed on the circuit board.

**40.3.3.2.3 Solder Paste.** The dispensing of solder paste is the most widely used means of providing flux and solder metal to the joint for the reflow process. The primary components of the solder paste are the solder metal and the flux. The solder metal is typically 80–90 wt. percent of the paste. Aside from the In- and Zn-containing solders, there is very little sensitivity of the paste properties to the solder metal composition for Sn-based alloys. Important properties of the paste with respect to dispensing are the solder powder particle size and weight percent or “metal loading” of the paste.

The flux can be any one of the various compositions—rosin-based, no-clean, low solids, and water-soluble. The flux also provides the tack that keeps the components attached to the board prior to the reflow step. Other ingredients in the paste are the thixotropic agents. It is the thixotropic agents, together with the metal content and flux, that determine the viscosity of the paste.

Viscosity controls the dispensing properties of the paste, irrespective of the particular technique (needle, screen printing, etc.). The viscosity and hence the dispensability of the paste change with time, whether slowly in an unopened jar on the shelf or more quickly when the paste is exposed to air while awaiting the dispensing step. Care should be taken to monitor strictly the manufacturers' recommendations for shelf-life and lifetime on the assembly floor. Poor solder paste dispensing accounts for the majority of solder-joint defects observed in surface-mount technology.

**40.3.3.2.4 Dispensing Methods.** There are five primary methods for dispensing adhesives, fluxes, and solder pastes:

1. Pin transfer
2. Screen or stencil printing
3. Time-pressure pump dispensing
4. Archimedes screw pump dispensing
5. Positive displacement pump dispensing

The latter three methods generally produce a single deposit per dispensing step. The first two methods enable the application of the material at multiple sites in a single step. Of course, the five techniques do not perform equally well for the three materials. This section discusses the advantages and disadvantages of each technique.

*Pin transfer* is the simplest technique for dispensing adhesives and flux. Although a single pin may be used to deposit material one location at a time, a matrix of pins can do so at multiple sites, the pin transfer process is illustrated in Fig. 40.15. This technique is suitable for adhesives

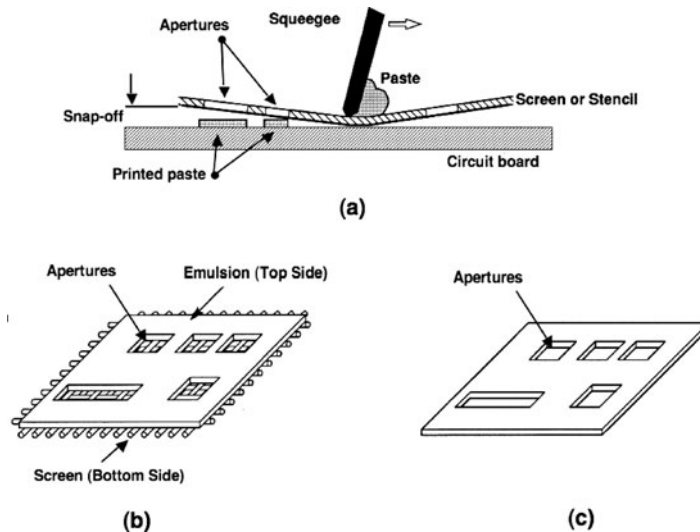

**FIGURE 40.15** Pin transfer technique: (a) The pin is brought down to the adhesive reservoir; (b) the pin is immersed in the adhesive; (c) the pin is withdrawn from the reservoir with a repeatable quantity of adhesive; (d) the pin is positioned on the circuit board, allowing the adhesive to contact the surface; (e) the pin is withdrawn from the surface, leaving behind a well-controlled volume of adhesive.

and fluxes; it does not work as well with solder paste. A pin is dipped into a reservoir of the adhesive or flux. The length and diameter of the pin determine the quantity of material that is picked up upon its withdrawal from the reservoir. The pin is then lowered to a position just above the surface of the printed circuit board that allows the flux or adhesive to contact the circuit board. Surface tension causes a portion of the adhesive or flux to be deposited on the printed circuit board. It is very important that the pin does not touch the board because this will cause inconsistent dot sizes and shapes. This system requires the substrate to be relatively flat and free from distortion. The nature of the pin array can also allow for adhesive to be applied to the board even after through-hole parts have been put into place.

A similar principle to pin transfer is used for the application of flux on the solder ball of FC components for DCA (See Fig. 40.14). The die is immersed into a thin film bath of flux. The flux depth allows only the balls to be coated so that, in effect, the solder balls become the pin, taking up the flux. The flux on the solder balls is transferred with the die to the circuit board, where it provides the tack function as well as fluxing action for the solder balls during the reflow step.

An important consideration about the pin transfer technique is that it requires an open bath of the adhesive or flux. Adhesives readily absorb water from the air. Fluxes lose vehicle (water or alcohol) and possibly other constituents through evaporation. By either mechanism, the material properties change, which affects the quantity of fluid retained on the pin and deposited at the site (including the flip-chip process previously described). Adhesives must have sufficient "wet strength," and the fluxes must have enough tack to hold the component in place for the duration of component placement activity as well as subsequent handling of the circuit board on its way to the curing oven or reflow oven.

*Screen or stencil printing* can be used for adhesives as well as solder paste. The low viscosity of most flux solutions precludes their successful dispensing by this technique. The adhesive or solder paste is deposited through openings in the stencil or screen called *apertures*. The apertures are located over the locations on the circuit board where the adhesive or solder paste is required. The placement of material is performed by a squeegee pushing a quantity of adhesive or paste ahead of it, over the screen or stencil, as illustrated by Fig. 40.16a.

**FIGURE 40.16** Screen and stencil printing: (a) the squeegee movement used to print adhesive or paste through a screen or stencil; the construction of a screen (b) and stencil (c) used for printing.

The difference between a screen and a stencil is in their respective structures, as shown in Fig. 40.16b, c. The screen is comprised of two layers: the emulsion layer and the actual screen that supports the emulsion layer. The apertures through which the adhesive or solder paste is deposited are created in the emulsion by photoimaging techniques. The adhesive or solder paste simply flows past the screen cross-hatched wires.

The stencil is simply a sheet of metal or alloy (commonly Mo, Ni, brass, or stainless steel) having the apertures formed in them. The apertures can be created by one or a combination of the following techniques:

- Photoimaging (photoresist definition) combined with etching by wet chemistry
- Laser cutting
- Build-up technology by electroplating processes

The choice of fabrication technique depends on the required sizes and densities of the apertures. The stencil has replaced the screen in most surface-mount printing applications, not only because of its simpler construction, but also because it can accommodate finer, denser circuit board features.

The thickness of the screen or stencil and the size of the individual aperture openings are the parameters that control the *quantity* of adhesive or solder paste deposited on the circuit board. Secondary factors are the aperture wall quality, the material viscosity, the hardness of the squeegee, and the speed of the squeegee. In the case of solder paste, the quantity that is actually deposited is usually *less than* the volume of the aperture, which is the product of the width, length, and stencil thickness. The degree of that discrepancy is called the *transfer factor* or *transfer coefficient*. Values can range from 60 percent for very small apertures to nearly 100 percent for larger aperture openings.

Screen or stencil printing is the most widely used means for depositing solder paste on a surface-mount circuit board. The preferred paste viscosity for screen printing is 250 to 550 kcps (kilo-centipoises) for an 80 mesh screen. In the case of stencil printing, the desired viscosity is 400–800 kcps. The ability to print consistently upward of tens of thousands of paste deposits per circuit board has been critical to the realization of high-volume electronics production. This process is being developed for through-hole circuit boards and is referred to as *paste-in-hole* or *pin-in-paste* technology.

Solder paste printing technology includes stepped stencils. Stepped stencils are made with two different thicknesses and are used when a circuit board has such a wide range of device pitches and joint configurations that a single stencil cannot yield the optimum paste deposits for all the components. The thinner sections are used for the very-fine-pitch packages, whereas the thicker sections deposit paste for the larger-pitch components. These stencils are more expensive to fabricate than the single-thickness products.

The printing of adhesive or solder paste with a screen or stencil has several limitations. It can only be performed in a single pass; if there is a fault during that pass, the board must be removed and cleaned prior to a second attempt. Second, the circuit board surface must be flat and have no obstructions that will interfere with the stencil or screen surface “sealing” against the board surface as the adhesive or paste is pushed into the apertures by the squeegee. As such, it is important that the screen or stencil be thoroughly cleaned of paste residues prior to use in order to minimize printing defects, which can subsequently become solder joint defects if not caught prior to reflow. Third, stencils and screens wear with time, resulting in an increased number of printing defects. The harder the metal or alloy, the longer is the lifetime. For example, brass stencils, which are relatively inexpensive, have a short service life. Stainless steel stencils have a longer lifetime, but are also considerably more expensive.

Referring to the solder paste printing process with a stencil, Pb-free solder pastes behave very similar to the Sn-Pb pastes for leaded and area-array pitches of greater than 0.5 mm. At the smaller pitches that are characterized by smaller apertures, it has been observed that the Pb-free solders have a slightly reduced transfer coefficient. The likely

cause is the reduced density of the Pb-free solder particles, which becomes a significant factor when so few particles are passed through the aperture. Therefore, it may be necessary to slightly open up the apertures to ensure a sufficient quantity of Pb-free solder at the joint.

*Time-pressure pump dispensing* is a method to deposit adhesive or solder paste by applying a pressure pulse for a specific time duration on a reservoir of material (see Fig. 40.17). A precisely controlled quantity of adhesive or solder paste emerges from the selected orifice size, which is deposited on the circuit board. Often, the material comes prepackaged in a syringe that is inserted into the machine.

**FIGURE 40.17** Time-pressure pump dispensing technique: (a) The dispenser is positioned at the circuit board site; (b) the dispenser is lowered to near the surface at which time, a pulse of air pushes the piston a distance  $\Delta x$  to dispense a set quantity of adhesive; (c) the dispenser is raised from the site, leaving the adhesive deposit.

As with all dispensing techniques, the flow properties of the adhesive or solder paste are important factors that determine the consistency of the deposit between the different sites. Shelf-life requirements should be strictly followed, particularly those pertaining to time allowed for the material to be present in the dispenser due to rapid degradation when open to the factory floor environment. The desired viscosity for pump dispensing through a nozzle is 100 to 400 kcps.

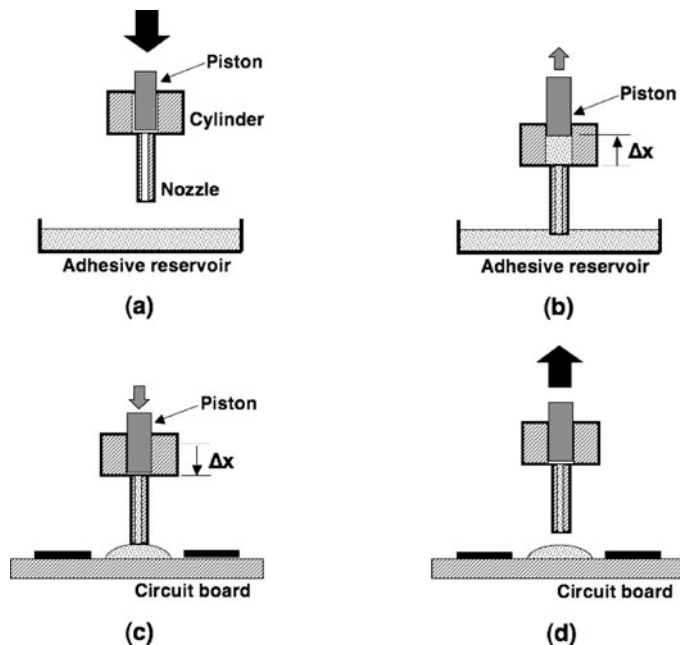

Machines utilizing the time-pressure dispensing technique can dispense different deposit sizes on a single board. One approach is to have multiple nozzles or syringes on a single head, using the same pulse profile. The second approach is to preprogram a different time-pressure pulse that alters the deposit quantity from a single orifice or syringe. This pump-dispensing technique (as well as those described in the following paragraphs) is slower than screen or stencil printing. However, it offers greater flexibility in terms of well-controlled deposit quantities and location.

*Archimedes screw pump dispensing* utilizes an Archimedes screw to push the adhesive or solder paste out of a nozzle (see Fig. 40.18.) The speed and duration of a turn, as well as the size of the opening, determine the quantity of adhesive or paste deposited on the site. As in the case of the time-pressure technique, different deposit quantities can be realized by multiple spindle (heads) or a computer program that alters the screw speed or turn duration to change the amount of material dispensed from the same orifice. All other considerations with respect to the roles of adhesive or solder paste viscosity and shelf-life also apply to this technique.

**FIGURE 40.18** Archimedes screw pump dispensing technique: (a) The dispenser is lowered to above the circuit board surface; (b) the Archimedes screw is turned a set rotation ( $\Delta x$ ), pushing adhesive out of the nozzle; (c) the dispenser is lifted from the circuit board.

*Positive displacement pump dispensing* uses a piston, rather than an air pressure pulse, to control the deposit quantity. This technique is used primarily to dispense adhesive (see Fig. 40.19). First, the nozzle is placed in a bath of adhesive, in which it retracts to draw a

**FIGURE 40.19** Positive displacement pump dispensing technique: (a) The dispenser is brought to the adhesive reservoir; (b) the nozzle is immersed into the adhesive and the piston withdrawn a distance  $\Delta x$ , resulting in a set quantity of material being pulled into the cylinder; (c) the dispenser is brought to just above the circuit board surface so that a reverse displacement of the piston pushes out a quantity of adhesive; (d) the dispenser is lifted from the circuit board.

quantity of adhesive that fills the orifice and small cylinder at the top of the orifice. This suction step works best with low-viscosity fluids. It is difficult to pull up relatively high-viscosity materials such as solder paste and some adhesives. Next, the piston moves downward into the cylinder, forcing an exact amount of adhesive out the nozzle and onto the printed circuit board. This technique consistently produces the same volume of material. Besides the dimensions of the cylinder as well as the speed that the piston displaces, the viscosity of the adhesive also affects the dispensed quantity. Shelf-life specifications should be strictly enforced.

The primary objective in each of the five dispensing techniques is to deposit *consistently* a *specific quantity* of adhesive or solder paste at each designated site. Too small of a quantity of adhesive, especially dot height, can fail to attach the part to the board. Too much adhesive causes it to run on to the solder pads, degrading solderability. In the case of solder paste, an insufficient quantity of paste will cause an incomplete joint or, in the worst case, an open circuit. An excess of solder paste results in a fillet that is difficult to inspect for solderability or risks formation of short circuits between neighboring interconnections.

**40.3.3.3 Component Placement.** The purpose of the component placement machine—also called the “pick-and-place” machine—is to select the proper component, orient it correctly, and then place it on the circuit board, all with degrees of accuracy and precision that minimize defects on the finished product. In addition, the component must be placed on the printed solder paste, the dispensed adhesive, or a combination of the two deposits with a controlled pressure or release distance that does not excessively spread out either material or damages the component package. Moreover, the placement machine must execute these tasks as quickly as possible in order to maximize the production volume. Lastly, the equipment must be sufficiently versatile to address continually changing electronic packages, specifically dimensions and I/O configurations.

The change to Pb-free solders does not have an explicit impact on component placement machine technology. Indirectly, however, the need for alternative surface finishes on both the components and circuit board fiducials, which have different reflectance characteristics, can affect the performance of the vision systems used to locate accurately both the circuit board and the tooling that delivers the component to the board.

Several machine types are available. The turret-style chip shooter and the gantry-style or flexible fine-pitch (FFP) machines have both been used extensively in the assembly of consumer electronics, telecommunications, mainframe and server computers, as well as for lower volume, high-reliability electronic products. However, the demands for even higher production volumes as well as the flexibility to change product lines rapidly have caused manufacturers to consider alternative machine architectures that include high-speed stepper motors and optical sensors as well as highly parallel methodologies that place multiple components at the same time.

**40.3.3.3.1 Turret Systems (Passive Devices).** The basic turret or “chip shooter” has been used to place passive components (i.e., capacitors, resistors, etc.) since the early development of surface-mount technology. A photograph of the turret head and schematic diagram of its operation are shown in Fig. 40.20. Multiple heads are positioned around a stationary, horizontally rotating turret. A moving feeder carriage positions tape feeders that deliver a component to each head. After the part is located in the head, the turret rotates it to a vision processing station where a charge coupled device (CCD) camera acquires an image of the part. This image is processed so that the part will be precisely located over the circuit board location. As the turret continues rotating, a moving table positions the printed circuit board so that the target location is in position under the turret head to receive the component. The part is lowered to the circuit board and released. The head rotates to acquire another component, and the cycle repeats itself.

Listed in Table 40.3 are general performance characteristics for turret chip placement technology. This technology is constantly addressing smaller passive devices (0101 and 01005) as

**FIGURE 40.20** Turret head used to retrieve chip components from a tape and place them on the circuit board. (Photo courtesy of Universal Instruments.)

well as an increased demand for placing bare die (flip-chip) components on more densely populated circuit boards. Equipment manufacturers and users must continually address new package configurations with different I/O geometries.

**40.3.3.3.2 Gantry Systems (Active Devices).** The gantry-style architecture differs from the turret because the printed circuit board is fixed in place and the moving gantry locates the

\*CPH = components per hour

component over the correct position (see Fig. 40.21). The part feeder is stationary. The gantry method is typically used to place larger components (e.g., SOICs, PLCCs, etc.). Several attributes of gantry technology are listed in Table 40.4.

Several equipment variations can be specified to increase the variety of parts placed on the circuit board. Each gantry is made to accommodate different parts when equipped with a multi-spindle placement head. The placement head is positioned at each feeder location to receive a part. Then, the head moves the component to the upward-looking vision station for inspection

**FIGURE 40.21** Gantry architecture used for placing larger components such as SOICs, PLCCs, and area-array packages. (Photo courtesy of Universal Instruments.)

\*CPH = components per hour

followed by its placement on the printed circuit board. A second option is a placement machine made with dual gantries, each placing a single component type or multiple components with the spindle head option.

Several features in gantry-style equipment allow component placement speeds to approach those of turret systems in “high-speed” models. See Table 40.5 for the performance

**TABLE 40.5** Capabilities of High-Speed Gantry Technology

Property	Range
Part range	Full SMT (Passives, SOD, SOT, SOIC, PLCC, CCGA, BGA), direct-chip attach (DCA), and odd-form components.

Placement speed	15,000–21,000 CPH*
Capabilities	<ol style="list-style-type: none"> <li>1. Oversized and odd-form parts placed with very high accuracy.</li> <li>2. Oversized board capacity.</li> <li>3. High volumes of tape, tube, bulk, and tray part supplies.</li> </ol>

\*CPH = components per hour

of some dual-beam (gantry) equipment. Machine options that enhance placement speeds include tape splicing for uninterrupted machine operation and simpler bank-changing capability to allow for the rapid changeover of components between different product lines. Also, part inspection can be made using a head-mounted camera while the gantry(ies) is (are) in motion, which eliminates the time interval required for part inspection with a stationary, upward-looking camera.

Further enhancements in capabilities of component placement equipment can be realized in *massively parallel* architectures. The attributes of this approach are listed in Table 40.6. Multiple placement modules are capable of picking up, inspecting, and placing components at the appropriate location on the circuit board. The circuit board is stepped by an indexing conveyor to locate the placement site precisely under the overhead component.

**40.3.3.3.3 Machine Vision Technology.** A brief which is description is provided of one of the most critical advancements in component placement *machine vision technology*. The earliest pick-and-place function relied on mechanical stops (*detents*), switches and precision tooling to ensure that components were placed at the correct locations and with the proper alignment of I/Os to pads. As both board densities and component varieties increased, this technology was too slow to meet the requirements for higher production volumes and reduced placement defects. A critical incentive to move away from mechanical registration toward vision-based placement came from smaller I/Os on components. DCA/FC uses die bump pitches as small as 0.1 mm. Passive device sizes are commonly 0402 and 0201. Fine-pitch, quad flat pack (QFP) components have lead pitches as small as 0.3 mm. Each of these cases underscores the need for very high placement precision that can be realized only with machine vision technology.

In addition, there has been a steady increase of odd-shaped devices that include inductors as well as LEDs, surface-mount connectors, etc. The result has been circuit boards with a greater mix of package types and sizes. Consequently, it is considerably less expensive and time-consuming to reprogram a computer-based, machine vision system to recognize these components than it is to retool a machine based on mechanical relays, detents, and such for component placement.

*Machine vision technology* uses electronic cameras and optics together with specialized computer software to control the stepper motors responsible for positioning the component and the circuit board (site) relative to each other with the required accuracy and precision. To realize this objective, the placement machine must identify the component in the turret or gantry and establish the position of the turret or gantry. At the same time, the placement machine must know the position of the circuit board. The computer software ties these two requirements together by being programmed with the artwork (drawings) that identify the location of each component on the circuit board. Component recognition and circuit board recognition are discussed next, followed by comments regarding vision system limitations.

*Component recognition* is typically obtained from the configuration of the I/Os. The I/O configuration includes two attributes: the I/O's shape, whether it is a beam lead, gull-wing

**FIGURE 40.22** Vision system images: (a) a flip chip component; (b) a printed circuit board fiducial. (Courtesy of Universal Instruments.)

lead, or solder bump; and the I/O's layout, which may specify, for example, peripheral leads on two rather than four sides, or solder balls as full area-array packages rather than perimeter, area-array packages. Shown in Fig. 40.22a is the machine vision image of a flip-chip die with a perimeter array of solder bumps. The vision system determines the position of the package based upon the coordinates of the I/O locations, for example, two or four of the corner leads or solder bumps. Additional fiducials and/or nonsymmetries in the I/O layout (e.g., missing corner leads or bumps) are used to establish the rotational orientation of the component.

Besides determining component type and orientation, vision systems have also been programmed to recognize damage to components. For example, fine-pitch quad flat packages are prone to bending of the very small leads, particularly at package corners, due to worn die sets or improper handling. In the case of area-array packages (BGAs, CSPs, and DCA die), there can be missing balls or solder bumps. The damaged component is rejected into the "scrap bin" and a new unit retrieved for placement. It should be noted that component recognition vision systems are designed primarily for part placement. Although defect recognition can be programmed into the software, increasing the degree of inspection function slows the placement process significantly. Therefore, the optimum approach is to allow the vision system to identify only gross component defects, targeting those defects that would occur between incoming inspection and the component placement step. Otherwise, full, incoming component inspection should be performed *before* the parts are loaded into the placement machine.

*Circuit board recognition* requires that the machine (computer) be able to locate the circuit board site precisely for the component. First, the circuit board is secured on the conveyor by mechanical clamps, vacuum chuck, or other technique. The circuit board is then positioned under a camera that identifies the registration marks or fiducials on the surface (see Fig. 40.22b).

This process is repeated for two to three other fiducials on the circuit board. At this point, the machine "knows" the location and orientation of the circuit board and thus, through the artwork design stored in the software, correlates the fiducial locations with the location of each component site. Subsequently, the software matches the coordinates of the circuit board site to those of the component positioned in the turret or gantry. Then the software instructs the stepper motors to position the component over that site and lower it on to the circuit board.

Some applications, such as those using ceramic substrates that are prone to inconsistent degrees of shrinkage during fabrication (e.g., low-temperature, co-fired ceramic, or LTCC), may develop a discrepancy between the software design and the actual circuit board component positions (pads). In this case, the placement site of each component is determined directly using fiducials in close proximity to that component site. Although local fiducials may enhance component placement accuracy to some degree, especially when tolerance stack-up in the product causes it to deviate from the design files, this approach requires added processing time by the machine computer. The result is a decrease in placement speed that can develop into an appreciable process delay, particularly for large production volumes.

*Vision system limitations* are determined by the speed with which the computer can process information (e.g., circuit board coordinates, component geometries, defects). The more information to be processed, the slower is the component placement step. For products requiring the placement of thousands of parts per circuit board, even an additional few tenths of a second per component can add up to a significant loss of production throughput.

Similarly, there are operational limitations on vision systems themselves (cameras and optics). The trade-off is between resolution and the range of processable part sizes. The underlying premise is pixel count. The vision system requires a minimum number of pixels to recognize a feature (lead, solder bump, fiducial, etc.). A very small feature (e.g., a flip-chip solder bump) requires both high magnification and high resolution (i.e., pixels/length or pixels/area) in order for the system to recognize the feature. However, using the same system to recognize a large BGA package would require a magnification that may well be outside the capability of those same optics. Moreover, even if the package could be brought into the field of view, using the same high resolution, which is now not necessary, will overload the computer memory and bog down the software processing step, resulting in a slowing of the placement process. And conversely, the same camera that can efficiently process a large, 32 mm QFP (208 I/O) in a single image would generally not have sufficient resolution to process a flip-chip solder bump of 0.1 mm diameter. Therefore, the choice of optics is critical to maximize the efficiency of the pick-and-place function for a particular product. For optimum efficiency, it may be necessary to place the two components on separate machines. Alternatively, multiple cameras and optics may be used on a single piece of equipment. Cost becomes a critical factor.

Once the components have been placed, the circuit board is soldered using one of the techniques briefly described in the following sections. The component placement step is synergistic with the soldering step and, in particular, reflow soldering. That synergism arises from the fact that placement inaccuracies can be compensated by the self-alignment of packages arising from the surface tension (more accurately, the solder-flux interfacial tension) of the molten solder. This self-alignment phenomenon opens the placement window for passive devices larger than about 0603, smaller LCCCs, and 1.27 mm pitch area-array packages of up to several hundred balls. Unfortunately, for smaller passive devices and larger area-array packages, the self-alignment process becomes less capable of compensating for placement errors. In the case of smaller passive devices, there is the increased likelihood that an imbalance of surface tension forces can result in an asymmetric movement of the part, causing the tombstoning defect. In the case of larger area-array components, poor placement (which is becoming more critical with the finer pitches of smaller balls) cannot always be remedied by self-alignment simply because of the greater weight of the component.

The topic of soldering is described in greater detail in Chap. 42. Therefore, this chapter offers only a brief overview of each approach, with the discussion limited to its relevance to the overall assembly process.

**40.3.3.4 Reflow Soldering.** Reflow soldering is the technique in which a circuit board, which has the components placed on the solder deposit (either as paste or preforms) is passed through a furnace (oven) in order to melt the solder and form the joints. The furnace may be a batch type in which the circuit boards must be loaded and unloaded, one group at a time. The operator inputs the batch furnace time-temperature profile into the controller that alters the power to a set of heating coils as a function of time. The atmosphere can be very well controlled, including the use of vacuum. The batch furnace is advantageous for small production lots, including development work or when the time-temperature profile and environment must be carefully controlled for the application.

The second furnace has an inline configuration. The circuit boards continuously enter one end unsoldered and exit the other end soldered. Therefore, the inline furnace can be part of an overall assembly line, receiving stuffed circuit boards from the component placement machine via a conveyor without operator intervention. The temperature of the different zones

along the length of the furnace and the conveyor speed determine the time-temperature profile. More zones (five to seven are typical) provide for better control of the soldering profile. Inert atmospheres, typically nitrogen ( $N_2$ ) to minimize cost, can be maintained to better than 20 ppm oxygen ( $O_2$ ). However, control of both the time-temperature profile as well as atmosphere cannot match that of a batch furnace. Also, vacuum conditions are not possible with most inline equipment. Nevertheless, inline furnaces are well suited for high production volumes and are the most widely used furnace type for electronics assembly.

Whether batch or inline, furnace selection is based not only on throughput rates, but is also determined by the type of product being assembled. A greater complexity to the circuit board requires more control of the time-temperature profile to ensure that all of the solder joints are completed at minimum defect levels. In some applications, the extra furnace zones are used to control the cooling rate of the soldered circuit board to prevent thermal shock damage to sensitive components or substrates.

The introduction of Pb-free solders has impacted reflow soldering, less so in terms of actual equipment temperature capabilities than in the development of a suitable time-temperature profile. The heat source technology (infrared, convection, or mixed) can provide the higher reflow temperatures of the Sn-Ag-XCu alloys ( $T_{melt} = 217^\circ C$  versus  $183^\circ C$  for the traditional Sn-Pb solder). Of course, higher energy usage and maintenance costs are likely. Two generalized reflow profiles are used for Pb-free soldering. They are illustrated graphically in Fig. 40.23. The soak-reflow profile in Fig. 40.23a derives from the traditional Sn-Pb eutectic solder profile, but with the reflow “spike” increased for the higher melting Sn-Ag-Cu alloys. The soak step provides for activation of the flux as well as heatup of the circuit board and components. The continuous ramp or “hat” profile in Fig. 40.23b allows for a more rapid heatup rate, which reduces the time that heat-sensitive components and materials spend at elevated temperatures. On the other hand, the relatively faster heatup rate can increase the chances of thermal shock damage to some components—for example, larger plastic and ceramic devices—or to circuit board structures such as vias.

**FIGURE 40.23** Generalized time-temperature profiles for Pb-free reflow soldering: (a) the soak-reflow profile; (b) the continuous ramp or “hat” profile. Peak temperatures will vary, depending on the particular circuit board product.

In terms of optimizing the time-temperature profile, a balance must be established between achieving sufficiently high temperatures that will reflow the solder of every component (size and shape) and preventing thermal damage to other components or the substrate. Therefore, the higher melting temperatures of Pb-free solders make it more challenging to develop a time-temperature profile that will successfully melt the solder paste of larger components without causing thermal damage to smaller devices or to the circuit board material.

Therefore, in the case of some very-high-mix products, it may be necessary to solder larger packages in a separate operation (e.g., hand soldering or selective soldering). Under this circumstance, the latter packages would be considered as odd-form components.

**40.3.3.5 Wave Soldering.** Wave soldering is used when surface-mount technology is mixed with through-hole components on the circuit board. (See Figs. 40.7–40.9 showing wave soldering as it is used for through-hole circuit boards.) Surface-mount devices that are present on the same side as the wave are soldered as well, being held in place by an adhesive. The surface-mount components must be resistant to thermal shock because of the temperature spike experienced upon entering *and* leaving the molten solder wave. The temperature on the topside surface of the circuit board typically remains well below the solder solidus temperature, thereby preventing the reflow of any solder joints present there.

Wave-soldering equipment can be used either in an inline or in a batch process since the equipment has generally the same construction. The inline approach is used to support high production volumes. Small systems that are used in a batch-like mode include those used for *selective soldering*. This equipment includes miniwaves or solder fountains and are used to solder only localized areas of the circuit board, such as when attaching through-hole connectors, transformers, or switches. The advantage of selective (wave) soldering is that the entire circuit board need not be exposed to an elevated temperature.

An important consideration in wave soldering is the supporting fixtures that hold the circuit board on of the conveyor. In reflow soldering, the conveyor can support the entire bottom side of the circuit board. However, in wave soldering, the conveyor does not offer such support, as it must allow the wave to contact the circuit board bottom side. Therefore, it may be necessary to provide an additional fixture to prevent warpage and sagging of larger circuit boards.

The impact of Pb-free technology on wave soldering has largely occurred in the equipment performance. It has been determined that the same solder bath temperatures that are used for Sn-Pb processes (250 to 270°C) are suitable for the Sn-Ag-XCu Pb-free alloys. Therefore, excessive dross formation and flux residue removal have not become a significant problem during equipment operation. The lack of shiny fillets with the Sn-Ag-XCu alloys has been addressed by modified alloys having Ni and Ge additions that alter the solidification process, which leads to shinier fillet surfaces.

The Pb-free alloy compositions are more prone to erode the wave machine's structures, such as the impeller, baffles, and pot walls. New wave-soldering machines address this problem through the use of alternative steel alloys and ceramic coatings.

**40.3.3.6 Condensation (Vapor Phase) Soldering.** Condensation soldering, also referred to a vapor phase soldering, uses a working fluid's heat of condensation to reflow the solder paste or solder preform to make the joints. Because the condensation reflow process had its origins in the early days of surface-mount technology when production runs were more limited in volume, these machines were primarily batch-type units. Subsequently, inline equipment was developed to "attach" the vapor phase reflow machine to the back end of the placement equipment for higher production volumes. Two particular attributes of condensation soldering are (a) the temperature of the product cannot exceed the vaporization (or condensation) temperature of the working fluid, thereby preventing overheating of temperature-sensitive materials; and (b) the temperature is very uniform over all of the components and the substrate, thereby minimizing temperature gradients that could warp or crack component or laminate materials.

This process fell out of favor in the early 1990s, for two reasons. First, the working fluid for Sn-Pb solder, Dupont's Freon TMF, was categorized as an ozone-depleting substance (ODS). Its use was initially restricted and then prohibited by the Montreal Protocols. Second, the increasingly more complex circuit boards that were being designed with surface-mount technology required more precise control of the time-temperature profile, which lead to the development of multizone reflow furnaces having convective and infrared heating capabilities.

There has been a resurgence in the use of condensation soldering. Alternative working fluids have been developed for both Sn-Pb and Pb-free processing that are compatible with

environmental regulations. Preheaters are added to reduce the thermal shock when parts entered the working fluid, thereby providing a more controlled time-temperature profile. Lower capital cost and properties of the condensation heat source previously noted cause condensation or vapor phase reflow to be well suited for prototype development programs and small production volumes.

**40.3.3.7 Hand Soldering.** As noted earlier, in the highly automated surface-mount assembly line having automated paste printing and component placement capabilities, hand soldering would not be particularly advantageous in terms of maximizing production volumes. However, in some applications, the assembly process includes a hand-soldering operation. For example, often odd-form components cannot be incorporated in a pick-and-place machine, or temperature-sensitive devices cannot be exposed to the reflow furnace environment. Under these circumstances, the hand-soldering step is performed *after* mass soldering (reflow, wave, etc.). The implication is that hand soldering is now being performed on what is potentially a very-high-valued circuit board. Therefore, factors such as handling damage, electrostatic discharge (ESD) damage, and thermal damage to nearby components by the soldering iron tip, as well as flux residue contamination, must be thoroughly addressed at the development stage of the hand-soldering process.

The use of Pb-free solders has not impacted the hand-soldering process itself. There is a slight lengthening of the soldering time, typically from 3 to 4 sec. to 5 to 7 sec., due to the higher melting temperatures of the Pb-free solders. The same soldering iron equipment can provide the necessary tip temperatures. The high-Sn solder compositions, coupled with their higher melting temperatures, can more quickly degrade the tip. Lastly, the operator should not mistake a duller appearance to the fillet surface for a “cold” solder joint.

**40.3.3.8 Conduction (Sikama) Soldering.** Conduction soldering is the process in which heat arrives to the solder paste by means of conduction through the substrate. The process, which is illustrated in Fig. 40.24, is also termed Sikama soldering, being named after the primary

**FIGURE 40.24** Schematic diagram depicting conduction soldering. The pusher bar presses the circuit board along the surface of platen. Heaters under the platen determine the time-temperature profile.

equipment manufacturer. The equipment is set up to accommodate an inline process, although it can be used in batch mode as well.

The circuit board is pushed along on top of the heated platen by rods attached to a conveyor. Different sets of heating elements under the platen heat the latter locally to different temperatures along its length, creating heat zones such as those in a reflow furnace. The soldering process can be performed in air or using an inert atmosphere. The fact that the substrate is fully supported along its entire footprint (which is needed to maximize heat input) precludes excessive warpage.

The conduction heating process has been used almost exclusively for ceramic substrate because these materials do not degrade when exposed to the high platen temperatures. Thermal degradation would be more likely for organic laminates. Best results are realized when this process is used with relatively thin substrates (<1.0 mm).

**40.3.3.9 Cleaning.** Cleaning is typically the final step in the circuit board assembly process. There is a variety of cleaning equipment, from hand-loaded, batch-type “dishwasher” machines for smaller production volumes, up to larger inline units that are integrated into the back end of the assembly line for large production volumes. In response to environmental regulations, cleaning solutions have moved away from the once popular organic solvents to aqueous and semi-aqueous cleaners based on water- and water-alcohol-based compositions. Similarly, the handling of the waste stream is also important. Closed-loop systems are preferable to once-through cleaning process because of regulations governing the disposal of the waste stream. In the case of assemblies requiring multiple soldering steps, the cleaning portion of the prior soldering step does not leave a residue on the surface that degrades the solderability required for the follow-on process.

The use of a Pb-free process does not necessarily have a significant impact on the cleanability of circuit boards. At one time, it was believed that flux residues from Pb-free processes would be more difficult to remove, due to the higher soldering temperatures. Subsequently, it has been determined that thermal degradation of those residues is not as severe, so current cleaning processes appear to perform adequately.

**40.3.3.10 Pb-Free Solders.** The equipment types described in the preceding sections are often combined to form an electronics assembly line. The term “line” implies that the equipment is physically located end to end, thereby allowing for the movement of circuit boards between the different functions or stations. Although this scenario is, in fact, typically the case, it need not always be so. Under some circumstances, it may be advantageous to locate some stations a distance away others on the shop floor, thus requiring operators to move product between the two sites on wheeled racks. This is usually the case with inspection and repair/rework functions as well as for some cleaning processes due to health or safety concerns. The setup and hence the flow of a product assembly process are referred to as the (assembly) line architecture.

Numerous variables are considered when developing any assembly line architecture. The underlying consideration is optimizing the *level of automation*. Some of these variables include the following:

- Available floor space and facilities (electricity, exhaust, computer networks, etc.)
- Equipment footprint and cost of ownership or lease
- Labor costs
- Production volumes and product changeover flexibility
- Circuit board technology (through-hole, surface-mount, or mixed)
- Soldering technology: Sn-Pb versus Pb-free
- Inspection and quality requirements

It is important for the manufacturing engineer to consider not only each of these points individually, but to also apply the proper weighting factors of their importance when integrating them together to develop a process for the product(s).

The introduction of Pb-free solder technology does not, in and of itself, alter the previously described principles with regard to assembly-line architectures. The equipment is very similar and the factors that determine an optimum line configuration remain unchanged. Instead, consideration must be given to the cost/benefit of having an *entirely separate* assembly line that is dedicated to Pb-free products. In the case of wave soldering, the need for a second line is intuitive; it is simply not practical to empty and refill the solder pot with different alloys from both a process time-management point of view as well as the metallurgical-based concern of mixing the two alloys. An interim approach is to exchange only solder pots in the machine, ensuring that all residues of the previous solder have been removed from all equipment surfaces.

However, even in the case of solder paste printing and reflow soldering, many manufacturers have determined that two separate assembly lines are required, even to the extent of physically locating them at separate locations in the plant. There are simply too many risks associated with potentially mixing the two assembly technologies, particularly in high-volume operations where a significant quantity of product may be built before an error is recognized. The potential mix-ups include:

- Use of the incorrect solder paste
- Placement of components with the incorrect surface finish—Pb-Sn (high-reliability electronics) versus 100 percent Sn (consumer electronics)
- Incompatible moisture sensitivity levels (MSLs) of plastic molded components
- Vision system settings for identifying fiducials of alternative surface finish
- Reflow furnace settings for the different time-temperature profiles

#### 40.4 ODD-FORM COMPONENT ASSEMBLY

---

An accurate definition of an odd-form component is one that cannot be placed and/or soldered with equipment *available in the assembly line*. The likelihood of having to address an odd-form component is actually quite high. Because of the wide range of current component technologies as well as those expected in the future—whether through-hole or surface-mount—there is always the chance that a package cannot be placed or soldered in the assembly line. Certainly, if volumes warrant, new equipment can be purchased, or special tooling made, for adapting the placement and/or reflow equipment for odd-form components. However, there is a significant cost penalty to this approach, especially if it is performed for a variation of sizes and configurations. Each package variation would require separate tooling designs or equipment modifications. However, the advantages of automating odd-form assembly operations include a higher production volume as well as fewer defects resulting from the automated rather than manual operations. Therefore, it is not unusual for odd-form component assembly to be a mix of both manual practices as well as automated techniques.

Generally, the introduction of Pb-free soldering affects odd-form components in a manner not unlike that for other surface-mount and through-hole components. The two primary issues are I/O surface finishes and temperature sensitivity of each component's material set. High-reliability applications have to monitor components for 100 percent Sn finishes. Because odd-form components often fit this category due to a large size, hot Sn-Pb solder dipping is a more viable option to remove the 100 percent Sn finish. Otherwise, the tracking of incoming material and verification of the actual surface finish may be required.

Temperature sensitivity of devices will have to be documented in terms of surviving the Pb-free reflow profile. In fact, some devices that were previously processed on a Sn-Pb assembly line may have to be set aside as odd-form components because they cannot be exposed to the Pb-free process temperatures. Another risk of the higher-processing Pb-free reflow temperatures is the damage to moisture-sensitive components. The typical Pb-free time-temperature profile adds one or two MSLs to a component. Therefore, devices at MSL levels 5 or 6 per a Sn-Pb profile may have to be assembled to the circuit board in a separate operation to avoid damage, thus causing them to be odd-form components.

#### 40.4.1 Components

Connectors comprise approximately 75 to 80 percent of odd-form components. See Fig. 40.6. For example, there are universal serial bus (USB) connectors, dual inline memory module (DIMM) connectors, phone jacks, and zero-insertion-force (ZIF) connectors, as well as a variety of surface-mount connectors. Other odd-form components include sockets, electrolytic capacitors, transformers or large inductors, LEDs, relays, switches, as well as speakers and vibrators for handheld communications devices. In surface-mount technology, odd-form components are most often through-hole packages, including both passive and active devices as well as connectors. When addressing such odd-form components, the first step is to check the availability of an equivalent surface-mount version since there has been a shift toward surface-mount versions of many of these devices. Of course, the materials used to construct the surface-mount replacement must survive the reflow furnace environment, and especially the Pb-free reflow temperatures, particularly connectors because of their complex internal construction. In some cases, it has been possible to replace the through-hole connector with one of a variety of solderless products.

Also, it is not necessarily size or weight that causes a component to be identified as “odd-form” per the particular assembly line. Temperature-sensitive and moisture-sensitive devices may also be excluded from a reflow step of the assembly process to prevent damage to them. The latter scenario is of particular concern when converting from a Sn-Pb to a Pb-free process.

DCA refers to the assembly of an *unpacked* active semiconductor device directly onto the circuit board. The interconnections are made either by wirebonding or by solder bumps on the front side of the die. The latter application is referred to as FC attachment and can be implemented into a surface-mount assembly process as long as existing equipment can accommodate the placement accuracy required for the very small solder bumps and pads. Otherwise, a dedicated cell may be required.

The DCA process, which uses wirebond interconnections, is based on the following steps. First, an adhesive is dispensed on the board and the die placed on it. The adhesive, which is often thermally conductive for heat management, is cured. The I/O pads on the die are wirebonded to the appropriate pads on the circuit board. Then, the die and wire bonds are encapsulated in an epoxy to prevent damage to them. The encapsulant, or “glob top,” is then cured. Critical to the glob top technology are the following factors: complete coverage of the die and wire bonds with minimal run-out beyond the circuit board pads; adequate adhesion between the die and circuit board; and good adhesion between the encapsulant and the circuit board beyond the perimeter of the die.

#### 40.4.2 Manual Assembly

In the least complicated format, only an operator places the odd-form components on the circuit board. The soldering process is automated in that the operator picks components from bulk bins and repeatedly positions them onto the circuit board as it is carried along the conveyor line. For paste-in-hole assembly, the solder paste and other components (surface-mount or through-hole) may already be on the board, being held in place only by the tackiness of the paste. Therefore, the operator must not inadvertently displace other components off of their sites during handling.

Also, the operator must pay special attention to handling and ESD damage while placing components. Also, those components that incorporate snap-in features (e.g., connectors) can require that the operator exert relatively high forces on the circuit board. Thus, the operator must not damage either that component or other components and the circuit board. Often, special tooling is used to press snap-in components on the circuit board to prevent such damage.

A large number of applications require the operator to place and then manually solder the odd-form component into place, often after the other components have been soldered into place. The operator must be cognizant of handling and ESD damage as well as prevent thermal damage or the inadvertent reflow of solder joints for neighboring components. The impact of

Pb-free soldering would be most significant in this circumstance. It is necessary to verify that a longer hand-soldering time or a higher tip temperature does not cause thermal damage to the component in question or cause the reflow of nearby solder joints.

It should be noted that irrespective of whether manual assembly is performed on only stuffed boards that will be subsequently soldered or on circuit boards that have already been soldered, the units have a higher value to them because of this processing, which is performed beforehand. Therefore, *any* damage (handling, ESD, thermal, etc.) will result in a significantly higher yield loss to production volumes as well as higher costs associated with the repair or scrapping of damaged circuit boards. Therefore, manual assembly steps must be given due consideration during product design and process development activities.

### 40.4.3 Automated Assembly

The automated assembly of odd-form components uses the same placement equipment as is used for other components, but with special tooling or a dedicated machine (cell), which is already set up with the required tooling and component feeder systems, that can be introduced into the assembly process. The latter equipment typically places more than one type of odd-form component for increased versatility. For example, the close-up photograph in Fig. 40.25 shows the type of gripper tooling that can place different component packages (to within its design limits, of course). After accuracy and component-type requirements are met, speed is the critical performance metric for odd-form placement machines. Odd-form component placement is nearly always a bottleneck or slow point in the line; therefore, minimizing assembly time devoted to odd-form components will speed up the entire process flow.

**FIGURE 40.25** Odd-form component placement machine having a flexible servo-driven gripper tooling that can place a wide range of different component configurations. (Courtesy of Universal Instruments.)

There are both advantages and disadvantages to the automated assembly of odd-form components. Advantages include the following:

- consistent as well as higher quality and faster throughput result from eliminating manual processes.
- Automated assembly saves floor space, as machines typically take up less area than operator work benches.
- Solder dispensing is integrated into the placement process flow, minimizing related defects.
- Automated assembly complements an overall, computer-integrated manufacturing infrastructure already in place with the other assembly steps that, in turn, facilitate process flow, quality control, and product changeover.
- Automation eliminates operator-related health and safety issues (fumes, repetitive tasks, etc).

The disadvantages of automation include the following:

- Capital equipment costs can be high for machines, dedicated tooling, and plant modifications.
- Prepackaging components are required for automated feeders.
- Equipment changeover for different product lines is somewhat slower due to the need for special component packaging and/or feeders.
- Higher production volumes can generate a greater quantity of defective product before a process problem is identified.

**40.4.3.1 Component Packaging Formats.** Odd-form components come in a variety of sizes, geometries, and I/O configurations that determine the ease with which the component can be “automated” into the assembly process line. Another important variable is the component placement machine. Typical component packaging formats for the placement machine include tape and reel (radial and axial leaded), extruded tube, tray, continuous strip, and bulk containers. Each of these formats has benefits and drawbacks, as noted in the following subsections. Industry specifications have standardized nearly all of these packaging schemes. For example, there is EIA-468-B for radial devices and EIA-296-E for axial components.

**40.4.3.1.1 Tape and Reel.** Tape and reel allows for the delivery of parts to the circuit board at very rapid rates. See Fig. 40.26. Tapes are available generally in three formats: flat-carrier tape, deep-pocket tape, and semi-deep-pocket tape. Flat-carrier tape is the traditional method of carrying both odd-form (as well as form-fit) radial and axial components. It is inexpensive and can provide a large quantity of parts for rapid placement rates. Deep-pocket and semi-deep-pocket tapes provide room for the larger component bodies. The packaging of multiple parts having a similar pitch is possible with semi-deep-pocket tape; the particular advantage is to conserve feeder space, particularly when only a few of each type of component are required on the circuit board.

**FIGURE 40.26** Radial components packaged in tapes that would come off of reels. (Courtesy of Universal Instruments.)

Several drawbacks are associated with tape carriers. For example, tall or heavy parts may change position or break the cover of deep-pocket tape carriers. The potential consequence is that the tape and/or components will jam or damage the feeder mechanism of the placement machine, thereby interrupting the assembly process.

**40.4.3.1.2 Extruded Tube.** Extruded tube is a commonly used format for odd-form components. See Fig. 40.27. Components such as D-Sub connectors, phone jacks, transformers, relays, and shrouded headers are typically supplied in tube packaging. Recently, component manufacturers have begun to supply long connectors such as single inline memory modules (SIMMs), DIMMs, and other designs of long-aspect ratios in edge-stacked tubes.

Tube packaging is particularly beneficial for protecting the component at a reasonable cost. Also, tubes are less likely than tape to cause problems feeding components into the placement machine. Of course, it is necessary to verify that the tube geometry is compatible with the feeder mechanism on the placement machine. The tube material should be sufficiently thick so as not to bend readily. Bending of tubes is the primary cause for the jamming of devices inside

**FIGURE 40.27** Components in tube packaging. (Courtesy of Universal Instruments.)

of them during the feeding process. Moreover, heavy components packaged in thin cross-sectional tubes may actually interfere with adjacent tubes when stacked in the automated feeder.

**40.4.3.1.3 Matrix Trays.** Matrix (or waffle) trays are an inexpensive means to supply components that are generally too large or heavy for tube or tape packaging and must be individually separated from one another. See Fig. 40.28. An important consideration is that the trays themselves may not be a suitable starting point for the automated placement processes especially for very small components. First of all, the components have too much room to move about in each bin to establish coordinates for initiating the pickup and insertion process. Also, component leads are not always oriented correctly in the insertion plane.

**FIGURE 40.28** Components packaged in matrix trays. (Courtesy of Sandia National Laboratories.)

Several potential issues may need to be considered when choosing trays. Trays lack the rigidity required by many assembly machines for part pickup. Also, trays hold a more limited quantity of parts to the placement machine, and thus require more operator changeout during assembly. There are no standards for vacuum-formed trays that are used for odd-form components. Lastly, trays simply take up a greater amount of feeder space in a placement machine and on the floor.

**40.4.3.1.4 Continuous Strip.** Continuous strip packaging is designed for high-volume automation applications of odd-form components. This technique eliminates the need for separate component packaging formats because the individual parts are all attached in sequence to a single metal or plastic strip as part of the assembly process. The parts are located with a specified pitch that can be accommodated by the placement machine. Some components that are packaged in this manner include headers, battery clips, transformers, and motor brushes. Either the metallic part (e.g., brushes) or the leads that are part of the component can be stamped from a continuous strip of metal or thermosetting plastic. This type of packaging provides high levels of online parts inventory. However, such strips are application-specific and may carry a higher cost to automate due to the need for specially designed feed mechanisms.

**40.4.3.1.5 Bulk.** Bulk packaging eliminates the expense of component packaging altogether by simply placing the devices in a large container. A significant number of odd-form components are shipped in this format. Of course, the component manufacturer has likely established the cost/benefit of the fallout of parts due to handling and shipping damage versus the cost of added packaging by one of the previously mentioned formats. On the other hand, the degree of part damage may not be acceptable to the circuit board assembly house because of increased downtime due to machine jams and part replacement.

Bulk packaging is the most difficult packaging format to automate for odd-form components. Generally, bulk components require a specially designed bowl feeder to supply parts to the machine with some degree of consistent orientation, which increases cost and process implementation lead times. Also, the unusual configuration of bowl feeders may require a dedicated placement machine (cell) that may have a significant idle time. The feeders usually take up considerable space and are not easily retooled for product changeover. The placement machine must have then the versatility to orient each part consistently from a haphazard “pile” of devices so that the pickup device can obtain each unit and correctly place it on the circuit board. In spite of these numerous drawbacks, bulk packaging is a cost-effective approach for odd-form components in numerous product applications.

**40.4.3.2 Equipment.** Advances continue to be made in the capabilities of odd-form assembly equipment. Early vintage, single-task robotic systems are giving way to machines that perform all of the alignment and functions of modern placement equipment, and which can be integrated into existing assembly lines. New machines are designed for speed and the flexibility to handle different odd-form component geometries as well as a variety of circuit board configurations.

Typically, automated odd-form component placement machines use an overhead gantry-style positioning system and vision and optics systems underneath the head. The emphasis is on placement accuracy given the high component density of surface-mount boards and, in some applications, the use of solder paste-in-hole printing methods for a 100 percent reflow soldering process. The component must be placed accurately into the solder paste the first time so that the solder paste is not disturbed, which can result in potential defects. Interchangeable grippers and vacuum pickups as well as improved component feeding mechanisms provide greater flexibility for different product types, faster placement rates, and minimum equipment downtime.

#### 40.4.4 Cleaning

The cleaning of assemblies having odd-form components, like the placement of those devices themselves, can occur at one of several points along the assembly process. If the components are placed prior to the principal soldering step, then they will be cleaned along with the rest of the circuit board. The higher temperatures of a Pb-free solder process can make this cleaning step somewhat more difficult, depending on the tenacity of the flux residues.

On the other hand, when the odd-form devices are soldered to the circuit board after the primary soldering process has taken place, the subsequent cleaning procedure must take into

account the other components that are already on the circuit board, particularly potential handling damage. It may be preferred to use a no-clean or low-residue flux to minimize or eliminate the added cleaning step required for the later placement of odd-form components.

Because odd-form components are often larger and/or have more complex constructions (geometry and materials), there is an increased likelihood of flux residues becoming trapped in confined areas. Therefore, the cleaning process must be sufficiently thorough to remove residues from those locations on the component. Similarly, it is necessary to verify that the cleaning solution has likewise been removed from those locations as part of the process.

## 40.5 PROCESS CONTROL

---

Process control refers to the capability of repeatedly making product units that meet performance specifications (including long-term reliability) within an allowable frequency of repairable and nonrepairable defects. There are two underpinning premises of process control, which can be described specifically with regards to circuit board assembly: (1) The assembly process is nominally capable of making a circuit board that meets the performance specifications; (2) the equipment and materials set are capable of making those acceptable circuit boards repeatedly. The types of defects, and the frequency of their occurrence, are the metrics for establishing and monitoring the process using statistical process control (SPC). Defects can be detected by visual or machine inspection, or are identified by electrical performance of the assembly (referred to as in-circuit testing).

It is beyond the scope of this chapter to provide a detailed explanation of SPC. Rather, there will be a qualitative discussion of process control that addresses those factors affecting circuit board assembly, beginning with defect types in electronic solder joints. Then the discussion will turn to process control as it pertains to the basic assembly steps (e.g., dispensing, pick-and-place, etc.). The various material sets (e.g., circuit board, solder paste, flux, etc.) will be incorporated in the discussion. Also, the use of Pb-free soldering technology will be addressed where applicable.

The yield drops that result from an out-of-control process impose significant cost penalties. High production volumes can potentially generate large quantities of defective printed circuit boards before a defect trend is discovered. Therefore, it is critical, first of all, to establish process control *and* maintain it throughout production and, second, be able to identify product defects, determine the responsible process parameter, and quickly correct the faulty equipment, material, or operation.

### 40.5.1 Defects

Defects are defined as those artifacts that are outside the window of acceptable attributes for the finished circuit board assembly. Thus, defects are not limited to the solder joints, specifically, but can also include damage to the circuit board material as well as degradation to component structures (e.g., molding compound, leads or terminations, etc.). Defect types and their allowable frequencies (often expressed in parts-per-million solder joints or product units) vary with the different assembly processes and applications. Therefore, product drawings, in conjunction with industry standards (e.g., IPC-610), are used to establish accountable defect types for printed circuit boards.

Defects are most often detected by visual inspection or automated optical inspection (AOI). Other means of nondestructive evaluation (NDE) include electrical testing, x-ray inspection, and ultrasonic inspection. The preferred NDE inspection technique for BGA and CSP solder joints is x-ray inspection. Automated x-ray inspection equipment is often placed directly into the assembly process line for circuit board products having a large number of area-array components.

There are destructive evaluation techniques that can also be used to find defects. Metallographic cross sections provide a means to inspect the internal structures of the solder joints, components, and circuit boards, albeit in only a single plane at a time. Mechanical tests (die shear, pull tests, etc.) can also be used to identify defects. However, because these approaches are destructive, and because they require long lead times to obtain results, they are generally inapplicable for real-time process control. They are better suited for process development or failure analysis activities.

Defects serve two functions for the process engineer. First, defects provide the quantitative metric with which to ascertain process control, using SPC techniques. Second, the microstructural details of the defect(s) can be used in a failure analysis study to identify the root cause of an “out-of-control” process.

There is very little difference between the types of defects that occur during a Pb-free assembly process and those that have been documented for Sn-Pb assemblies. The two exceptions are grainy solder fillets and fillet lifting of Pb-free, through-hole interconnections. The grainy fillets resulting from the use of some Pb-free alloys are intrinsic properties of their solidification behavior. Because they do not necessarily represent a cold solder joint—that is, one that is only partially melted—the appropriate revisions have been made to industry specifications to account for this effect. The second phenomenon, fillet lifting, occurs on some Pb-free plated through holes. Although several studies have concluded that fillet lifting does not necessarily impact either the short-term performance or long-term reliability of these interconnections, they may still be categorized as defects, depending on the particular product requirements.

Finally, the frequencies of defects on a Pb-free product may differ from those for the same Sn-Pb assembly. Of course, proper process optimization will minimize the frequency of such defects. However, slightly different solder paste printing characteristics at finer pitches, as well as overall poorer wetting and spreading behavior of Pb-free solders, may result in an optimized process that simply cannot achieve the low defect rates of a Sn-Pb process under the capabilities of the equipment set. Additional mitigation steps that can be taken by the design and process engineers include altering the stencil design (e.g., slightly wider apertures); using alternative circuit board and component I/O surface finishes that enhance Pb-free solderability (e.g., one with a Au protective finish); changing the solder alloy composition (Bi-containing solder); replacing existing equipment to provide wider process window capabilities; or taking no action and simply accepting the reduced process yields, based on an accurate cost/benefit analysis.

## 40.5.2 Dispensing

Dispensing processes include those for an adhesive, solder paste, or both (e.g., surface-mount wave or selective soldering). Because the adhesive is dispensed prior to the solder paste, it is possible to inspect for defects—incorrect dot volume, run-out on nearby solder pads or lands, and stringers—prior to dispensing solder paste.

By and large, the greatest number of solder-joint defects can be traced to the solder-dispensing process and, specifically, the stencil or screen printing step. Therefore, process control is critical here. An absence of the control of any one of these attributes can significantly impact process yields. Important factors include the following:

- Have the appropriate stencil or screen design and materials (e.g., thickness, aperture geometry, wall finish, etc.) for the circuit board product. Design considerations must also address the need to widen fine-pitch aperture openings slightly for printing Pb-free solder paste.
- Properly design the circuit board to provide recognizable fiducials and an absence of burrs or other artifacts that can interfere with the dispensing machine and/or stencil performance.
- Ensure that the stencil is free of particles and other contamination.

- Establish the optimum dispensing equipment parameters and, in the case of solder paste printing, squeegee materials.
- Select the correct solder paste (powder size, metal loading, and flux type) for the dispensing process and adhere to shelf-life and shop-floor-life recommendations.
- Select and properly maintain dispensing equipment (e.g., squeegee replacement schedules, vision system calibration, cleaning, lubrication, etc.).

Dispensing defects can be detected by visual inspection or automated inspection techniques. Such automated techniques include those based on visible light images as well as laser profilometry that determines the actual volume of the adhesive or solder paste deposit. However, inspection slows the process assembly line. The more joints that are selected for inspection (that is, not all joints need to be inspected) and the greater the information detail required from the inspection results (referring to the height profilometry data collection), the longer the delay in the process flow.

It may be preferred that, on the detection of a dispensing defect, the board is cleaned of all adhesive or solder paste and the dispensing process repeated again. However, in other cases, it may be possible to correct isolated dispensing defects, such as the manual assembly of odd-form components or when as many or more defects would be created by a redispensing step. The latter case is particularly pertinent for very dense circuit boards.

### 40.5.3 Component Placement

Successful control of the placement process, whether a highly automated chip “shooter” step or the manual placement of odd-form components, must meet the following objectives:

- Select the correct component for the designated circuit board location.
- Place the component at that location, in the proper orientation, and within the tolerances of the x, y, and z (height) coordinates as well as angular rotation specification.
- Minimize damage to the component being placed, the circuit board features, and nearby components.
- Minimize disturbing the dispensed adhesive or solder paste under the placed component prior to curing and reflow, respectively.

Important automated placement equipment factors are the stiffness of the support frame and positioning system, the geometry and size of the placement head (chip shooter or gantry architecture), as well as the capabilities of the camera and vision system. The machine frame must be sufficiently stiff to withstand the accelerations and decelerations of the placement heads, which are becoming heavier to accommodate more part types to reduce changeover intervals. The configuration of the placement head must not cause damage to neighboring components nor disturb already-dispensed adhesive or solder paste. Vision system capabilities—resolution and field of view—and associated software are a trade-off between information gathering and component placement speeds.

Linear motors can achieve placement accuracies of 5 to 10  $\mu\text{m}$ . The required degree of accuracy is a function of the size of the I/O (either lead, ball, or termination geometry) and the size of the circuit board pads on which the part is to be placed. Although it is preferred that the entire termination be centered on the pad footprint, this is not a practical objective due to tolerance build-ups. Errors are designated by the individual x and y linear (offset) coordinates, together with the rotational offset. In general, industry standards have allowed I/O-to-pad offsets of between 50 percent and 25 percent depending on the class of electronics (i.e., consumer electronics to high-reliability military and space assemblies). Placement errors can also be expressed by a single parameter, the lead-to-pad (LTP) ratio, which is calculated by an equation based on the x, y, and rotational offsets. The LTP is typically computed for the one

lead that is most impacted by the machine error, resulting in a single LPT value per component type. An industry standard is available (IPC-9850) that provides a methodology by which to compare the placement accuracies of different machines. Statistical process control can be used to establish the placement performance of a particular machine *and* the components for a specific circuit board product.

As noted previously, placement defects can be identified in the machine by automated inspection. Alternatively, such defects may be detected by a separate machine inspection station or through visual inspection. A trade-off must be made between the number of parts inspected and detail of that inspection on the one hand, and the assembly process flow on the other. The more information that must be processed by the inspection step, the slower the placement process. Finally, every attempt is made to correct placement defects prior to the soldering step.

#### 40.5.4 Soldering

Control of a soldering process must address the two premises previously noted. First, the soldering process—be it reflow soldering, vapor phase soldering, or manual soldering—must nominally be capable of making every joint on the printed circuit board without damage to the components or the laminate materials. Second, the soldering step must perform the assembly process repeatedly to meet product quality (defect) specifications.

Although the first premise seems intuitive, it must be recognized that some circuit board products may simply be outside the process capabilities of some equipment or manual capabilities, no matter the degree to which the machine parameters or operator actions are optimized. For example, in the case of manual soldering, it becomes increasingly more difficult to make a satisfactory joint when a multilayer circuit board exceeds approximately 2.4 mm. The soldering iron cannot provide sufficient heat to the joint structure to support wetting and spreading by the molten solder without causing thermal damage to the component or the Cu pad. A similar circumstance can come to pass with automated soldering process equipment.

Generally, with the increased thickness and/or complexity of the circuit board as well as with the increased mix of components, the gap widens between the process requirements of the product and the process capabilities of the equipment or operator. There are two possible solutions to this discrepancy: Either a capital investment can be made to upgrade the equipment (if available) to assemble the product successfully, or the primary assembly process must be limited to those components having similar geometries and thermal characteristics. The remaining devices are then treated as odd-form components and are soldered to the circuit board using secondary processes (e.g., selective soldering or manual assembly).

There are ancillary measures that can be taken to enhance the capability of a soldering process. For example, in the case of manually soldering components to a thick circuit board, the latter may be preheated to augment the heat input of the soldering iron. Similar approaches have been used for selective soldering, particularly when both the component and the circuit board are thermally massive.

However, these ancillary steps must be thoroughly investigated prior to implementation. First of all, these added steps not only impact the production throughput, but they may also affect the defect rate of the next-assembly process. For example, excessive preheating of a circuit board can degrade the solderability of the other pad features or cause thermal damage to vias or the underlying laminate material. Second, to maintain minimum defect rates for the assembly, these ancillary process steps must be as tightly controlled as the primary soldering processes.

Lead-free assembly generates an increased concern for the nominal process to make all of the solder joints on a circuit board. The issue has less to do with the ability of the actual equipment and fluxes to accommodate the high process temperatures than it has to do with temperature gradients across the circuit board versus the temperature sensitivity of components.

**FIGURE 40.29** Schematic diagram illustrating the available process window for the Sn-Ag-Cu Pb-free solders (having melting temperatures of 217°C) referencing the typical reflow process time-temperature profile. The 230°C mark is the minimum process temperature to ensure adequate solderability. Temperatures exceeding 245°C increase the likelihood of thermal damage to larger plastic-molded area-array and flat-package devices. Temperatures above 260°C increase the chances of thermal damage to smaller passive devices (e.g., chip resistors, capacitors, inductors, and filters) and the circuit board structures (e.g., vias) and laminate material.

This point is illustrated by the schematic diagram in Fig. 40.29, which pertains primarily to the reflow process and typical time-temperature profiles.

A minimum temperature of 230°C is required to ensure adequate wetting and spreading by the Pb-free solder on circuit board pads as well as on component leads and terminations. Temperatures exceeding 245°C increase the likelihood of thermal damage to larger, plastic-molded packages (e.g., BGA and QFP devices). When temperatures exceed 260°C, there is the potential for thermal degradation of passive chip components (chip capacitors, inductors, or filters) as well as to circuit board structures (e.g., vias) and laminate materials. In the case of Sn-Pb eutectic solder that melts at 183°C, the minimum process temperature of 215°C ensures adequate solderability, which is 15°C lower than that of a nominal Pb-free process. The available Sn-Pb process window is 215°C to 260°C, or a  $\Delta T$  equal to 45°C, rather than the  $\Delta T$  of 30°C for the Sn-Ag-Cu Pb-free solders ( $T_{\text{melt}} = 217^\circ\text{C}$ ).

The important consequence of the smaller process window is that, as the mix of components increases on the circuit board, the likelihood increases that the solder joints on some of the larger components will not reach the minimum 230°C required for good solderability when the maximum circuit board temperature is required to be less than 260°C. Similar process window scenarios can be evaluated for wave soldering and manual processes. For example, in the latter case of manual soldering, the operator is unable to use the same soldering tip or iron to assemble all of the components. On the other hand, a soldering iron that is found to be effective for soldering large components may be too hot and/or too large for smaller devices, causing thermal and/or physical damage, respectively, to them.

The second premise of process control is the repeatability of making an acceptable solder joint on each assembled circuit board. With the exception of a major equipment failure that alters the time-temperature profile, the capability to solder the same joint repeatedly in an acceptable manner is more a function of the *consistent* solderability of the material set's properties. Those solderability properties include the efficacy of the flux, the properties of the solder metal (e.g., surface oxidation and particular to the case of solder paste, the solder powder particle size, and metal loading), and the solderability of the component I/O and associated circuit board feature. Moreover, the solderability of component I/Os and circuit board features is often identified as the primary factor in repeatedly making acceptable interconnections.

Unfortunately, because poor solderability is often the leading cause of poor reproducibility of acceptable solder joints, this does not bode well for Pb-free solders. Intrinsicly, the Pb-free solders generally show poorer solderability than the eutectic Sn-Pb composition.

Therefore, to minimize assembly (solderability) defects, process engineers must be particularly vigilant to ensure that the surfaces of component I/Os and circuit board pads have optimum solderability.

#### 40.5.5 Cleaning

The use of no-clean and low-solids fluxes has reduced the need to clean a greater number of circuit boards. Nevertheless, high-reliability electronics, as well as those used in harsh environments, may still require the removal of flux residues. The primary metric used to control the cleaning process is the quantity of residues that remain on the circuit board or components. Visual inspection (white light or ultraviolet light) and ionic testing are the two most commonly used methods to assess a cleaning step. In addition, in-circuit testing (ICT) provides a secondary means to indicate excessive residue presence. The residues prevent the electrical probe from reaching the conductor, which is registered as an “open” in the data collection routine. Unexpectedly large numbers of “open” defects may indicate excessive flux residues on the circuit boards as well as signify an actual electrical performance defect. Also, in the case of high-frequency circuit boards (radio frequency and microwave), ICT can identify flux residues as indicated by signal leakage and other parasitics when inspecting for electrical performance.

The cleaning step must be carefully considered for a Pb-free soldering process. The higher processing temperatures can increase the tenacity of residues, particularly those of fluxes designed for Sn-Pb processes. This point addresses fluxes used separately, as in manual or wave soldering, as well as the flux in solder pastes. The cleaning step may need to be enhanced to ensure that these residues are removed satisfactorily from the circuit board surface. On the other hand, flux formulations that have been developed specifically for the Pb-free soldering processes may create residues that are not compatible with cleaning processes developed specifically for Sn-Pb technology.

#### 40.5.6 Network Communications

The generation, transmittal, and storage of process information is critical for real-time control of a circuit board assembly process, whether that process is for building consumer electronics in high volume or involves a low-volume assembly line for high-reliability military, space, or satellite electronics. The information that is generated by operators or automated machines on the shop floor typically includes commodity usage (i.e., circuit boards, components, etc.) as well as defects and machine malfunctions. Commodity usage information can then be made available to inventory control in the plant stockroom or even to the bill-of-material (BOM) suppliers across town and around the world, identifying the need for additional components, flux, and such at that particular site.

Process information is also accessed by the manufacturing engineer, who is monitoring the overall assembly flow, as well as by the process engineers or technicians who are directly responsible for equipment operations (e.g., furnace zone temperatures, flux levels, etc.). In addition, information may be shared between the different machines on an assembly line to prevent slowdowns in process flow due to equipment outage. Such slowdowns and stoppages can impact upstream steps. For example, there can be shelf-life issues with solder paste that is left out in a printer too long due to a stoppage created at a subsequent component placement machine or reflow oven.

It is often necessary to archive process-related information. Archived data are used to track defects as a means of process control. These data can assist in quickly determining the root cause of an out-of-control process. Process information can also be used to monitor long-term equipment performance, indicating the need for periodic preventive maintenance or machine replacement. Easy access to historical process information can also facilitate the reintroduction of a particular product line with a minimum investment in process development efforts.

Finally, archived process data are useful in an investigation of field failures. The traceability of the troubled product to the exact process parameters used on the assembly line at that time, material lots, operators, and so on can be accessed; these data are invaluable for the follow-up root-cause analysis, particularly in the case of high-valued, high-consequence electronics systems (e.g., military equipment, space and satellite hardware, as well as medical and automotive electronics). Understanding the circumstances under which the defective product was made can also provide insight into implications regarding long-term reliability and specifically warranty costs versus liability and the need to implement a product recall.

The need to access information quickly as part of assembly operations extends beyond process and inventory control. Peripheral information such as equipment software and operations manuals must also be quickly accessible. The ready availability of boot-up software and instructions minimizes the downtime required to reestablish a product line or effect repairs on a malfunctioning machine.

Once the need for a network has been determined, the locations of terminals, servers, and information storage equipment must be established. Local area networks (LANs) and the worldwide web (WWW, or Internet) can link access points located in adjacent rooms or halfway around the world. However, it is critical that the network uses consistent computer and data transmittal protocols in order to provide uninterrupted, information handling in an efficient manner. For example, serial communication via an RS-232 port is relatively common, but too slow for most machine applications. Ethernet communication via transmission control protocol/Internet protocol (TCP/IP) is a preferred method because most equipment suppliers offer this network option. The TCP/IP method allows computers to share resources, no matter whether the operating system is for an Apple®, a version of the Microsoft® operating system for PCs, or the UNIX operating system. Also, the Semiconductor Equipment Communication Standard (SECS)/Generic Equipment Model (GEM) is widely used as the interface between the host computer and assembly machines.

Lastly, the need for efficient network communications is particularly acute with the advent of Pb-free solders. In the case where OEMs as well as contract manufacturing service (CMS) companies are assembling both Sn-Pb and Pb-free technologies, it is essential to control all aspects of the assembly process with precision. In fact, process control extends beyond simply certifying that the reflow, wave, or soldering iron correctly reflect the higher soldering temperatures. It must also make certain that components and circuit boards have been delivered to the appropriate process line having the correct surface finishes and/or MSLs. Also, process control must establish that other factors, such as flux type and cleaning procedures that may be unique to the Pb-free process, are being used on the appropriate product line.

## **40.6 PROCESS EQUIPMENT SELECTION**

---

The selection of assembly process equipment is an extensive undertaking for the manufacturing engineer. The three principle variables are equipment utilization, costs, and physical plant requirements. These three areas are listed in order of consideration, not in the order of importance. The analysis behind equipment selection can be very complex, given the wide variety of product designs, potential automation options, and access to worldwide labor markets. Unfortunately, the failure to consider thoroughly the details underlying any one of these three factors can result in a significant financial burden, lost time to market, and poor product quality/reliability for the OEM or CMS. The following sections provide relatively general discussions of these three areas. The reader is referred to many excellent texts on the topic of manufacturing engineering, as well as source books that specifically address assembly process equipment for electronics manufacturing.

### 40.6.1 Equipment Utilization

Equipment utilization refers to two aspects of the equipment. The first aspect is the operational time during which the machine is actually performing its intended function. The second aspect is production volume (expressed as parts or assemblies per unit time) provided by the machine while it is in operation. The consequences of operational time can be considered as follows: When the machine is performing its intended function, it is making product and as such is making a profit for the company. On the other hand, when a machine is idle, not only is it not making product (or profit), it may be losing money for the company. Those monetary losses result from wasted electricity and other utilities while the machine is on standby, labor costs for idle operating personnel, continued draw-down on the maintenance interval, and overall loss the equipment lifetime.

Next, equipment utilization is discussed in terms of throughput or product volume. It should be noted that the general approach is nearly the same for both Sn-Pb and Pb-free technologies. Only the specific cost factors may differ slightly between the two cases. A determination of equipment utilization requires that the appropriate metrics be defined that accurately reflect the machine activity. For example, in the case of component placement machines, the utilization metric may be components placed per unit time or it may be the number of stuffed circuit boards that are completed per unit time. Printed circuit boards or finished assemblies per unit time are the typical metrics for paste printing and reflow furnaces, respectively. For example, component placement rates are expressed as, components per hour (CPH). Some manufacturing engineers prefer to analyze utilization in terms of time per product unit, which is the inverse of production rate. Such an approach would be exemplified by measuring the time required to print the paste on, or to stuff, a single circuit board.

It is important to select a metric that is most appropriate for the machine and the products that are processed in it. Moreover, the metric should allow the process development engineer to monitor the performance of the machine process accurately; it can also be used to compare specifications between different equipment brands for a procurement activity.

Different methodologies can be used to exercise an equipment utilization analysis. The details of these techniques are many and beyond the scope of this text. Nevertheless, it is important to be familiar with several key attributes that are used to make utilization assessments. Descriptive definitions of several attributes are shown below:

- *Theoretical throughput* is the output of a machine based upon its underlying design.
- *Actual throughput* is the output of the machine for the particular product line or application. This value is always less than the theoretical value.
- *Utilization or utilization efficiency* is the ratio of actual throughput to theoretical throughput.
- *Operation time* is the total time during which the equipment may be required to operate. For example, it may be an eight-hour shift or it may be 24 hours if three shifts are running in the factory.
- *Equipment uptime* is the time that the machine is available to perform its task; it may not necessarily be performing the task. Therefore, this time period takes into account the various contributions to downtime, such as preventive maintenance, unexpected breakdowns, resupply of commodities, and so on.
- *Productive time* is the time during which the machine is actually performing its task.

These various attributes can be further broken down as the need arises; for example, several factors can account for loss of equipment uptime, including scheduled maintenance versus unexpected machine failures, commodity resupply, etc.

These attributes are reduced to mathematical variables that are used in equations to calculate the performance of a particular machine. However, the assembly process for electronic circuit boards is comprised of several machines or cells that are *in series*. Therefore, once the

performance attributes are determined for a given machine, they must be integrated to predict the performance of the entire assembly line. For example, it is preferred that the throughputs of the individual machines be matched for the product application. A mismatch of machine capabilities can generate bottlenecks in the assembly process. The slowest machine or function then controls the production rate of the entire line. The obvious consequence of a bottleneck is an underutilization of the other equipment, which ultimately appears as an increase in manufacturing costs.

But there are also quality control reasons to smooth out the flow of bottlenecked assembly processes. For example, if the component placement machine has a throughput of 100 circuit boards per hour, but the reflow machine can only process 90 circuit boards per hour, then printed and stuffed boards will spend time in the open factory air awaiting entry into the reflow step. The consequence is a degradation of paste properties, resulting in the increased likelihood of solderability defects and a drop in product yield. Such technical ramifications must also be addressed when considering equipment utilization for an assembly process.

### 40.6.2 Costs

There are several cost factors to consider when establishing an assembly line: the initial capital investment for the machine(s); depreciation and lifetime (obsolescence) of that equipment; operational costs such as labor rates, electricity, water, or the use of inert atmospheres; and maintenance support costs. Many of these cost factors are determined on a “per product unit” basis so that an estimate of potential production volumes is often required for their calculations. Many OEMs and CMS providers have had to establish their own cost models to take into account labor rates, energy costs, shipping costs, and tax structures that are specific to the assembly plant location—on-shore as well as overseas. Because of the cost variables just mentioned, it is difficult to establish a universal model for these calculations.

When addressing the implementation of Pb-free soldering technology, one must consider two aspects regarding equipment costs. First are the direct costs of purchasing and installing equipment that can provide a Pb-free assembly capability. Second is the cost of simply developing a Pb-free assembly line in the factory.

Regarding the first point, equipment capability vis-à-vis Pb-free solder pertains primarily to the soldering process, including the reflow furnace, wave-soldering machine, soldering irons, etc. Printing and placement equipment is largely unaffected by the Pb-free soldering technology. Most reflow equipment used for Sn-Pb soldering is nominally capable of also supporting Pb-free soldering for moderately complex circuit boards. Changes are simply made to the time-temperature profile of a reflow furnace. On the other hand, for more highly complex products, a replacement reflow furnace may be required that has more than the typical five to seven zones. A larger number of zones allows more flexibility—and greater control—over the time-temperature profile. In the case of wave soldering, the exchange of Sn-Pb solder for a Pb-free alloy may also require the replacement of the pot, impeller, and baffles to prevent excess erosion by the higher Sn solders. Last, it is expected that erosion of soldering iron tips will be greater with the Pb-free solders. Tip technology has changed little from the Ni-coated or Fe-coated Cu core construction. Therefore, it may simply be a matter of stocking extra tips for those operators using Pb-free solders.

The second cost aspect addresses the manner in which a Pb-free capability is to be implemented on the factory floor. Specifically, the decision must be made whether to have separate Sn-Pb and Pb-free solder assembly lines or to mix the two technologies using the same assembly equipment. Critical factors include capital costs, factory floor space, infrastructure required to prevent inadvertent mixing of technologies, and projected product volumes. It is preferred to separate the two assembly capabilities physically. This separation is not limited to the actual machines, but also includes support functions such as solder material storage and component inventory control in order to prevent the use of the wrong solder or components and circuit boards with incorrect finishes. The extent of this separation of capabilities will determine the

need for the capital investment in new machines as well as the cost of duplicating some support functions and personnel that are needed for adequate process control.

### 40.6.3 Physical Plant

The cost of having a soldering process line extends beyond the capital costs of the equipment or even the labor costs for operators and process engineers. There are also the costs of operating the machines themselves. The factory must have adequate floor space for the assembly line footprint, as well as the access required to move parts and finished assemblies to and from the line. There are also space requirements to perform maintenance functions safely and make repairs to equipment. Finally, there are assembly costs arising from utility usage: electricity, compressed air (pneumatic actuators), and water (cleaning).

If the reflow or wave-soldering machine is to have an inert atmosphere—typically nitrogen is cheaper than argon—then it becomes necessary to select between the options for the gas source. Those alternatives are compressed gas tanks, a liquid nitrogen tank, or an onsite nitrogen generation facility. The compressed gas tanks are usually used only for short production runs. For most moderately sized electronics assembly factories, the most cost-effective option is to use one or more liquid nitrogen tanks, off of which is bled the nitrogen gas. Only for very-large-scale manufacturing facilities is an onsite generation plant the best option. Ancillary costs include the installation of pipe lines that transport the gas to the specific machine sites on the factory floor as well as the provision for adequate ventilation of the used gas from the machine to the external environment.

The physical plant costs are generally similar for both a Pb-free assembly process and a Sn-Pb line. The two possible differences would be electricity usage, which may be greater with the Pb-free line due to the higher soldering temperatures, particularly with respect to a reflow process, and the need for an inert atmosphere capability for the soldering machine.

## 40.7 REPAIR AND REWORK

---

It is necessary to clearly define the terms *repair* and *rework*:

*Repair*, which is also referred to as “touch-up,” describes the *single-step* procedure of applying flux, solder, and heat to a previously formed joint in order to improve it. Besides meeting acceptance criteria, improving the fillet geometry may also be required to bring the interconnection into a geometry “window” that is commensurate with long-term reliability predictions.

The benefits of repair operations have long been debated. On the one hand, optimizing the fillet geometry or hole fill will improve solder-joint consistency in order to accommodate long-term reliability prediction criteria. However, the opposing viewpoint is that the added reflow temperature “cycle” degrades the reliability of the other solder-joint structures, such as solder mask adhesion, the bond between Cu features and laminate, as well as damage to the laminate material itself. It is likely that any repair-induced degradation will increase with a lesser quality of the circuit board. Therefore, particular consideration should be given to the use of repair steps on consumer electronics circuit boards, which are typically made of lower quality materials. Fortunately, repair steps would be most likely used on high-reliability electronics (military, space, and satellite applications), which typically use higher-quality circuit board materials and construction.

A *rework* procedure is typically performed to replace a defective component on the circuit board. Therefore, the rework procedure has the following *multiple steps*:

1. Remove the previous solder joints in order to release the defective component from the circuit board.
2. Dress the circuit board solder pads by removing any excess solder while the latter is molten.

3. Clean the circuit board of solder metal (spatter or balls) and flux residue.
4. Place the new component on the circuit board site. Solder is supplied to the joint area by preplaced paste or preform as well as by solder wire (in a hand-soldering process). Flux must also be added to the joint area when using preform or when hand soldering with a wire, unless the latter is flux-cored.
5. Apply the heat source in order to re-create the joints.
6. Clean the circuit board of solder metal (spatter or balls) and flux residue.

The obvious distinction between the repair and rework processes is the number of heating cycles to which the printed circuit board is exposed in the latter case. There is one heating cycle in a repair operation that requires melting of the solder, whereas there is a minimum of three such cycles in a rework procedure. The circuit board laminate material, solder mask, and adhesion of the Cu conductor to the laminate must be sufficiently robust against degradation caused by these heating cycles. Poor thermal stability can result in manufacturing defects that reduce production yields, or aging defects that jeopardize the long-term reliability of the product once it reaches service. Often, preheating of the circuit board is used to reduce thermal shock and thermal gradients that may potentially damage the laminate material, vias, Cu pads, etc. Also, the replacement component must have adequate thermal stability to accommodate the typically faster heating and cooling rates of the more abbreviated rework time-temperature profile vis-à-vis the original assembly process.

A second distinction made between repair and rework procedures is the heating methodology. A repair operation addresses one solder joint at a time. Therefore, heating is localized to a relatively small area. On the other hand, in a rework procedure, the heat is supplied to the site in a more de-localized manner because of the need to de-solder multiple joints at one time. Similarly, in the re-soldering of a multiple I/O component, it is preferred to make all of the joints at one time in order to minimize the rework time. The heat source may be a hot-bar placed across a row of gull-wing leads or hot air that envelops the entire component site; for example, such a heat source might be used for the rework of a BGA package.

The de-localized heat flow raises concerns regarding thermal damage. For example, with respect to the component in question, there is potential thermal damage to the package material and internal components (e.g., the Si die) and interfaces. Also, there is possible heat damage to the Cu bond pads as well as hole and via structures in the underlying circuit board. Beyond the immediate component, there is the potential risk of remelting nearby solder joints or thermal damage to the neighboring component packages, particularly on very densely populated circuit boards. Thermal damage to nearby components can arise from any one or any combination of the three heat transfer modes: radiation (hot-bar or soldering iron), convection (hot air), or conduction (through holes or along other conductor features). During process development, strategically placed thermocouples should be used to determine the temperature rise of the reworkable component as well as those of neighboring structures prior to implementing a repair or rework procedure.

A third distinction between repair and rework is product time frame. Repair steps are typically performed on circuit boards that have been inspected immediately following the assembly process, prior to shipment to the customer. However, rework is not limited only to being performed immediately following a post-assembly inspection (visual or in-circuit testing). Rework activities can also be performed on electronics assemblies well after the products have entered service. The rework may be performed to replace a broken device or to upgrade the functionality of a legacy system. Although the nominal process steps are similar in the latter case, there are complicating factors that must be addressed in the process. The electronics must be taken apart to the level of the component or daughter-board in need of repair. The removal of potting material and conformal coatings must not damage the other components or their solder joints. Also, dirt, corrosion products, and other contaminants must be removed from the assembly prior to the first heating cycle. Following the rework procedure, it will be necessary then to reapply conformal coatings and encapsulants as well as to reassemble all hardware. Each of these steps must

now be taken outside the scope of the original assembly process, yet achieve the same quality without ancillary damage to components, circuit boards, or other solder joints.

A further complication to the rework procedure performed on either post-assembled or field-return hardware is the use of adhesives or staking compounds to anchor the device to the circuit board. Because many adhesives used for this purpose are thermosetting, they do not readily soften with the application of heat. Care must be exercised when applying heat to soften adhesives so that the temperature rise does not damage the underlying laminate or neighboring components. Organic solvents such as those containing alcohols, acetone, methyl chloride, and so on (the use of some of which may be strictly controlled for environmental health and safety reasons) can successfully dissolve a number of adhesive compounds. However, it must be confirmed that these solvents do not attack the package materials of the components, the solder mask and laminate, or critical markings.

Lead-free soldering raises the following two concerns regarding repair and rework procedures: higher melting temperatures of the Pb-free solders, and the mixing of Sn-Pb and Pb-free solders. Clearly, the higher melting temperatures of the Pb-free solders increase the likelihood of thermal effects that include remelting of neighboring solder joints and thermal damage to component packages and the circuit board laminate. As noted previously, this concern can be readily addressed during process development efforts, through the use of thermocouples placed on the targeted component as well as on neighboring components, solder joints, and circuit board surfaces.

The second issue is that of mixing Pb-free and Sn-Pb solder. This situation would be less likely to occur with newly fabricated product, when repair and rework procedures are performed immediately after assembly inspection. The same solder would be used for both processes. Rather, the concern arises particularly with regard to the rework of legacy products that are returned from service. Older, field-return electronics were most likely assembled with a Sn-Pb solder. In those cases where Pb-free rework procedures are in full use, there is the likelihood of intermixing Sn-Pb and Pb-free solders in the interconnections. In terms of the rework process itself, the poorer solderability of Pb-free solders will be improved by Sn-Pb residues remaining on the circuit board pads. (The I/O finish of the replacement component will likely be Pb-free, unless the component was in storage as a life-of-program-buy [LoPB] for that system. Then, the Sn-Pb finish on the I/O will also improve Pb-free solderability.)

However, because there are concerns regarding the long-term reliability of mixed-solder interconnections, it may be necessary to remove more thoroughly any Sn-Pb solder residue from the circuit board pad or through hole. Care must be exercised to not overwork the Cu features, which may result in a loss of their adhesion to the laminate (e.g., pad lifting). Other degradation modes include excessive dissolution of the Cu features, particularly at the knee on the top and bottom of through-hole barrels as well as damage to the solder mask or underlying laminate material.

Repair and rework procedures differ between through-hole-mount and surface-mount interconnections. That difference is due to the size and geometries of the interconnections, the number of I/Os on the packages, the thermal sensitivity of the components, and the overall density of the printed wiring assemblies. The following subsections describe these factors for the two technologies.

### 40.7.1 Through-Hole Technology

By and large, the repair and/or rework of through-hole solder joints still uses hand-soldering procedures (see Fig. 40.30). In the case of a repair procedure, the first step is to add flux and solder to the joint. Then the soldering iron is contacted to the lead, thereby allowing the solder to reflow. The tip should be removed from the joint as soon as possible to prevent excessive heat conduction up the lead and into the component, where it may damage the active (Si chip device(s), glass-to-metal seals, etc.

**FIGURE 40.30** Hand-soldering techniques using point, tweezers, and hot-bar tips to perform repair or rework procedures. (Courtesy of OK International and Electronic Products and Technologies.)

In the case of rework procedures, the most difficult step is often de-soldering the damaged component for the latter's removal from the circuit board. In the case of axial leaded devices, it may be possible to cut the leads of the damaged component. The component can then be removed from the circuit board, thereby increasing access to the joint area for the de-soldering operation. Lead-cutting is more difficult for radial leaded and high-pin-count components such as DIPs, PGAs, and connectors due to their shorter lead lengths and limited clearances between the package and circuit board surface.

Typically, the operator must remove the solder from the joint, usually one joint at a time, to release the component. A light coating of flux is applied to the Cu braid; the braid is then placed between the fillet and the soldering iron, with preference given to resting the tip near the top of the fillet, against the lead. This technique limits possible damage to the Cu pad, solder mask, or laminate. Sufficient solder must be removed from each joint so that the component can be extracted with *minimum* force to prevent damage to the Cu barrel or the Cu pad.

The "dressing" of the through-hole and Cu pad is the next step. An excess of solder remaining in the hole will hinder lead insertion for the new component. It is difficult to extract physically all solder residue form inside a hole, even at modest aspect ratios (board thickness-to-hole diameter). This difficulty is further compounded with thicker, multilayer circuit boards because the soldering iron tip cannot compensate for the large thermal mass of the laminate or the heat-sink effects caused by the internal Cu layers. Finally, it is often necessary to contact the Cu pads of the circuit board briefly, with the braid between the pad and the tip, to remove any excessive solder residue.

Soldering of the replacement component on to the circuit board has fewer complications than does part removal. Using a hand-soldering process, after the device has been inserted into the circuit board, each joint is made one at a time. The operator provides real-time inspection of the joint for any defects. Finally, if necessary, flux residues can be removed from the circuit board using the appropriate cleaning procedures.

Thicker, multilayer boards are more difficult to solder due to their greater thermal mass and the heat-sink effects of the internal layers. Preheating of the circuit board can be used to augment the soldering iron heat source. Typically, the circuit board is heated to a temperature in the range of 100 to 125°C. However, because the preheating step is applied to a full-up

assembly (minus the defective part), consideration must be given to the heat sensitivity of other components on the circuit board. Preheating with a hot plate may be acceptable for some applications. However, when temperature-sensitive components are nearby, other heating methods such as hot-air (gas) sources may be required to localize the temperature rise away from other components or structures.

Several techniques can be used to assist with the hand-soldering process (de-soldering or re-soldering), or even substitute for it altogether. For example, there is equipment that can heat multiple joints at a time. The so-called hot-bar technique is a soldering iron with a long bar for the tip. The bar simultaneously heats up a row of leads for the de-soldering or re-soldering step. Hot air or hot gas guns can provide more diffuse heat sources that can melt all of a component's solder joints at the same time, thereby facilitating the removal and replacement of larger components that have a greater number of I/Os.

Selective soldering, or solder "fountains" that perform like miniature wave-soldering machines, are an effective approach for the de-soldering and re-soldering of through-hole components. In fact, this technique is particularly well suited for connectors. The thermal energy provided by the molten solder fountain can overcome the heat-sinking effects of the connector structure and thick, multilayer circuit boards. However, it may be necessary to pre-heat particularly thick circuit boards (>3.0 mm) having multiple internal layers in order to melt the solder joints of a defective product successfully, as well as to achieve hole fill and adequate fillets on the replacement part. Again, care must be exercised to prevent thermal damage to neighboring components or the undesirable remelting of their solder joints.

It was noted previously that a Pb-free solder option raises two concerns: the higher soldering temperatures required by the new alloys, and the mixing of Sn-Pb and Pb-free solders, particularly when performing rework procedures on legacy hardware. Both concerns are generally of lesser magnitude for through-hole solder joints. The physical separation of axial or radial leads lessens the likelihood of thermal damage to the circuit board or replacement component. Potential processing and reliability effects resulting from the mixing of Sn-Pb residues with Pb-free solder are less significant due to the greater quantity of solder required in through-hole interconnections. In particular, the solder composition within the fillets, which provide most of the strength and service life of the joints, would be least impacted by Sn-Pb contamination.

## 40.7.2 Surface-Mount Technology

Solder-joint repair and the rework of surface-mount components pose a greater challenge due in large part to the reduced size of the devices and associated I/Os. (In fact, the difficulty of repairing or reworking surface-mount circuit boards was one of the leading drivers for the electronics industry, as a whole, to re-embrace more stringent process control techniques, including SPC, to minimize assembly defects.) Contributing hurdles included the higher board densities that accompany the small part sizes; an increased sensitivity of component materials to potential thermal damage including the Si die resulting from flip-chip attachment and thinner molded packages; as well as solder joints that are out of direct view from the operator, as in the case of area-array packages.

Another important consideration is the overall fragility of surface-mount Cu pads on the circuit board compared to through-hole structures. In the latter case, damage to the bond between the Cu pad and the laminate was less likely due to a greater robustness of the feature. When such damage in the form of lift-off occurred, it was of a lesser consequence because the hole barrel provided an additional mechanical attachment to the laminate. On the other hand, surface-mount pads are smaller in order to accommodate finer package I/O pitches and overall higher board densities, giving them less overall bond area with which to adhere to the board. Also, the pads are attached to the laminate without a hole or, at best, with only a small via, which also increases the sensitivity of Cu pads to thermal damage in the form of lift-off.

Repair procedures are typically performed on surface-mount interconnections using hand-soldering techniques. A stereomicroscope of 10 to 50× magnification is essential at the workstation. The soldering iron tips are miniaturized to accommodate the smaller component sizes and higher board densities. In general, this technique does not necessarily reduce the time to repair the smaller solder joints, because the smaller tips also have a reduced thermal mass for supplying heat to the joint. As always, the soldering time should be minimized as much as possible. Also, in the case of ceramic chip resistors, inductors, and MLTF capacitors, direct contact between the tip and the component termination should be avoided to prevent de-lamination of the metallization. It is particularly important to avoid contacting multilayer chip capacitors with the soldering iron, as these materials are particularly sensitive to thermal shock, which can lead to cracking of the device body.

Rework procedures based on hand-soldering techniques are still used for surface-mount technology. Manual techniques include equipment innovations that can accommodate the smaller part sizes, multiple I/Os per package, and higher board densities. However, it is recognized that more precisely controlled procedures are required for reworking fine-pitch, peripherally leaded packages and area-array components (BGAs, CSPs, and flip-chip). Often, an operator simply does not have the physical ability to perform the necessary actions or to execute steps that must be done simultaneously. Therefore, rework “stations” are available that can perform some or all of the steps in a semiautomated or even fully automated fashion, depending on the equipment capabilities. Predetermined thermal profiles are used to remove a defective component and then to install the new part. Positioning of the replacement part is achieved manually or by stepper motors that can be executed manually or controlled by software commands.

The three steps in the rework process for surface-mount technology are as follows. First, there is removal of the defective part. The component removal step subjects the circuit board to the first of three solder reflow cycles. Different heat source methods are available to address the variety of package I/O configurations (e.g., leadless, gull-wing leads, etc.). The removal of the defective component, particularly high I/O fine-pitch leaded and area-array packages, is best done when all of the solder joints are simultaneously molten to prevent damage to the more fragile Cu pads. Soldering tweezers are used to melt both solder joints of chip resistors, capacitors, inductors, or diodes. The tweezers are then used to pull the component quickly from the site. The hot solder bar “tip” is used to melt, simultaneously, all of the solder joints in along a row as may be required for peripheral leaded packages, such as gull-wing leaded and J-leaded packages.

Hot air or hot gas (nitrogen) has been used to reflow, simultaneously, all solder joints of fine-pitch (high I/O count), peripheral leaded packages (e.g., QFPs) as well as those of area-array packages that include BGA components, CSPs, and FC components. An example of a hot-gas nozzle applied to a BGA package is shown in Fig. 40.31. Control of the hot-air flow maximizes heat delivery to the solder joints and minimizes the temperature rise in the component body. The shroud also limits the exposure of neighboring devices and their solder joints to elevated temperatures.

Unfortunately, unlike with one or two solder joints, it is not always possible for an operator to “sense” the presence of a few unmelted solder joints among the several hundreds or thousands of small interconnections on a fine-pitch peripherally leaded or BGA package. The consequence is damage to the Cu pad, which must then be repaired if possible. Under these circumstances, rework stations have become invaluable. Vacuum pickups or finger mechanisms attach to the component and then pull on it with only enough force to release it from the circuit when all of the solder joints are molten, thereby preventing damage to the pads.

Once the defective component has been removed from the circuit board, the second step is to remove excess solder from the Cu pads. This step is also referred to as *dressing* the pads. Remaining solder bumps and spikes interfere with the placement of the new component. More importantly, excess residual solder, the quantity of which is not tightly controlled, causes variability to the replacement component’s solder joints, which can lead to possible opens, shorts, or a loss of long-term reliability. Because the cleaning or dressing step requires a solder reflow heat cycle (the second of three), the time-temperature profile of that cycle must be

**FIGURE 40.31** A hot-air shroud that is used to simultaneously reflow all of the solder joints on a BGA package. (Courtesy of OK International.)

minimized to prevent damage to the more fragile Cu bond pads and nearby traces as well as to the laminate itself. This procedure is typically performed manually.

The third step in the rework process is the assembly of the new component to the circuit board. Here, the circuit board site is exposed to the third of three solder reflow cycles. Also, it is at this point that semiautomated or automated rework capabilities can be particularly advantageous when compared to a manual operation. First, there is the step of providing solder to the joint pads. The presence of other components precludes the use of stencil or screen-printing dispensing techniques. Although solder preforms are a viable approach for components of larger I/Os, the most versatile and repeatable method for surface-mount components is dispensing paste through a syringe. This method may be performed manually when the number of I/O are relatively small. However, for particularly small passive components, fine-pitch peripheral leaded packages, and area-array devices, automated solder paste dispensing is the preferred technique to control both position and paste quantity.

In the case of some BGA and DCA/FC components, there may not be the need for additional solder. Only a flux is dispensed on the Cu pads prior to the component placement step. The tackiness of the flux anchors the part in place prior to reflow soldering.

Next, the new component is placed on the circuit board. The extent of rework placement automation depends on the mix of components. Specific variables include the package type (a passive chip device, a QFP with leads, an area-array package, etc.); the package size and its fragility, which determine handling requirements; and the number and pitch of the interconnections. At one extreme, manual assembly procedures are well suited for large leadless chip resistors and capacitors (generally sizes >1206 English) as well as LCCCs and peripherally leaded packages having pitches as small as 0.4 mm. Smaller components, particularly passive chip devices having sizes less than or equal to 0402 (English) are best placed by the mechanical handling and positioning capabilities of a rework station. At the other extreme are the 1.0 mm, high I/O count area-array packages. In these cases, the fine ball pitch, coupled with the inability to position the underside balls accurately over the circuit board pad, nearly always requires some level of automation to ensure the correct placement of the component.

After placement of the component, the soldering process is performed to make the joints. Irrespective of the exact method whether it is hot gas or a soldering iron, or the extent of automation the overall objective should be that the time-temperature profile resemble as closely as possible the process used to make the original solder joints. The solder paste is the same as that used in the initial assembly process. As a result, each step, from the preheat stage

to melting of the solder and subsequent cooling sequence, must be controlled to minimize defects in the rework solder joints.

The cleaning step can be eliminated by the use of no-clean or low-solids fluxes in the rework procedure, whether the flux is used alone or is contained in the solder paste. However, if a flux was used that requires that the residues must be removed, some precautions must be followed. In the case of a circuit board product that was reworked immediately following the initial assembly process, one can use the same cleaning steps used in that original process again by simply passing the circuit board through the cleaning cycle a second time. On the other hand, in the case of hardware that is typically built-up further by next-assembly steps, additional materials compatibility concerns must be addressed with respect to the cleaning solutions. For example, it may be necessary to apply the cleaning materials only to the immediate location of the rework activity, avoiding otherwise sensitive materials elsewhere on the circuit board.

As noted previously, the two general concerns that must be addressed regarding Pb-free solder rework are higher soldering temperatures and the mixing of Sn-Pb and Pb-free solders for fielded electronics. By comparison to through-hole technology, both issues are amplified in surface-mount technology. Surface-mount components have greater temperature sensitivity due to the materials used in their construction as well as their smaller size. Multilayer chip capacitor ceramics are particularly prone to cracking under thermal shock conditions caused by too fast of a heating ramp or too fast of a cooling rate. In the case of area-array packages, excessively high temperatures cause the larger packages to warp or "potato chip." In the extreme cases, warpage can cause opens between the solder ball and pad due to an increased gap or result in short circuits caused by a shortened gap that compresses the solder balls, allowing neighbors to contact one another.

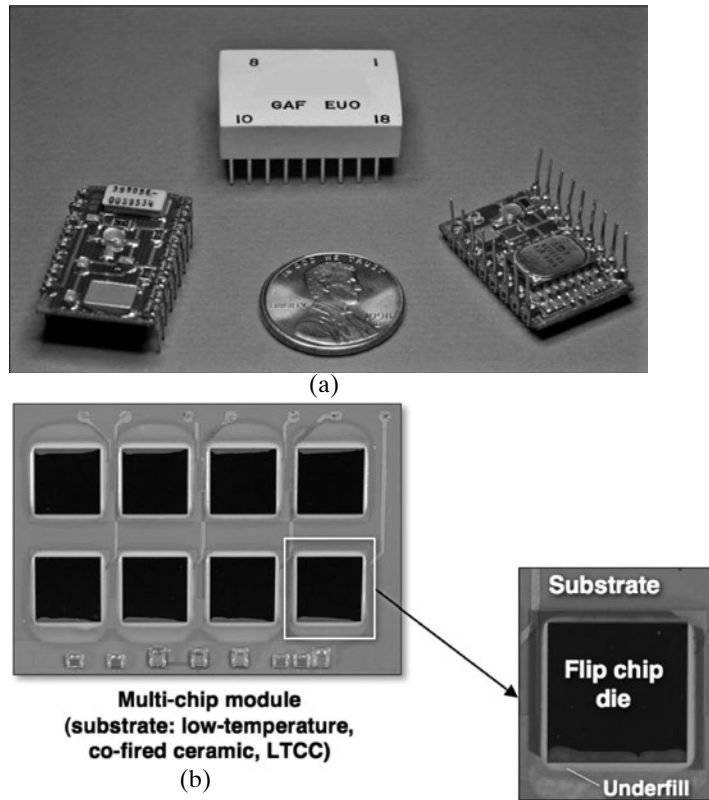

The second concern is that of mixing Pb-free solders with a Sn-Pb solder residue that may remain on the circuit board after removal of the defective component. Again, this issue pertains primarily to field-return hardware that had a legacy of Sn-Pb solder. The levels of Pb contamination are potentially higher in the smaller, surface-mount solder joints than they are in through-hole interconnections, so that the impact of Pb on melting point depression, solderability, and, more importantly, long-term reliability is similarly more significant. This concern is acute with Bi-bearing, Pb-free solders, especially those with greater than 5 wt. percent Bi, in which the formation of a low-melting-temperature (96°C) Sn-Pb-Bi ternary phase can potentially degrade long-term reliability. However, studies indicate that simply exercising due diligence with current pad-cleaning techniques will remove Sn-Pb residue to an extent that such effects are minimal. The consequence of unnecessarily subjecting the pad to additional heating cycles to remove all traces of Sn-Pb solder is damage to the Cu/laminate bond, which can result in a loss of electrical reliability.

When there is a likelihood that a significant amount of Pb contamination (generally >5 wt. percent Pb) will remain in the Pb-free interconnection, ensuring a minimal impact on long-term reliability requires that the Pb be completely intermixed throughout the interconnection. Under the circumstance when the Pb is not completely distributed in the joint, two distinct microstructures are created: one that is Pb-rich, and the other in which Pb is absent. This condition is of particular concern with BGA and CSP solder joints. The boundary between the two segregated microstructures is weakened with respect to thermal mechanical fatigue failure, thereby potentially reducing the reliability of the interconnection.

## **40.8 CONFORMAL COATING, ENCAPSULATION, AND UNDERFILL MATERIALS**

---

When required, the final steps in the assembly of a printed circuit board are the applications of conformal coatings, encapsulants, and underfill materials. Conformal-coated circuit boards are shown on the bottom of the stereo photograph in Fig. 40.32a; the same circuit board,

**FIGURE 40.32** Stereo photographs showing (a) conformal-coated (bottom) and encapsulated (top) versions of a surface-mount circuit board and (b) underfilled flip-chip components. (Courtesy of Sandia National Laboratories.)

encapsulated, is shown in at the top of the photograph. An example is shown in Fig. 40.32b of underfilled flip-chip devices.

The role of the conformal coating is to protect the circuit board and components against large-scale contamination from dirt, water, liquid chemicals, corrosive gases in air pollution, mold, and fungus. Because the layers are very thin (<0.25–0.50 mm) and relatively soft, they do not offer significant protection against handling damage or mechanical loads in shock-and-vibration environments. Protection against the latter conditions is obtained from encapsulants, also called *potting* materials, and underfill materials. Underfill materials perform a function similar to adhesives by securing the component to the circuit board. The difference is that the underfill material is applied after soldering and must fill the entire gap between the package and the circuit board. In the case DCA/FC, the underfill also improves the thermal mechanical fatigue reliability of the solder joints.

The details of these materials are discussed in other chapters. However, it is important to understand their role in the overall circuit board assembly process. First of all, the functions of these three materials require that they have good adhesion to all surfaces. Therefore, the printed wiring assembly must be cleaned of any flux residues as well as those residues left behind from the cleaning procedure.

Second, the application of conformal, encapsulant, and underfill materials must be tightly controlled in order for them to function properly. The nominal thickness and its uniformity are critical for conformal coatings. A coating that is too thin is a less effective barrier against harsh environments. Thickness and uniform coverage have become even more critical as many designers are relying on conformal coatings to mitigate the consequences of Sn whisker growth on 100 percent Sn coatings. On the other hand, a conformal coating that is too thick can interfere with rework procedures as well as prevent fit-up of the circuit board into racks and backplane cabinets. In general, visual inspection is used as a nondestructive method to control the application processes.

In the case of encapsulant or potting materials, there must be complete filling of the mold, especially around the components, to prevent stress concentrations that can damage surface-mount solder joints. Potentially damaging stresses can also be generated when the density of the potting material varies excessively about the circuit board. The resulting variation of physical and mechanical properties of the foam encapsulant (thermal expansion coefficient, modulus, etc.) can lead to excessive board bending that damages solder interconnections, particularly those of large components (e.g., BGA devices). Therefore, it is necessary to control the encapsulant material itself as well as the “casting” process to prevent these defects.

Unfortunately, most nondestructive evaluation techniques are not effective at finding encapsulation defects. Voids and density variations are not readily detectable by visual inspection or by x-ray analysis. In the case of x-ray, the inherently low density of encapsulant foams limits the contrast between filled and unfilled (void) regions. Scanning acoustic microscopy (SAM) has had some limited success when the encapsulant layer is relatively thin, which is not often the case. Witness samples taken during the casting process are used to confirm foam density.

A number of studies have been performed that underscore the crucial requirement to control the underfill process used on flip-chip devices. Even small variations in underfill material properties (e.g., viscosity, percentage of filler, etc.) or the method for dispensing the underfill material between the die and substrate can significantly alter the long-term reliability of these interconnections.

The accepted method of nondestructive testing used to control the underfill process is SAM. The thin layer allows this technique to detect voids in the underfill material, which when located near the solder interconnections can be responsible for a significant loss of thermal mechanical fatigue reliability. X-ray techniques can be used to monitor the density of the underfill material, specifically, the distribution of filler material within the layer under the die. Density variations can indicate a larger distribution of underfill mechanical and physical properties, which may affect long-term reliability performance of the solder joints. Quantitative image analysis can be coupled into SAM and x-ray analysis data to provide valuable process control tools for the factory floor.

## 40.9 ACKNOWLEDGMENT

---

R. Boulanger is acknowledged for contributions to this chapter, which is based on “Assembly Processes,” *Printed Circuits Handbook, 5th ed.*, Clyde E. Coombs (ed.), 2001, Chap. 40. The author also wishes to thank M. Dvorack of Sandia National Laboratories for his careful review of the chapter.

## 41.1 INTRODUCTION

---

Once a circuit card assembly (CCA) has been fully assembled and tested, it often needs to be protected from the environments in which it will ultimately be used. Moisture, salt, dirt, fungus, and a variety of other contaminants as well as mechanical shock and vibration will cause failure on an unprotected assembly. The CCA's last line of defense against the elements is a thin layer of coating that conforms to the shape of all the part leads, solder joints, and other complex features on the completed CCA. This conformal coating (or flow coating) is applied as liquid to the fully assembled CCA, and is cured in place to form a protective layer of insulation for the assembly.

This chapter presents:

- An overview of the five basic conformal coating types
- Preparatory steps necessary to ensure a successful coating process
- Various methods of applying conformal coating
- Repair and rework processes
- Design guidance on when and where coating is required, and which physical characteristics and properties are important to consider

### 41.1.1 Objectives and Applications for Conformal Coatings

Besides protecting the CCA from the elements, conformal coating also provides:

- Mechanical support for components during mild shock and vibration
- Electrical insulation for high-voltage components, especially at altitude
- Chemical resistance
- Prevention of short circuits due to tin whisker growth from pure tin-plated part leads and cases

Because of the extra cost involved with the cleaning, coating, curing, and touchup operations, conformal coating was usually reserved only for equipment that required high reliability, such as military and aerospace electronics, and equipment that needed to operate in severe environments. With the introduction of automated application robots and ultraviolet (UV) curable chemistries, conformal coating has become more common.

### 41.1.2 Overview of Types of Conformal Coatings

Conformal coating materials are available in five basic chemistries, each with multiple application methods and several drying/curing options. As such, no one material will fit every application, but the wide variety will allow the designer to select a material that meets most technical, budgetary, and manufacturing needs. The various coatings and their characteristics are summarized in Table 41.1.

The five basic chemistries are:

- **Urethane** This coating has good moisture and chemical resistance and good electrical insulation.
- **Silicone** Being soft and having good adhesion, silicone is useful over a wide temperature range.
- **Epoxy** This coating is tough, durable, and very chemically resistant.
- **Acrylic** Acrylic is easy to apply and remove.
- **Para-xylylene** This very thin, pinhole-free coating is vapor deposited instead of being applied as a liquid.

More information on the less common types of conformal coating may be found in IPC-HDBK-830.

### 41.1.3 Environmental Issues

The predominant environmental issue with coatings was the use of solvent thinners to aid the application process. Most coatings are available in low-solvent or zero-solvent formulations, so that the emission of solvents can be reduced or eliminated. The change to lead-free solders and plating has produced an increase in the use of conformal coatings, since conformal coating has been shown to prevent tin whiskers (see Chap. 29 on tin plating) from causing short circuits, and is used for that purpose in types of products that have not been coated before. The higher-temperature lead-free soldering processes are irrelevant to the conformal coating step, since the coating is applied after the soldering process.

## 41.2 TYPES OF CONFORMAL COATINGS

---

The most commonly used types of conformal coatings include:

- Urethane (Type UR)
- Silicone (Type SR)
- Epoxy (Type ER)
- Acrylics (Type AR)
- Para-xylylenes (Type XY)

### 41.2.1 Urethane (Type UR)

Urethanes are relatively easy to apply with dip, spray, or brush. Cure times (other than UV-curable) range from a few hours for two-part heat curable, to several days for a single-part room temperature cure. Typical application is .001 to .005 in. thick. They are often used for space applications due to their low outgassing characteristics.

TABLE 41.1 Conformal Coating Materials and Their Characteristics\*

		Material type	Urethane			Silicone			Epoxy				Acrylic			XY
		Solvent evap.	Heat cure	UV Cure	RTV	UV Cure	Catalyzed	Solvent evap.	Heat cure	UV Cure	Catalyzed	Solvent evap.	Heat cure	UV Cure	Vapor deposited	
Cure methods		hand paint	x	x	x	x	x	x	x	x	x	x	x	x		
		dip	x				x		x			x				
		hand spray	x	x	x	x	x	x	x	x	x	x	x	x		
		automatic spray	x	x	x	x	x	x	x	x	x	x	x	x		
		selective coating	x	x	x	x	x	x		x	x	x	x	x		
		vapor deposited													x	
Removal	Solvent	x	x	x	x	x	x					x	x			
	Thermal	x	x	x	x	x	x	x	x	x	x	x	x	x	x	
	Mechanical	x	x	x	x	x	x	x	x	x	x	x	x	x	x	
	Plasma etch														x	
Benefits	Easy to rework											x	x			
	moisture resistant	x	x	x	x	x	x					x	x	x	x	
	simple cure											x	x	x		
	Biologically compatible														x	
	High temperature use				x		x	x	x		x					
	Abrasion resistant	x	x	x				x	x	x	x				x	
	Solvent Resistant		x	x					x	x	x				x	
	Complete coverage															x
	Reversion resistant		x	x								x	x	x	x	
Cold temperature Use		x	x	x	x	x									x	
Risks	High VOC	x	x					x					x			
	Requires strict viscosity control												x			
	flammable												x			
	aided by primer				x	x	x	x	x	x	x				x	
	cure affected by thickness and mass		x						x					x		
	cure inhibition or reversion	x					x	x			x	x	x			
	High cure shrinkage								x					x		
	not for low temp	x						x	x					x		
	Incomplete cure in shadow			x		x				x					x	
	Has pungent odor			x		x				x	x				x	
	Brittle at high temp			x						x					x	
	rework difficult			x				x		x	x				x	
	UV wavelength affects cure			x						x					x	
	potential for contamination							x								
	difficult process							x								x
	Poor edge cure								x							
	Short work life					x					x					
	Moisture affect cure	x														
	Long complete cure time	x														
	Health and safety concern	x														
	Violent reaction with water			x												
	Requires moisture for cure					x										
	Low abrasion resistance					x	x	x								
	High CTE					x										
	May contaminate other products					x	x	x								
	Intermittant solvent resistance					x	x	x								
	difficult adhesion						x									
	batch process															x
	Full masking required															x

\*Disclaimer: Due to the widely varying nature of the different formulations even within a single column heading, the above information is general in nature and cannot reflect the nature of all available materials that fall under that heading.

**FIGURE 41.1** Elastic modulus versus temperature for three different type UR coatings.

**41.2.1.1 Chemistry.** Urethanes are based on a di-isocyanate and polyol backbone. They are available in solvent evaporative cure, heat cure, and UV cure formulations.

**41.2.1.2 Properties.** Since urethanes are polymerized and cross-linked in place, they have excellent resistance to chemical, moisture and solvents. They are available in hardnesses ranging from tough, abrasion-resistant varieties to low-modulus versions suitable for extreme temperature ranges (see Fig. 41.1).

**41.2.1.3 Advantages and Disadvantages.** Urethanes have good adhesion to most materials, including epoxy part bodies, metals, and ceramics. As such, the coating process is fairly robust. Since urethanes are chemically resistant, they are also difficult to remove except by thermal or mechanical means. Urethanes can be soldered through, although this often results in a brownish discoloration that must then be removed.

## 41.2.2 Silicone (Type SR)

Silicones are very flexible, and stay that way over a wide range of temperatures. They have good adhesion to a variety of surfaces, but contaminate the surface and, once applied, prevent other materials from adhering. Typical application is .002 to .008 in. thick. They are often used in automotive applications, where high temperature and moisture-resistance are needed.

**41.2.2.1 Chemistry.** The silicone polymer chain is based on an alternating silicon-oxygen backbone. SR coatings are available in three types, room temperature vulcanizing (RTV), UV cure, and catalyzing (addition) cure.

**41.2.2.2 Properties.** Silicones have relatively stable properties from  $-55^{\circ}\text{C}$  to  $200^{\circ}\text{C}$ . Their coefficient of thermal expansion (CTE) is higher than that of urethanes, but this is mostly offset by their lower modulus, so that the level of stress exerted on parts is still relatively low. They have high resistance to moisture and humidity, as well as polar solvents.

**41.2.2.3 Advantages and Disadvantages.** Silicones are usable over a wide temperature range and are relatively easy to remove via mechanical or thermal means. If mishandled, silicones

may contaminate the work area, causing adhesion problems on other CCAs. Careful process sequencing and process separation is necessary to prevent this.

### 41.2.3 Epoxy (Type ER)

Epoxyes are chemically stable and very resistant to chemical attack. Typical application thickness is .001 to .005 in. Epoxyes are useful in extreme environments where chemical vapors or high temperatures are present.

**41.2.3.1 Chemistry.** Epoxy coatings are based on epoxy resin systems and come in four types: solvent evaporation, heat curing, UV curing, and catalyzed.

**41.2.3.2 Properties.** Epoxyes have a low CTE that matches well with printed wiring board (PWB) epoxy resin, since they share very similar chemistry. They have a higher  $T_g$  than most of the other coating materials. They are also very tough and abrasion resistant, so that rework is very difficult; epoxy coating can form the basis of an antitampering coating.

**41.2.3.3 Advantages and Disadvantages.** Epoxyes are useful at moderately high temperatures, up to about 150°C. Because of their strength, they also provide mechanical support for components.

The disadvantages of epoxy coatings are their usually pungent odor and the possibility of skin irritation. They are difficult to rework. Some formulations of epoxyes are chemically delicate and do not cure properly in the presence of inhibiting compounds. Cure shrinkage is also of concern for fragile components; a softer buffer coating should be applied locally before the epoxy, particularly for assemblies that need to withstand wide swings in temperature.

### 41.2.4 Acrylics (Type AR)

Acrylic coatings are applied .001 to .005 in. thick and are often used in military and consumer electronics.

**41.2.4.1 Chemistry.** Acrylic coatings are usually supplied as dissolved pre-polymerized acrylic chains. The acrylic chemistry does not cure by polymerization and cross-linking as the other coating materials do, but instead hardens gradually as the solvent evaporates. Acrylics are also available in heat-curable and UV-cured formulations.

**41.2.4.2 Properties.** Acrylics are easy to apply, and are the easiest coating to remove, since relatively mild solvents soften and dissolve the acrylic coating while leaving the epoxy encapsulated parts and PWB unharmed. They can be cured quickly.

**41.2.4.3 Advantages and Disadvantages.** The greatest strengths of acrylic coating are the ease of rework and the fast room temperature cure. Acrylics provide good moisture resistance and fluoresce easily, aiding inspecting under UV lamps.

Since they are so easy to rework, acrylics are also susceptible to inadvertent chemical attack from solvent splash during hand cleaning of solder joints elsewhere in the assembly. The high emission of solvent inherent in the acrylic process makes them less environmentally friendly than other materials. As the solvent evaporates, the coating shrinks and exerts stress on the components, so acrylics may not be suitable for all low-temperature applications.

### 41.2.5 Para-Xylylene (Type XY)

Para-xylylene coatings are unique, since they are applied by vapor deposition (see Sec. 41.4.6) rather than as a liquid. They are applied .0005 to .002 in. thick. Para-xylylene coatings are often used in biomedical devices due to the inert character of the coating.

**41.2.5.1 Chemistry.** XY coating is supplied as a dimer, a polymer chain only two units long. During the vacuum deposition process, the dimer powder is gradually vaporized and is recondensed onto the CCA, polymerizing with the material already deposited. Typical application is .0005 to .002 in. thick.

**41.2.5.2 Properties.** XY coating is chemically inert and moisture-resistant. Very thin, uniform layers are possible, with no pinholes or voids. XY coating also has very high dielectric strength. Due to the nature of the deposition process, no volatiles are generated.

**41.2.5.3 Advantages and Disadvantages.** XY coating is the highest performing coating in many regards. It has the highest dielectric strength, and is the lightest weight, lowest out-gassing, mostly chemically inert, and most moisture-resistant. It provides the most uniform coating over, under, and inside parts where liquid coatings cannot be applied.

The coating process must be performed in batch mode, using specialized coating equipment. It may be impossible to mask adjustable components such as potentiometers adequately. Rework is difficult; since the thin coating cannot be peeled, a microabrasion process is usually required to remove the coating. Additional staking or adhesive bonding of parts is required, since the thin coating provides little mechanical support.

## 41.3 PRODUCT PREPARATION

---

Most coating problems can be traced to improper preparation. The four preparation steps are:

- Cleaning to remove flux, oils, and contaminants
- Masking to ensure coating is applied only where desired
- Preparing the surface or priming to promote adhesion of the coating
- Baking out to prevent moisture from being trapped under the coating

### 41.3.1 Cleaning

Thoroughly cleaning the CCA before conformal coating is the best way to ensure proper adhesion of the coating. The various cleaning chemistries and their effectiveness on different kinds of fluxes are treated in depth in the Chapter on, "Fluxes and Cleaning." Besides removing flux, the cleaning process removes any contamination such as mold release agents on plastic part bodies, fingerprints, etc.

No-clean fluxes reduce the need for waste water and waste solvent treatment. For boards that require conformal coating, the benefits of a no-clean system must be balanced with the risks of poor coating yields. A minor change in flux or coating chemistry could render the coating incompatible with the no-clean flux being used, causing delamination, cure inhibition, or other defects. In general, coating results are not as good with no-clean flux as with standard flux plus cleaning, yet in some cases may still be adequate to do the job.

### 41.3.2 Masking

To control the areas where coating is applied, some kind of masking is usually needed. Masking tapes or adhesive circles may be used to keep flat areas and holes free of coating. Since the tape needs to be removed completely after the coating operation, the tape adhesive must be capable of withstanding the cure temperature without peeling or becoming permanently bonded to the surface.

To mask irregular surfaces, latex masking material is used. This material is applied with automatic or manual dispensing equipment and is cured in an oven before the coating operation is performed. It then peels off easily after coating.

For high-quantity production, boots or covers can be molded to fit over the areas that do not require coating. These are reusable, easy to install, and produce well-defined repeatable results.

Rather than being masked, areas may be sealed with a permanent bead of a thixotropic (non-runny) adhesive. This eliminates the demasking step, and is useful for complicated geometries such as the back of connectors and the perimeter of ball grid arrays (BGAs).

### 41.3.3 Priming and Other Surface Treatments

The adhesion of some coatings—notably epoxies, silicones, and para-xylylenes—will be improved if the CCA surface is primed before coating. Primers are applied as a very thin coat using dip or spray (generally the thinner the better) and oven-dried to drive any remaining solvent from crevices, vias, and such. If the primer fails to wet all areas of the board, the coating will not wet either but will easily delaminate instead. Such surfaces are not compatible with the primer, and an adjustment in primer chemistry is required. For difficult surfaces, such as large fluoropolymer parts or substrates, a more aggressive measure such as plasma-etch or mechanical abrasion may be needed to promote adhesion.

Mechanical abrasion (grit blasting) may be used to roughen troublesome surfaces to promote coating adhesion. It may be easier to do this step as the parts are fabricated (in the case of mechanical parts) or as part of the make-ready process before assembly. Microabrasion can be used with proper care on the finished assembly as long as electrostatic discharge is controlled by the design and use of the abrasion equipment, and is monitored daily to ensure that it is working properly. Microabrasion is also a viable method for removing coating.

### 41.3.4 Bake-Out

Since the coating is intended to be waterproof, it is imperative that all moisture be baked out before the coating is applied, especially for hygroscopic substrates such as GI polyimide. If moisture is left in place, it can cause corrosion of traces and/or parts and will promote dendritic growth between conductors, as well as enabling the growth of conductive anodic filaments (CAF) along the glass fibers in the weave of the PWB. A bake of 93°C for 4 hours will be sufficient to drive out moisture from the CCA.

## 41.4 APPLICATION PROCESSES

---

The liquid coatings can be applied by a variety of methods, including:

- Hand painting the coating with a brush
- Dipping the board into the coating
- Hand spraying with an aerosol can or handheld spray gun
- Automatically spraying the board with coating as it passes by on a conveyor
- Selectively applying coating to certain areas of the board with a robotic nozzle
- Vapor depositing para-xylylene onto the board with specialized equipment

### 41.4.1 Hand Paint

Hand painting allows coating to be applied wherever desired with no setup time and low equipment cost. It is still the preferred method for touching up thin spots in a bulk applied

coating and for coating replaced components. It can be used to reach areas where spray or automatic nozzles cannot reach, and works well for smaller, one-of-a-kind items. Hand painting is the most variable of all methods.

#### 41.4.2 Dip

Dip coating works best for coatings that have a long pot life at room temperature, such as solvent evaporation cured coatings and one part materials. Since the unused coating remains in the dip tank, a long (or infinite) pot life keeps the waste down to a minimum.

The viscosity of the material in the bath should be checked daily, using a flow cup viscosimeter or other method, and solvent added to keep the viscosity of the material within the acceptable range. For a given dip speed, a lower viscosity will produce a thinner coating. The dip machine (see Fig. 41.2) will have bars or hangars on which to hang the board to be coated. Insertion speed should be slow enough to prevent the formation of bubbles as the coating flows around and under surface mounted parts, etc. Withdrawal speed should range between 1 to 6 in./min and will dictate the finished coating thickness; a slower withdrawal will produce a thinner coating.

FIGURE 41.2 Dip coating machine.

Dip coating cannot be used multiple times to build up thicker layers of acrylic coating, since solvent in the bath will loosen or dissolve previously applied layers of acrylic.

Any areas that are not to be coated must be completely masked before dipping. Assemblies can be partially dipped to leave the top edge of the board uncoated if the board is designed so that all components that need coating are below the level of the bath.

#### 41.4.3 Hand Spray

Hand spraying is used for all types of liquid coatings. The boards to be coated are sprayed several times; the angle is changed 90° each time so that complete coverage is achieved. Tall components may shadow or block the spray from lower profile components behind them, so care must be taken to ensure all areas of the board are fully coated. A witness strip is often sprayed at the same time for use in measuring the coating thickness.

As with the dip method, viscosity control is a key factor to reducing bubbles, cobwebs, and improper coating thickness.

Two part materials are mixed immediately prior to filling the spray gun container, or are mixed in line if a continuously fed mixing gun is used. Single-part materials (particularly acrylics) are also available in aerosol cans, eliminating mixing altogether.

#### 41.4.4 Automatic Spray

For high-volume coating application, a semiautomatic spray machine is used to eliminate the dependency on the operator and allow in-line coating. The boards enter the machine on a paper-covered conveyer and are sprayed by a rotating or reciprocating spray head. The motion of the spray head(s) is designed to cover a given width of the belt completely from all angles. Shadowing is of greater concern with semiautomatic spray equipment, since special treatment cannot be given to any one area of the board.

Full masking is required to keep the coating out of areas that should not be coated.

Once the board is coated on one side, it is partially cured (or fully cured), turned over, and coated on the other side.

#### 41.4.5 Selective Coating

The selective coating process utilizes a robot similar to the automated pick-and-place machine to dispense coating only where it is needed. Four or five axis machines can be used to coat the sides of tall parts and around corners.

The greatest benefit to selective coating is that it drastically reduces the amount of labor needed for masking and mask removal; areas that need to be free of coating simply have no coating applied there. Coating utilization is highest of all methods, since almost no coating is lost in continuous production.

Spray patterns may be either atomized, spraying droplets onto the board and providing a thinner coating (see Fig. 41.3), or continuous, applying a stream or sheet of liquid to the board

**FIGURE 41.3** Selective coating using an atomizing nozzle. (Courtesy of Asymtek.)

**FIGURE 41.4** Selective coating using a continuous flow nozzle. (Courtesy of Chipco, Inc.)

(Fig. 41.4), producing a well-defined boundary between the coated and uncoated areas and eliminating the need for masking.

In the same way as the semiautomatic sprayer, the board is tack-cured and then turned over and coated on the other side. An automated board flipper may be used to accomplish this to automating the entire coating process.

#### 41.4.6 Vapor Deposition

Vapor deposition is only used with XY coatings, and requires specialized coating equipment. In the evaporator, a measured amount of dimer is placed in a crucible. The coating cycle is then started, and the chamber is pumped down to an almost complete vacuum (see Fig. 41.5).

**FIGURE 41.5** Para-xylene vapor deposition process.

During the deposition process, the dimer powder is vaporized and recondenses onto the batch of CCAs, forming a uniform coating covering all corners and edges evenly.

The vapor deposition process drives the vapor into any crevices and openings. Vapor deposition has the most stringent masking requirements, since leaks in the maskant will still admit vapor that will contaminate the surface behind, and air pockets inside masking boots or tape may dislodge the boot in the vacuum and create leaks as the air escapes.

## 41.5 CURE, INSPECTION, AND FINISHING

---

The finishing steps require most of the labor involved in conformal coating process. Three finishing operations are:

- Curing the coating
- Inspecting under UV light to verify complete coverage and touch-up
- Removing mask materials

### 41.5.1 Cure

Each of the four liquid chemistries is available in a formulation offering different cure mechanisms, as shown in Table 41.1.

**41.5.1.1 Solvent Evaporation.** Systems that are cured by solvent evaporation can be air dried, or slightly heated to drive the solvent out faster. Care must be taken not to overheat the freshly coated assemblies; the coating will skin over and cause bubbles. Long-term exposure to the unevaporated solvents trapped in the coating may also be deleterious to the materials in the parts and PWB. Drying of solvent cure assemblies must be done under a ventilation hood or other properly ventilated area.

**41.5.1.2 Room Temperature Vulcanization (RTV).** Some silicone-based coatings use the room temperature vulcanization (RTV) cure process, which consumes moisture from the surrounding environment as part of the cure process. Some means of humidity control is required; if cure is attempted in a dry oven, the material will not cure properly, if at all.

**41.5.1.3 Heat Cure.** Oven-curable systems use an extended bake, ranging from 15 min. to several hours or longer, for the material to cure fully. Thermally activated systems require the increased temperature to start the curing process, whereas thermally accelerated systems will cure eventually at room temperature but are baked to speed up the process and improve material properties. Generally, the hotter the oven, the quicker the cure, and the harder the finished material.

**41.5.1.4 UV Cure.** For high-volume production, UV-curable materials are used. Immediately after the coating machine is a booth with high-intensity ultraviolet lamps to illuminate the assembly. After several seconds, the assembly has cured enough to be able to be handled at the next stage of assembly, such as coating the opposite side. UV-curable materials do not cure fully under components, where the coating is not illuminated. Therefore, most UV-curable materials also contain a secondary curing mechanism, such as heat cure, so that at the end of the line the CCA can be fully cured in a single baking step or naturally come to full cure in ambient conditions inside the finished product. Since different coatings are sensitive to different wavelengths of UV light, it is important to coordinate the purchase of the light source with the supplier of the coating.

**41.5.1.5 Catalyzed.** The catalyzed process involves mixing two parts together just before application, to initiate polymerization and cross-linking. This process occurs slowly at room temperature but may be accelerated by elevating the temperature in an oven. Catalyzed coatings may be affected by contaminants present in the PWB or parts being coated, resulting in uncured areas or peeling coatings. Since the pot life of catalyzed materials tends to be short, it is imperative that the mixed material be cleaned from sprayers, tubing, and so on, before it thickens and hardens.

## 41.5.2 UV Inspection

Coatings contain a fluorescent dye that will glow under UV light and show where the coating has (or has not) been applied. Areas without coating can be touched up at this time.

The areas most susceptible to insufficient coating are corners of parts, where the coating can flow away and leave little behind; the protruding ends of through-hole part leads; and shadowed areas under or behind larger components. If large flat areas are uncoated and show beads of coating, there is a wetting problem due to improper surface preparation or a material incompatibility.

The coating should also be inspected for improper thickness, bubbles, trapped material or debris, and incomplete curing (see Fig. 41.6).

**FIGURE 41.6** Various conformal coating defects. (a) Coating on connector pins (b) Cracked or crazed coating (c) Delaminated or blistered (d) Uncoated areas (e) Excess coating drips and runs (f) Excess coating bridging flat pack leads (g) Solvent runoff from rework affecting surrounding coating (h) Overheated, burned coating from rework (i) No buffer coating applied to Glass parts when used with hard coating at cold (j) Dewetting; coating beading up instead of wetting to board (k) Excess coating interfering with movable items (l) Excess coating in masked areas (m) Excess bubbles from trapped solvents (n) Insufficient coverage on corners and edges (o) No coating applied under parts (p) Uncured coating under parts.

### 41.5.3 Mask Removal

Mask materials should be removed carefully; to prevent peeling, it may be desirable to score or cut the coating at the edge of the mask so that the coating tears along the correct line. Ensure that the mask is removed entirely and that no residue has been left behind on the board. Latex mask that has been overheated will be sticky and difficult to remove completely, as will overheated masking tapes.

## 41.6 REPAIR METHODS

---

Since the different varieties of available coatings vary widely in their properties, removal methods must be evaluated and developed on practice boards first before being used on deliverable CCAs. The coating can then be removed as easily as possible, with the least risk to the CCA. Several methods to remove conformal coating are:

- Using a solvent to loosen or dissolve the coating
- Using a hot soldering iron or hot-air nozzle to solder through the coating while simultaneously removing the offending electrical part
- Mechanically cutting, abrading, or picking away the coating
- Etching the coating away using rarefied gas plasma (typically for XY coating only)

### 41.6.1 Solvent

The easiest coatings to remove are acrylics, since they do not react when they are applied. For local coating removal, the area to be repaired can be cotton swabbed several times with the proper solvent. Care must be taken to keep the solvent only in areas that are to have the coating removed. The entire board may be stripped of coating with a solvent soak. This is most useful on acrylic coatings, but is also possible for some urethanes and silicones, which swell and loosen when soaked. Note that this process may damage the components or solder joints on the board, which will be stressed as the expanding coating pushes up the components. The solvent may attack the components and PWB itself; epoxy coatings cannot be removed with solvent or chemical strippers, since many parts and the PWB are also made of epoxy.

### 41.6.2 Thermal

Thin coatings may be loosened from solder joints with a soldering iron or a hot-air reflow tool, while the faulty part is being desoldered. The area is then cleaned of charred and or damaged coating, and the repair completed. Although this method is simple, it usually produces toxic gases, and must be performed with adequate ventilation. The decomposed coating is also difficult to clean off of the board and soldering iron.

### 41.6.3 Mechanical

Mechanical means such as scraping and picking are necessary to remove all coatings, even if the bulk has been removed via one of the preceding methods. Softer coatings such as UR or SR can be scraped away with a wood implement, so as not to cause damage. A soft rotary tool may be used for larger areas. The board may be heated slightly to make the job easier. For harder coatings, a hot knife is used to cut through the material.

A microabrader can also be used to abrade the material away. The surrounding board areas must be protected from contamination by the abrasion media.

#### 41.6.4 Plasma Etch

An extended plasma etch will remove XY coatings from large areas, since the plasma erodes the surface evenly. Since the plasma will chemically change the surface (leaving behind oxides, reduction products, and ash), compatibility of the plasma-stripped surface with the new coating must be verified.

### 41.7 DESIGN FOR CONFORMAL COATING

---

When designing a conformal coating system into the product, the designer needs to consider a number of questions:

- Is coating required for this product, or should it be omitted for cost savings or other reasons?
- What material properties are most important for this application, and which materials will provide the best balance?
- What areas should not be coated?

#### 41.7.1 Is Conformal Coating Required?

One of the basic questions to consider is whether or not to coat the particular assembly. Generally this will be a trade-off between reliability and cost.

**41.7.1.1 Why Use It?** Customers may flow down requirements for conformal coating for industries where it is commonly used such as military or aerospace electronics. The following are some of the reasons to consider the use of conformal coating:

- The end products are used in humid or condensing atmospheres, such as electronics boxes for military and shipboard applications. It should be noted that although conformal coatings are moisture resistant, they are not waterproof, and should not be used for items that will see extended or continuously wet conditions. For those applications, use a watertight enclosure and conformal coat the boards inside. Conformal coating will protect against condensation, such as when the product is brought from a cold environment into a warm humid one.
- Clean conformal coating does not support mold and fungus growth.
- The end products can become contaminated by dirt and debris. Conformal coating is especially useful in space applications, since loose debris will float readily from place to place inside the electronics box.
- Conformal coating greatly improves the board's capability to withstand high voltage, especially at altitude or low pressure, since an electrical arc now has to travel through two layers of insulation rather than just jumping from one trace to its neighbor.
- Conformal coating protects against tin whiskers. Pure tin plating has the tendency to recrystallize and extrude long (>1 mm) whiskers of pure tin, which can short to neighboring part leads and cause short circuits. Conformal coating provides protection against short circuits caused by tin whiskers. Even if a tin whisker can force its way through a layer of coating on the way out, it cannot force its way back through the coating on the neighboring lead without bending and buckling.

- Conformal coating provides mechanical support for components during shock and vibration. Components weighing more than  $\frac{1}{4}$  oz. per lead should be supported by other means as well, such as staking with a bead of adhesive along the side.
- Lastly, conformal coating may be made opaque, and thus provide a level of security. A thick opaque epoxy coating will prevent the casual observer from determining what is under the coating.

**41.7.1.2 Why Not Use Coating?** Most of the reasons for not coating on an assembly stem from the recurring cost of cleaning, masking, demasking, touch-up, etc. The target cost of the product may not support the extra cost incurred by the coating, and if reduced reliability of the uncoated assembly is still acceptable, the rational decision is not to coat the assembly.

Since the coating is a dielectric material, it changes the impedance of high-speed traces on the surface of the PWB. Boards with microstrip are usually not coated for this reason. Radio frequency (RF) PWBs for severe environments can still be coated if the traces are buried microstrip or stripline, which are unaffected by the additional coating on the board surface.

## 41.7.2 Desirable Material Properties

When selecting a coating, the entire suite of material properties must be considered in order to choose the best coating for the application. Unfortunately there is no “one size fits all” solution, but many different coatings, each suited to different applications, as shown in Table 41.1. The following are some of the properties to consider:

- **Ease of application and producability** The intended production environment may determine the cure process and application process that is best for the job, and will narrow the field of alternatives.
- **Compatibility** The coating must not be inhibited from curing by any material on the completed assembly. Often the best way to address this is to ask the manufacturer and try out the coating in question on a sample of the materials that you are going to use.
- **Moisture resistance**
- **Dielectric constant** For RF and high-speed circuits, a material with a low dielectric constant will change circuit performance less than a material with a higher one.
- **Dielectric strength** For high-voltage application, materials with a high dielectric strength should be used. For a valid comparison, tests must be performed on samples of equivalent thickness, since thin samples will break down at a higher volt/mil than thick samples of the same material.
- **Insulation resistance** Also known as *resistivity*, insulation resistance is of concern in high-voltage or high-impedance circuits, where the resistance in the circuit is very high ( $>10\text{M ohm}$ ) and is significant compared to the resistance of the coating and PWB laminate. For these applications, choose a coating with high ( $>10^{15}$  ohm-cm) resistivity and excellent moisture resistance.
- **Hardness** For products that need to withstand cold temperatures  $<-10^{\circ}\text{C}$ , a soft coating is recommended so that at cold temperatures the coating will not exert excessive force on fragile components (see Fig. 41.7). For products that need good abrasion resistance and protection from external handling damage, a harder coating must be used.
- **Glass transition temperature ( $T_g$ )** For assemblies that need to withstand cold environments, select a coating that either has a  $T_g$  below the coldest temperature required or a  $T_g$  of  $25^{\circ}\text{C}$  and above. Coatings that have a low  $T_g$  in the range of operation will suddenly get hard at cold temperatures and impose great stress on the surrounding components.

**FIGURE 41.7** Glass diode cracked by high-modulus coating.

- **Elongation** Materials with high elongation are resistant to cracking and abrasion.
- **Reworkability** AR coatings are the easiest to rework, whereas XY and ER are the hardest.
- **Abrasion resistance** This is ability of the coating to withstand damage from handling and later assembly operations, as well as in the field.

### 41.7.3 Areas to Mask

During the design, the designer needs to consider all the areas and parts on the board that need to be uncoated and identify them on the assembly drawing, shop instructions, or other paperwork that the coating technician will use. Although it is obvious to the design engineer that an expensive infrared (IR) sensor element should not be coated, it may not be so obvious to the technician holding a drawing that says, “Coat entire board,” and nothing else. Being specific on the drawing clarifies what should be coated and how.

Consider the following areas:

- Coating on connector pins can cause open circuits, and may interfere with the full mating of the connector. It is necessary to mask the back of the open back connectors as well as the front, to keep the coating from flowing along the back of the pin into the active area. Also, pin alignment depends on a certain amount of looseness on the pins, and filling the connector shell with coating will defeat this feature.
- Coating should be kept from the edges of plug-in CCAs where the card guides travel. The coating will interfere with proper operation of the card guide and may prevent proper grounding of the card.
- Mounting holes for screws should be masked to keep the coating from filling or reducing the size of the hole and to ensure that the PWB is properly grounded.
- Test points should be masked so that they can be reliably accessed during testing.
- The adjustment screws of adjustable components. If the adjustable components have openings in them, the openings should be masked also.

- If the product contains sensors for air temperature, pressure, humidity, etc., the coating should not block the air from entering the sensor.
- Optical devices, light-emitting diodes (LEDs), infrared sensors, and light sensors may have their operation affected by the coating. This is especially true for UV and IR devices since the coating may be opaque to UV and IR wavelengths of light. The coating may also darken, cloud, or turn brown as it ages, eventually affecting the operation of the circuit. Connectors for fiber-optic cable should also remain clear of coating for the same reason.
- Components mounted in sockets should have the sockets masked and the components inserted after coating.
- Areas under BGA packages should not be underfilled with conformal coating but with an underfill adhesive particularly suited for that purpose. If no underfill is used, the edges of the BGA should be masked, or dammed with a permanent adhesive barrier to prevent the coating from entering under the BGA. Due to the shrinkage of conformal coating, during thermal cycling the balls will be crushed and the reliability of the BGA will be adversely affected.

## CHAPTER 42

---

# SOLDERABILITY: INCOMING INSPECTION AND WETTING BALANCE TECHNIQUE

---

**GERARD O'BRIEN**

*S.T. and S. Company Bayport, New York*

---

### 42.1 INTRODUCTION

---

The power of solderability testing can be lost, even to people who routinely perform solderability tests, because of the function of the test method and a lack of understanding the process. Most solderability testing has been used as a means of testing incoming components or boards in the hope of catching defects and thus avoiding line-related issues. When a defect occurs on the line it is too late.

#### 42.1.1 Dip and Look

Testing has most often used a protocol best described as “dip and look,” in which a technician completely immerses the wettable area of a PCB or component into a solder bath for a prescribed period of time and then evaluates the sample visually once it has cooled down. Pictorial guidelines were used to help the technician to accept or reject the samples being tested. Some incoming inspection departments may have stressed the solderable deposit by exposing it to steam for eight hours and then performed the solderability test. Steam exposure for tin lead coatings is a well documented and applicable stressing technique, but the same isn't true for Pb-free surface finishes. In all cases, the result is basically subjective and the “data” produced from these tests provides little information either to the process engineer responsible for the assembly line or the plating line that is applying the solderable deposit. With the exception of the very extreme “it wet or it did not wet with solder” which is very rare, the remaining population of results achievable are lost in dip and look testing.

Plating, solderability, and soldering in the tin lead world has such a large process window that in the majority the dip and look testing suffices with defects normally in the parts per billion. The occasional disaster does occur but it is rare and attributable to an assignable cause. This process latitude and statistical process control has resulted in the demise of the incoming inspection departments at the CM or OEM. The technician who would have once performed the testing has been replaced by a clerk whose only job is to reconcile the purchase order quantity with the received quantity.

### 42.1.2 Introduction of Lead-Free Assembly

The introduction of lead-free assembly as a direct consequence of the European Union as shown in “Reduction of Hazardous Substances (RoHS) and Waste Electrical and Electronic Equipment (WEEE) directives,” changes everything. While lead-free assembly is nothing new, it has existed as a function of design requirements and has been a niche market in a lead-dominated one. Plating and assembly of these non lead-bearing platings and solders were learned and understood by the users in this unique market. However, with the RoHS and WEEE directives, this niche, highly-specialized market has become the norm overnight and the forgiving tin lead process is gone. Up and down the supply chain, it’s a new game that the supplier base needs to learn and learn quickly if quality and costs are to be maintained. This “new game” can be learned quickly if real and useable data is available to the process engineers supporting the plating and assembly processes. This means the re-introduction of the “incoming inspection departments” once used for the testing of components and PCBs, but with more sophisticated tools than the tweezers and solder pots of old. Solderability testing, if performed as outlined and detailed in this chapter, will help with process development, aid with the choice of surface finish, distinguish marginal from excellent suppliers and if followed widely can short circuit the time to return to the process latitude that tin lead provided.

## 42.2 SOLDERABILITY

To understand the issues of solderability it is first important to understand what is meant by the term, including appropriate definitions, the physical properties of the materials involved, and the various standards developed to guide the user to ensure that the solder process will be successful.

### 42.2.1 Industry Standards

Two common solderability specifications for Components and Printed Circuit Boards are ANSI-JSTD 002 and ANSI-J-STD 003 respectively. In each specification, there are detailed test protocols as well as accept and reject criteria. While there are different specific test methods, the general test method can best be described as “dip and look” with the responsibility of accepting or rejecting the parts being tested being placed firmly into the hands of an inspector that evaluates by eye. With this test, the inspector uses the percentage of area that is wet with solder: with 95 percent as a pass and 94.999 percent as a failure. It should be stated that these “dip and look” tests do not usually represent what actually occurs during the assembly process. Both specifications have process simulation tests, but the action of immersing a component or PCB coupon into a static solder pot using tweezers remains the most common test method in use. Table 42.1 details the test protocols found in these J-STD documents.

**TABLE 42.1** Solderability Test Methods with Accept/Reject Criteria

Test document	Test method	Comments
ANSI-JSTD-002	Test A, Test B, Test C, and Test S	All basically dip & look methods that have little to no possibility of meeting GR&R requirements
ANSI-JSTD-002	Test D	A vital test for Pb-free
ANSI-JSTD-003	Test A, Test B, Test C, Test D, and Test W	All basically dip and look methods that have little to no possibility of meeting GR&R requirements

In both these specifications are test methods that are *not* approved for accept/reject criteria, but that produce data that is useful for process development, shows what really happens during the assembly process, and if tested correctly meets the most stringent of evaluations to modern measurement analysis. These are tests E, F, and G for the J-STD-002 and test F for the J-STD-003. The test protocol detailed in this chapter is designed to change the test status of the wetting balance to one capable of producing accept/reject data, and more importantly, to provide accurate data for process improvements.

### 42.2.2 Definitions of Terms

For soldering to occur some obvious fundamentals must be met:

1. The part needs to be fluxed—see following definition.
2. The part must be solderable—see following definition.
3. There must be sufficient thermal energy to allow wetting to occur—typically 35° to 50°C above the Liquidus point of the alloy being used.

*Soldering* is defined as a metallurgical joining method using a filler metal (the solder) with a melting point below 842°F (450°C). Soldering relies on wetting for the bond formation, and is defined in the ANSI-JSTD-002 as the ability of a metal to be wetted by molten solder.

*Wetting* is defined as the formation of a relatively uniform, smooth, unbroken, and adherent film of solder to a basis metal.

### 42.2.3 The Choice and Impact of Fluxes for Solderability Testing

Flux is an integral part of soldering and solderability testing. A flux used for solderability testing should *never* produce false positives or negatives. It should demonstrate the true characteristic of the sample being evaluated. Some examples are whether it's old, composed of intermetallics, buried under a layer of oxides, contaminated with organics, hiding a poorly wettable basis metal, or showing a clean fresh readily solderable surface.

**42.2.3.1 Flux Functions.** A flux has three main functions:

1. To act as chemistry that reduces oxides on a wettable surface.
2. To provide the correct interfacial energy potential between the flux/solder interface and the solder substrate interface.
3. To prevent oxidation from forming during the soldering process and to a lesser extent in the case of liquid fluxes they may protect the surface on the PCB from the extreme temperatures. It may also act as a heat transfer medium.

Fluxes are necessary for soldering. While flux-free soldering is possible, in the presence of a reducing gas atmosphere, it is very uncommon. When attempting to check for solderability characteristics without the use of a flux, at best the solder will stick to the sample but will not wet the surface to form a true metallurgical bond. At the other extreme end of the scale are people using fluxes so strong that nothing will ever fail a solderability test. These fluxes do not represent anything used in the assembly industry. A great example of this is the use of the Hot Air Solder Level (HASL) flux for outgoing solderability testing. This type of flux typically uses 5 percent HCl or 5 percent HBr as the active ingredient which, when applied to a surface finish, will reduce any oxide layer present and reactivate any potentially passivated nickel layer and thus always produce a pass result. This is not what is supposed to be used and it does not provide any information pertaining to the actual solderability of the sample being tested because it passes all the time.

**42.2.3.2 Fluxes and Evaluation of Solderability.** There has been a fundamental change in how solderability is evaluated. The need to demonstrate a year of shelf life has been

replaced with a test for how robust a deposit or plating is. The more robust the deposit, the greater the potential shelf life and the ability to survive the complicated higher temperature exposures found in Pb-free assembly. When making the choice in terms of solderability testing, it is important that the chosen flux is active enough to overcome finger oils and light surface oxidation and to promote wetting. At the same time, it should not be capable of reducing heavy oxides or wetting to exposed and oxidized intermetallic compounds. For many years the use of the R flux for solderability testing was the norm, and it was referenced in that venerable specification MIL STD 202, method 208. The weight consists of 25 percent colophony and 75 percent alcohol. The activation level is approximately 0.05 percent as measured by chloride content, since this is not very active and being a naturally occurring substance there is variation year to year and location to location.

The JSTD-002/003 committees working with NIST, NEMI, and Industry undertook a study to look into the use of this flux. Using an R type flux for solderability testing produced excessive noise in the data, which was generated from the flux alone. The inability of the flux to deal with simple soils, such as a finger print for example, could produce a false negative result. The outcome of the study was a recommendation to add a known quantity of an active ingredient, low enough to not produce false positives but strong enough to deal with normal sample contamination not related to the plating or surface preparation of the sample. Testing of OSP, ENIG, and Palladium surface finishes with an R flux inevitably produced failures that were never seen in production. These surface finishes, particularly ENIG and OSP, are in common use and a suitable flux needed to be created to test them. The added ingredient was diethylammonium hydrochloride and the flux specified for solderability testing became known as “a standard activated rosin flux (type ROL1 per J-STD-004).” This flux has been shown to be excellent in differentiating solderability issues from finger oils and sample issues. It is sold under many names. The list of current suppliers can be found in the appendix of both J-STD-002 and 003.

**42.2.3.3 Lead-Free Solderability and Fluxes.** For lead-free solderability testing, a further extensive study was undertaken by the J-STD-002/003 committees again. The outcome of the testing was to recommend and specify the use of a more active flux. The activation level has been increased to 0.5 percent as measured by chloride content. This flux and the increase in test temperature are specified in the J-STD-002C and 003B.

**42.2.3.4 Wetting and Solderability.** Soldering is governed by the laws of physics. In soldering, three phases are present:

1. The solid phase (parts to be soldered)
2. The liquid phase (molten alloy)
3. The vapor phase; flux evaporation (atmospheric air in the majority, could be nitrogen)

The molecular interactions of these three phases taken in pairs are surface tensions (see Figs. 42.1 and 42.2).

FIGURE 42.1 Theory of wetting.

**FIGURE 42.2** A graphical representation of a lead immersed in molten solder and wetting.

Figure 42.1 shows a soldering alloy pellet put onto the surface of a metal plate, which has been previously fluxed and heated to a temperature at least equal to the Liquidus point of the alloy, where :

1.  $\gamma_{SL}$  represents the solid—liquid phase
2.  $\gamma_{SV}$  represents the solid—vapor phase
3.  $\gamma_{LV}$  represents the liquid—vapor phase
4. Represents the junction between the solid, liquid (solder) and fluxed surface

When a lead, component, or PCB is immersed into solder during a solderability test, the following can be derived from the component solder interface Equation 42.1

$$\gamma_{SV} + \gamma_{SL} + \gamma_{LV} = 0$$

$$\gamma_{SV} = \gamma_{SL} + \gamma_{LV} \cdot \cos\theta \text{ (YOUNG's relation)}$$

$$F = \gamma_{LV} \cdot \cos\theta \cdot P - \rho \cdot v \text{ (LAPLACE law)}$$

- where
- F = capillary forces
  - $\rho$  = specific mass of Sn/Pb (molten alloy in the pot)
  - v = volume of the component part immersed in the molten alloy
  - $\rho \cdot v$  = Archimedean thrust or buoyancy generated by the component part immersed in the molten alloy.
  - $\gamma_{LV}$  = alloy/flux surface tension
  - P = component wettable perimeter

Where  $\theta$  is the angle formed by the surface of the solid and the liquid at their extreme point of contact—also known as the wetting angle.

It should be noted that

1. The relations are true only if the sample is immersed in a perpendicular direction at the surface of the alloy and the dimensions are constant.
2. The angle  $\theta$  is directly linked to surface tensions and is thus representative of the wetting quality.
3. The smaller the wetting angle  $\theta$  the better the solderability!

A rating of solderability, quality-based on contact with the wetting angle is listed in Table 42.2.

**TABLE 42.2** A Relative Index of Solderability as a Function of Contact Wetting Angle

Angle value (°)	Quality rating
$\theta \leq 30$	Excellent
$\theta \leq 40$	Good
$\theta \leq 55$	Acceptable
$\theta > 55$	Rejectable

### 42.3 SOLDERABILITY TESTING—A SCIENTIFIC APPROACH

Solderability defects can result from poor line management, poor chemical management, incorrect deposit thickness (whether real or incorrectly measured), poor choice of chemical supplier, poor understanding of metallurgy and solderability, and/or a combination of all of these items. Being able to measure solderability correctly and accurately is necessary for fixing these problems and for producing acceptable parts for the end user. If the test always accepts the sample, or there is little to no discrimination between inputs to the line, the supplier will never develop a robust process and then will never supply parts with zero defects accordingly. However, if the solderability test is performed correctly, data can be generated to determine whether significant relationships exist between two or more variables that have a positive or negative impact on the final product performance. These are known as *analytic studies*, as defined by Deming, and are used to increase the knowledge about the system of causes that affect the process. These are considered among the most important uses of measurement data because they lead ultimately to better understanding of processes.

The benefit of using data-based procedures is largely determined by the quality of the measurement data used. If the data quality is low, the benefit of the procedure is likely to be low, such as from dip and look solderability testing. Similarly, if the quality of the data is high, the benefit is likely to be high also. The quality of measurement data is related to the statistical properties of multiple measurements obtained from a measurement system operating under stable conditions. For example, someone might be testing plated lead frames of varying deposit thicknesses and stressing the parts using steam exposure. If there is a reduction in solderability, as a function of thickness and time exposure, then the data produced would be considered of high quality. If there is no discrimination between any of the groups, and all pass or all fail, then the quality of the data would be considered low.

#### 42.3.1 Commonly Used Statistical Properties

The statistical properties most commonly used to characterize the quality of the data are *bias* and *variance*. Bias refers to the location of the data relative to the true value and variance refers to the spread in the data. Variance is a major player in producing low-quality data.

Over the years, the science of evaluating pieces of test equipment and their suitability to accurately measure whatever they are being used for has evolved. By having a test that is scientifically and statistically believable, the results obtained can be trusted and thus correct

judgments can be made on their results. Using a child's toy to measure the thickness of a lead frame is obviously silly, but attempting to fix a plating line problem for solderability using tweezers and a solder pot falls into the same category—just silly!

### 42.3.2 Gauge Repeatability and Reproducibility (GR&R) and Measurement System Analysis (MSA) Background

The first evolutionary step was the use of Gauge Repeatability and Reproducibility (GR&R) testing that took into account both the suitability of the test equipment as well as the operator/technician/engineer performing the test. Detailed worksheets were created by the likes of IBM and it became commonplace to speak of a gauge with a 10 percent GR&R rating being very acceptable for its task, with minimal negative influences imparted by the person conducting the test. A gauge with values between 10 and 30 percent was said to be acceptable, and anything above 30 percent required immediate attention to determine whether it was the piece of equipment, the operator, or the interaction between the two that was producing such unacceptable results.

Solderability testing by dip and look methods do *not* meet this minimum requirement.

The science of GR&R has since evolved into Measurement System Analysis (MSA), where GR&R is only one part of a system that evaluates the total measurement capability. MSA is an experimental and mathematical method of determining how much the variation within the measurement process contributes to overall process variability. It takes into account

- **Bias** The difference between the observed value and reference value.
- **Stability** The total variation in the measurements obtained with a measurement system, on the same master or parts, when measuring a single characteristic over an extended time period.
- **Repeatability** The variation in measurements obtained with one measurement instrument when used several times by an appraiser; all while measuring the identical characteristic on the same part.
- **Reproducibility** The variation in the average of the measurements made by different appraisers using the same measuring instrument when measuring the identical characteristic on the same part.
- **Linearity** The difference in the bias values through the expected operating range of the gauge.

All of these requirements can be attributed to solderability testing, even though at first glance it would appear to have nothing to do with it. Being able to test to a protocol that meets the previous requirements provides useable data for process development and improvement and hopefully will facilitate a much shorter development time than might otherwise be the case.

Classic solderability testing, using dip and look techniques, cannot meet any of the previous requirements.

### 42.3.3 The Wetting Balance and Measurement System Analysis (MSA)

For solderability testing there is only one method that has the potential to meet the requirements of MSA and that is testing by wetting balance. Not all wetting balances are, of course, created equal and the ease of use, or lack thereof, can have a serious impact on the final MSA analysis and ultimate acceptance of the data. Part of the problem in previous evaluations of the wetting balance has been the samples used for testing the performance of the machine. Typically, with GR&R or MSA, samples are tested repeatedly by numerous people in a random order. When testing with a wetting balance, soldering a part is required. This means that it is a one use item that cannot be tested again. Testing components clearly is not an option, as the natural variation from a plating process (assuming it is one that is in control), may contribute enough variation to fail the evaluation. To get around this one-time test, the solution has been to place known weights that are calibrated and certified on to the wetting balance (which is measuring force as a function of displacement of a sensor) and then record the force measurement as a function of the weight applied. Calibrated weights in the range of 100 milligrams to 5 grams were used

and this was thought to provide the necessary range and usability for running a GR&R test. The results obtained from numerous round-robin industry studies have been terrible, with no correlation test site to test site or machine to machine from the same manufacturer being obtainable let alone obtaining an acceptable MSA, until the methodology and equipment was understood.

A very detailed study was performed on the failed GR&R's of the past and an examination into the source of variation was undertaken. The results showed that slight misplacement of the test weight could have a huge impact on the result, especially in the lower weight ranges where small components are typically tested. Figure 42.3 shows normalized data from one round of testing with calibrated weights. The correct value should be 0.98 mN. It is clearly evident that the degree of spread and variation in this one-person test, which is typical for this type of test, would result in a rejection of the wetting balance as a scientifically acceptable measuring device for solderability force measurements.

**FIGURE 42.3** Normalized data for one individual from a “placing the test weights” wetting balance test—the correct value is 0.98 mN.

#### 42.3.4 Wetting Balance Protocol to Meet the Requirements of an Acceptable GR&R

What was needed was a test protocol that allowed the wetting balance to be used for what it was designed for: measuring solderability. This required producing a test sample that is considered uniform and consistent, sample to sample. This “known good coupon” was created and subsequently a test protocol developed. This detailed test protocol maybe found in the Appendix sections of the ANSI-JSTD-002 and ANSI-JSTD-003 documents.

**42.3.4.1 Wetting Balance Protocol Development.** This protocol was run using three types of wetting balance. To demonstrate the power of both the protocol and the wetting balance, three individuals were requested to run the test at every location: an expert in wetting balance

use, a technician who knew about the wetting balance, and someone who never even heard of solderability testing, let alone a wetting balance. Generally secretaries and customer sales people were used for this group. Figure 42.4 shows the results obtained for one wetting balance combining ten test per individual. A series of industry-wide, round-robin tests were conducted on three different manufacturers of wetting balance machines and among ten individuals. The results show that while there may be some performance differences from machine manufacturer to machine manufacturer, it is nothing that cannot be fixed now that a MSA-capable test protocol exists for the wetting balance. Based on the data produced, the test protocol was accepted by both the solderability specification committees and inserted into the next released revisions—ANSI JSTD-002C and ANSI-JSTD-003B.

Based on this work, the industry has a test protocol that stands up to any scrutiny pertaining to statistical GR&R and MSA evaluations or critiques.

**FIGURE 42.4** An example of the consistency of wetting balance using the test protocol—ten individuals participated in the generation of the previous data.

**42.3.4.2 The Output from a Wetting Balance.** The output from a wetting balance test provides detailed information in both graphical and numerical formats. Depending on the software, multiple tests may be displayed on one graph, showing consistency or lack thereof in the performance of a test group. Average values may also be displayed; some softwares even displays the contact angle. It also clearly distinguishes between non-wetting (soldering never took place) and de-wetting (soldering initially occurred but due to basis metal issues the solder could *not* remain wetted to the substrate). Figure 42.5 depicts the action of soldering using a wetting balance, the same motion applies if using a globule or immersing at an angle. Figure 42.6 shows the typical outputs from a wetting balance.

- a. Sample reaches the surface of the solder bath
- b. Sample at end of immersion depth—(buoyancy)
- c. Forces at equilibrium
- d. Maximum wetting force
- e. Sample lifted out of the solder bath
- f. Sample is out of the solder bath

**FIGURE 42.5** An example of the consistency of wetting balance using the test protocol—ten individuals participated in the generation of the data.

**FIGURE 42.6** Possible outputs from a solderability test using a wetting balance.

**42.3.4.3 Reporting the Results—*mN* or *mN/mm*.** The output from a wetting balance is typically a force measurement. The force value in and of itself does not help interpret how good or bad the test specimen is, but obviously, the higher the force the better. The size of the test specimen and the wettable length of the specimen are key characteristics in how much force is produced, and the buoyancy of the device also is a key characteristic. To rationalize solderability performance over a myriad of components and PCB thicknesses, the use of normalized data is recommended. The wetting force is then reported as *mN/mm* and the ability to standardize on minimum acceptable values regardless of part size is now possible. Some wetting balance software does this normalization automatically, but other software that doesn't will need to be manipulated by exporting to Excel(tm) or similar programs to normalize the output data.

**42.4 THE INFLUENCE OF TEMPERATURE ON TEST RESULTS**

The test temperatures specified for solderability testing with SnPb is 235°C and 245°C for PCBs and components respectively. The test temperature for SAC305 testing should be 255°C for both the component and PCB solderability specifications. Testing at lower temperatures will produce slower wetting times that maybe reported as failures incorrectly. As the temperature increases, there is the possibility of the thermal degradation of the flux being used for the test, but unfortunately not everyone follows the recommendations of the solderability specifications. If this occurs, a false negative result may be obtained—check with the flux supplier before using temperatures above 260°C for testing regarding the stability of the flux.

Figure 42.7 is a comparison of average wetting times for ENIG, tested at 235°C as a function of solder alloy used. The SnPb alloy wet the coupon after 0.75 seconds, SAC305 took more than 4 seconds and SnCu did not wet during the 10 seconds of the test.

**FIGURE 42.7** Wetting speeds for three common solder alloys at 235°C.

## 42.5 INTERPRETING THE RESULTS: WETTING BALANCE SOLDERABILITY TESTING

Solderability testing results should be useable in process development. The classic dip and look tests produce only go/no go data that has little value in troubleshooting or developing a plating line. It cannot differentiate if one pre-clean chemistry is better than another or the effect of the micro-etch rate on basis metal removal because it does not produce useable data. The part tested by dip and look is immersed into the solder bath and it either wets or it doesn't wet—with no shades of gray in between. Solderability testing with a wetting balance can detect subtle changes in many of the process steps that are part of the plating process of a PCB or a component.

The shape of the curve and the rate of rise give the informed user the vital information necessary to troubleshoot or refine their process. A slow rise of the wetting curve is indicative of oxides. That is, is the rinsing too aggressive, the pH too low, or the temperature too high? Initial good wetting, followed by low forces being produced, indicates poor surface preparation of the basis metal. Is the micro-etch able to attack the basis metal or is the preclean leaving a barrier film that prevents it from doing its work? Table 42.3 details some of the powers of a useable solderability test (as compared to a dip and look test) for the process of an immersion chemistry such as tin or silver. It is assumed that the process is in control and all process sequence steps are being followed.

**TABLE 42.3** Comparison of the Power of a Wetting Balance Test to a Dip and Look Test for Process Development

I Sn or I Ag Process Flow and Solderability Testing		
Process step	Dip and look testing	Wetting balance
Acid Preclean	Changes in chemistry <i>not</i> detectable	Changes in chemistry detectable
Rinse		
Microetch	Changes in chemistry <i>not</i> detectable	Changes in chemistry detectable
Rinse		
Pre-dip	Changes in chemistry <i>not</i> detectable	Changes in chemistry detectable
I Sn or I Ag plating	Changes in chemistry <i>not</i> detectable	Changes in chemistry detectable
Rinsing (too short, too long, too much oxygen, incorrect pH)	Changes in chemistry <i>not</i> detectable	Changes in chemistry detectable
Drying (leaving parts wet or over-drying)	Not detectable	Detectable

Testing with a wetting balance will provide the following information:

1. The speed of wetting This will show how solderable the part is. This will show if the part is old, how well or poorly the part has been stored, and/or how well the process control is for the plating process.
2. The rate of rise to maximum wetting force This will show the level of oxides present on the surface in the case of a gold-plated part, and how thick the deposit is. This again will provide information on process control and/or age and storage of the parts being tested.
3. The maximum wetting force produced The higher the force the better—provides information on the basis metal solderability, the surface preparation, or lack thereof. Low forces recorded on a test, even if the wetting time is fast, is of *major* concern.
4. Once the part wets and produces positive wetting forces, do they remain consistent (ideal), continue to increase (indicative of oxide reduction), or begin to de-wet (the worst

solderability defect)? It should be noted that some 100 percent tin surface finishes and other lead-free finishes have such a smooth surface that adhesion of sufficient flux for a five or ten second test is not possible and the de-wetting being recorded is a function of flux consumption rather than a fundamental solderability test.

5. The output of the wetting balance provides “hard data” which then gives the engineer the ability to perform a statistical comparison of both the population being tested and the other production batches from the same supplier or off the same plating line.
6. The impact of changing fluxes This is especially useful for lead-free assembly development, given the myriad of surface finishes the assembly engineer is now faced with.
7. The impact of stressing (steam exposure or dry bakes or temperature/humidity) on the robustness of the plating can easily be determined as a function of reduced wetting forces or increased wetting times.

The importance of the previous information cannot be over stated as the industry transitions to Pb-free assembly. A test that provides everything in the previous list as its output can improve a process. It can also be used to improve a supplier or disqualify a supplier, select a flux or a surface finish, and/or the best combination of both to minimize defects.

## 42.6 GLOBULE TESTING

---

All the previous information provided has been based on the use of a solder bath for testing when using a wetting balance. There is another test method possible for the wetting balance known as the *globule test method*, in which a pellet of solder of known weight, for example 25 mg, or for size, 4 mm is placed onto a solder iron tip of suitable size that is encapsulated in a non-wettable aluminum block. The solder pellet is fluxed, melts on the heated tip and then forms a globule into which the part to be tested is immersed. Historically, the globule was designed for testing wire or leads of a component that are circular in cross section. In that process, the sample to be tested was positioned horizontally to the globule and then, using a microscope and a stop watch, the time needed to reform the globule after wetting the wire was recorded. Similar to the mathematics explaining the physics of soldering in Fig. 42.1, using the globule for testing components of circular cross sectional areas can be logically explained.

The use of the globule test method for other components is very common. The output of the globule test is in mN and consistent placement of the sample, relative to its immersion point in the globule, is critical if variation due to the test is to be minimized. Three globule sizes are popular: 4mm, 2.5mm, and 1mm, and these are chosen based on the size of the component to be soldered. Placing a large chip endcap into the smallest globule will provide insufficient solder to totally wet the part causing artificially low values to be recorded. Placing the part offset to the globule will affect the true immersion depth that the machine has been preprogrammed to; again providing insufficient solder to wet the part resulting in low forces. Modern globule test machines use video and programmable XY stages to consistently position the sample in the same place relative to the solder globule. After each test, the globule needs to be replaced with a fresh pellet in order to maintain the same dimensions. This is necessary so that the immersion depth and solder available for wetting are consistent. Because of the need to prevent the globule from oxidizing so that it doesn't impact the solderability results, it must be fluxed with a rosin flux that does not evaporate. Testing with fluxes other than rosin-based results in a mix of flux types being used. If a VOC or VOC-free flux is used to prevent oxidation of the globule, it will evaporate rapidly and produce false readings. The ANSI-JSTD-002 has detailed component-orientation diagrams to help minimize variation due to placement error when using the globule test method.

## 42.7 PCB SURFACE FINISHES AND SOLDERABILITY TESTING

The PCB surface finishes all have their unique wetting curves and shapes. Understanding what a good curve should look like for a given surface finish is very important, especially when using the wetting balance to detect subtle changes that are process indicators of potential problems to come. A test that does not provide numerical data will never be able to achieve this.

It is very important that the solderability test, including any stressing that may be imparted on the deposit, be representative of the failure mode that the surface finish finally succumbs to naturally over time. The use of steam to stress a deposit other than a lead-bearing one is not to be used; the recommended stressing is eight hours of exposure to 72°C/85 percent R.H.

### 42.7.1 Typical Solderability Failure Modes By Surface Finishes

The typical failure modes for the most common PCB surface finishes are listed next. It should be noted that these wetting curves are for PWB's that were *not* packaged and purposefully exposed to the environment for a worst case scenario. PWB's correctly packaged and stored will last a lot longer in the majority:

- **HASL (standard 63/37 Sn/Pb)** This has been the standard by which all other surface finishes have been measured. It is said that, "nothing solders like solder." It is a very robust deposit if the solder is maintained for correct alloy ratio and the copper concentration is kept below 0.3 percent by weight. The thinner the deposit the shorter the mean time to failure, whereas the thicker the deposit the more problems with chip placement and paste transfer. A good solder level deposit for a 1206 chip pad should not have thickness readings below 50 microinches with an average value of 120 microinches being excellent! The ultimate failure of solder is that after many years in storage, the copper migrates through the deposit and ultimately becomes oxidized upon reaching the surface. This renders the deposit unsolderable. Before reaching the surface and oxidizing, the growing copper tin intermetallic is solderable. Surface oxides are typically not an issue for HASL. Wetting times are instantaneous for a new deposit, with rapid rise to the maximum wetting force  $-0.25$  to  $0.27$  mN/mm is common when using a standard 0.2 percent activated test flux. As the part ages, there is a slight reduction in wetting forces and a slight increase in wetting times. (See Fig. 42.8)
- **HASL (Pb-free)** The majority of Pb-free HASL deposits use Cu. This is constantly added to as a function of the leveling process. In the tin-lead world, this copper is a source of contamination and needs to be controlled tightly. For Pb-free HASL it is a more important control point for the deposit. Additional copper in the bulk may mean a shorter shelf life as well, and may have an impact on the Liquidus of the surface finish. Be cautious of using this finish unless the supplier has excessive amounts of data and can show control of the alloy composition
- **I Ag** This finish is perhaps the most susceptible to correct storage and packaging. Packing materials that contain sulfur will destroy the solderability of the deposit in a very short period of time. The use of dessicants (in the majority containing sulfur, though sulfur-free is available), rubber bands, and slip sheet papers that are *not* pH neutral and sulfur-free should *never* be part of the packaging materials. Never take the PWB's out of their original packages unless to assemble the boards. If there are left over PWB's then place them inside a bag and fold it over to prevent air impingement. Exposure to the air will result in tarnishing of the surface (sulfate formation) that will destroy solderability. This can happen in as little as 28 days. (See Fig. 42.9) If stored correctly with no exposure to air, a gradual reduction in wetting force due to copper oxide growth will occur.

Figure 42.10 shows the natural reduction in wetting forces for the same I Ag deposit when stored in a bag. The deposit is porous by definition and the reduction in wetting forces is a

**FIGURE 42.8** The normal deterioration of a 63/37 Sn/Pb HASL finish after 510 days in unprotected storage. Wetting times increase only slightly to 0.05 seconds.

function of copper oxide growth that is forming at the Ag/Cu interface. The speed of wetting is not impacted; even after 629 days of storage, Ag dissolves rapidly at the test temperature of 235°C (approx 50 microinches/second).

- **ENIG** the immersion gold deposit is porous by definition. It does offer very good protection to the underlying nickel, but over time the porosity of the deposit results in the passivation of the nickel surface and as the soldering is done to this layer and not to the gold, the wetting forces are reduced. (See Fig. 42.11) This process should take years to occur. Normal storage of the boards will not impact the initial wetting time, as the dissolution rate of the gold is not impacted—it dissolves at 153 microinches/second at 235°C. An example of the power of the wetting balance is the ability to detect excessive rinsing post nickel deposition: it will passivate the surface and produce slow wetting times similar to old parts. Depending on the flux activation levels used, the degree of nickel passivation can produce a total non-wet condition to an excellent wetting result. After 842 days of unprotected storage, the nickel deposit continues to wet under 0.5 seconds, but again the exterior metal—immersion gold—is porous by definition. So, while doing an excellent job at protecting the underlying basis nickel from passivation, time eventually takes its toll.

**FIGURE 42.9** The rapid decrease in wetting forces for I Ag when stored incorrectly. While this may seem to be a problem, it is actually an advantage as I Ag is supposed to tarnish as a function of exposure to air. If it does not tarnish, there is too much “organic” contamination in the deposit which will produce its own series of problems.

- **OSP** With the exception of the first generation of organic coatings, which were mono layers of approx 40Å in thickness and were very sensitive to handling/storage, the current generation of OSP coatings are robust and have excellent shelf life. (See Fig. 42.12 Their ultimate failure is a gradual break down of the deposit and subsequent formation of copper oxide. Even as this occurs, the reduction in solderability performance is not as dramatic as with other surface finishes—naturally occurring copper oxide not being very tenacious and/or hard to reduce.
- **I Sn** This is one of the more difficult surface finishes to correctly apply and maintain from a chemical view point. As such, the possibilities for solderability defects are many. Both the basis metal (copper) and the I Sn deposit have a natural affinity for one another. The copper migrates through the tin as a function of time and temperature; the hotter the temperature the shorter the time to reach the surface. Once there, the intermetallic oxidizes and becomes non-solderable. As a function of plating, copper is displaced from the surface of the PWB and contaminates the plating bath; potentially reducing the mean time for copper to reach the surface of the part. The deposit thickness likewise plays a crucial role in determining shelf life—the thinner the deposit, the shorter the shelf life all things being equal. In addition to this, the catalyst used to make the plating chemistry work (Thiourea) can

**FIGURE 42.10** A gradual reduction in wetting forces over 629 days of “correct storage” for Immersion Silver (I Ag) is shown.

break down and co-deposit sulfur into the tin, which will destroy solderability. This co-deposition may not be seen with a standard solderability test—even a wetting balance test—as it requires the heat from a first pass assembly process to move the sulfur to the surface, which then destroys the solderability of the deposit. It is recommended that thermal stressing of the deposit is used in conjunction with wetting balance testing to ensure that the deposit is robust and free of sulfur. Finally, I Sn has two oxides—SnO and SnO<sub>2</sub>—the former easily reducible and solderable, the latter *not*. SnO<sub>2</sub> can occur due to poor bath maintenance or poor rinsing control. Again the use of stressing techniques, such as 8 hours of 72°C/85 percent R.H., is recommended to help detect the presence of such surface oxides. (See Fig. 42.13 for an example of I Sn gradual decline).

- **Direct Immersion Gold (DIG)** This is a relatively unknown deposit, but one with major potential. The application of a special immersion gold deposit does not corrode the underlying copper, and based on the density of the deposit it performs more like a 30 microinch deposit rather than the 3 microinch deposit it actually is. The underlying copper does migrate through the gold eventually, but it takes many years under normal storage conditions and the failure mode is a simple copper oxidation that is easier to reduce than a passivated nickel layer. (See Fig. 42.14).

**FIGURE 42.11** The gradual decrease in wetting forces for ENIG can be seen as a function of the passivation of the underlying nickel. The deposit, after 842 days of unprotected storage continues to wet under 0.5 seconds, but the exterior metal (immersion gold) is by definition porous and will eventually deteriorate.

### 42.7.2 PCB Surface Finishes and Solderability Testing for Plated Through Holes

The one area where dip and look type testing works better over a wetting balance is in the examination of solderability of plated through holes. While the majority of assembly is surface mount, there remain a large number of connectors that are through-holes as well as other devices—capacitors etc that are still assembled with wave soldering or intrusive paste reflow. Verification of through holes solderability is equally important if line defects are to be prevented. A solder float is still the preferred method as this forces the solder to rise against gravity to wet the plated through-hole. A number of points need to be made:

1. There are no requirements saying that vias need to be filled with solder—sometimes they do, sometimes they do not. The size of the via and of the solder mask clearance defining the

**FIGURE 42.12** The gradual reduction in wetting forces for an OSP deposit after 22 months in unprotected storage. This shows the growth of the copper oxide layer which is obviously less solderable than an oxide-free copper surface.

via, are key factors that influence whether they wet or not. The surface finish, however, must be plated inside the vias if required by the specification or purchase order.

2. With the exception of tin-lead surface finish—HASL—there is *no* requirement to produce a positive meniscus for meeting class 3 acceptability. The solder should wet the hole completely, but it does not have to show positive meniscus.
3. The requirement to have flux wet the hole and drain, while may be seen as stating the obvious, cannot be overstated. The flux needs to be adjusted to the specified specific gravity to allow for wetting to occur. If the holes are small or the aspect ratio is high, additional agitation rather than a simple dunk will be required to ensure complete wetting of the hole wall with the flux. Additionally, the need to tap the sample to ensure complete drainage is also necessary. Failure to do both will result in either incomplete hole fill and/or non-wets: both of which are failures but a function of the test rather than the surface finish.
4. Adhere strictly to the  $2 \times 2$  coupon-size specification and if the sample has many power or ground planes or a heavy overall copper-rich PCB, use *pre-heat*!
5. Hole fill with Pb-free alloys are typically more difficult and may require an increase in test time to allow for the final outcome of the test—hopefully complete hole fill. Experiment

**FIGURE 42.13** An excellent example of a good I Sn deposit's gradual decline in solderability performance as a function of intermetallic growth over 716 days. The wetting times increase slightly, which is also as a function of SnO growth on the surface of the deposit.

with test times as a function of board thickness and copper weight. Any data generated from such experimentation should be submitted to the ANSI-JSTD-003 committee.

## 42.8 COMPONENT SOLDERABILITY

The majority of components require the use of some form of plating to provide solderability and shelf life—very similar to what is needed for PCBs. There are myriad plating options, both from the metallurgy used to the application methods employed. Process control for component plating could be argued to be more critical than for PCBs due to the speed of plating and the number of components plated /hour as well as the various plating techniques and alloys. Prior to the RoHS directive, the component surface finish in the majority and of choice has been tin lead. Suitable for all plating applications from barrel to rack to strip, the plating of this surface finish was easily controlled; hence its solderability. The chemistry used in the majority was

**FIGURE 42.14** A gradual reduction of wetting forces as a function of copper migration through the Direct Immersion Gold (DIG) deposit after 877 days in storage.

initially formulated in the 1960s and may have seen some tweaking over the years for plating efficiency. In addition to the common place tin lead, exotic deposits such as nickel palladium, nickel gold, or palladium silver etc have also been used. While these deposits also offer extensive shelf life and excellent solderability performance, fear of gold embrittlement has resulted in the pre-tinning of gold plated devices prior to assembly to remove the gold from the component. The tinning process changes the solderability performance dramatically.

### 42.8.1 Solderability of Component Basis Metal

Unlike the PCB world where the basis metals used are inherently solderable, such as copper or nickel, the component world deals in basis metals that are non-solderable such as stainless steel or brass (solderable with fluxes not typically found in the electronics industry), marginally solderable (such as Alloy 42—a nickel iron alloy), to easily solderable (such as C194 copper alloy). This fact needs to be realized when designing with or choosing a metal or alloy for a given component and the simple question, “Will this part solder if the surface finish application or quality is marginal?” needs to be asked. If the answer is no, as when using stainless

steel for example, then great care will need to be exercised in both the process control and metallurgy chosen for the part. If the answer is inherently yes then a greater process window should be expected. It should be noted that testing and soldering with Pb-free alloys only acts to reduce any process window.

While this is a chapter on solderability and not necessarily metallurgy, it is important to point out a few factors that may have been missed in designing for component solderability 101. If these fundamentals are followed then the results obtained from solderability testing of components may make more sense and help you deal with problems on the line. The following points should be followed to minimize solderability issues as a function of basis metal choice:

1. Is the basis metal solderable by itself when tested with the flux specified by the ANSI-JSTD-002? Brass, stainless steel, and beryllium copper—common basis metals for components—will not solder as tested to the JSTD-002. C194 or C197, phosphorous bronze, alloy 42, thick film Ag, or Pd Ag are solderable.
2. The ideal method to make a non-solderable basis metal solderable is to use either a barrier or intermediate metal that *is* solderable, such as nickel or copper. A less ideal method, and one commonly used, is to plate a heavy deposit of tin lead or 100 percent tin over it and hope that sufficient plating remains post soldering.
3. The use of thin deposits of a final finish, over a non-solderable basis metal, may result in initial wetting. This is followed by de-wetting when the surface finish is consumed by the tin in the solder.
4. If soldering to a surface finish, plated over a non-solderable basis metal, the reliability of the solder joint will be a function of the adhesion capability of the plating to the basis metal. Even if a good solder joint is formed between the assembly alloy and the component surface finish, the reliability will be poor if the plating peels from the surface. The reliability of the component will be placed firmly back into the plating process and the surface preparation by the plater. You should ask yourself if you trust your plater and the consistency of the process.
5. The preferred method for dealing with a non-solderable basis metal is to plate with a solderable metal. Adhesion of this plating to the basis metal is critical. Acid copper plating does not have great adhesion qualities to alloy 42 or alloy 52, so the use of a cyanide copper strike prior to acid copper plating is the correct protocol. By doing this, the adhesion is guaranteed and provides an excellent solderable surface beneath the surface finish.
6. The conversion to Pb-free has resulted in the dominance of 100 percent Sn as the solderable surface finish. Deposits as thin as 1.5 micron over non-solderable basis metals are being specified, possibly as a cost saving issue, but if the contact time with the solder is slightly longer or rework is needed, this very thin deposit is consumed and defects are inevitable.
7. One positive aspect of the RoHS directive is the use of defusion barrier metals. Nickel is the most common, but copper greater than 1.5 micron seems to work as well, acting as a tin whisker mitigation strategy. By requiring the defusion barrier, the possibility for solderability improvements exists. The quality of this diffusion barrier is likewise very important and its solderability should not be sacrificed for a whisker mitigation strategy.
8. Switching from a tin lead-plated component to a lead-free finish is something not to be taken lightly. Changing from tin lead to 100 percent tin may seem to be relatively easy and logical but a 100 percent tin deposit is more susceptible to line issues such as rinse pH control. Also, its impact on the surface finish is more than tin lead ever was. Similarly, changing from a base metal to an exotic such as nickel palladium gold will require the purchase of some expensive sophisticated measurement tools that were not necessary before. Plating a tri-metal deposit to an accurate thickness is of itself not easy and failure to do so has produced some interesting solderability challenges.

### 42.8.2 Solderability Testing and the JSTD-002

A very useful test is specified in the document called Resistance to Dissolution of Metallization. Parts are tested by immersing them in solder at a higher temperature ( $-260^{\circ}\text{C}$ ) for an extended period of time and once removed, examination of the deposit is undertaken. This test will certainly catch the thin deposits applied over non-solderable basis metals and will also catch poor surface preparation of solderable basis metals. This test should be used on *all* non-solderable basis metal components and for *all* thick film metallization parts and should be used before basic solderability testing is begun.

As per the JSTD, the test time for components is typically five seconds. The part is completely immersed into the solder bath and then removed, cleaned, and evaluated for dip and look testing. The part may have wetted instantaneously or it may have wetted at 4.999 seconds. This is something that can never be discovered via dip and look testing. This wetting time becomes critical if there are differential wetting times between endcap metallizations. When a chip with two endcap metallizations wets inconsistently endcap to endcap, the resultant forces of soldering will cause one end to rise up off the pad and the chip will exhibit the classic “tombstone” appearance, in which one end of the component becomes detached from the land area and the surface forces on the other end cause the component to stand on end, resembling a “tombstone” (See Fig. 42.15).

Testing of these parts with a wetting balance revealed the problem and, more importantly, gave information to the supplier about the potential root cause of the problem.

**FIGURE 42.15** This shows a test for some surface mount components that pass the five second dip and look test, but clearly show an issue with surface oxides prior to reaching a very acceptable final wetting force. The supplier of these parts, using dip and look testing, certified them to meet solderability requirements but the end customer had line problems.

### 43.1 INTRODUCTION

---

Cell-phones, iPods, digital cameras, laptops and desktop computers, DVDs, and indeed all electronic equipment in our world have one thing in common: They each contain an electronic assembly composed of integrated circuits and discrete components soldered to a printed wiring board (PWB) to create an electrically functional circuit.

In years gone by, printed circuit assemblies were made exclusively with through-hole components. Today's assemblies contain components that are both through-hole and surface-mount, and some contain unpackaged integrated circuits (ICs) attached directly to the PWB. Except in the case of direct chip attachment by wirebonding or conductive adhesive, the use of a soldering flux to ensure good joining is almost universally practiced. Thus, soldering flux choice has become an important consideration in the manufacturing of electronic assemblies. As electronic product designs have moved to more densely packed PWBs with fine lines and spacing, double-sided surface-mount technology, fine-pitch components, ball grid arrays (BGAs), chip-scale packages (CSPs), stacked packages, etc., the role of the soldering flux has become a critical link in the chain of events required for a successful manufacturing process.

In the past, the soldering process was usually followed by a cleaning step to remove flux residues and to ensure the reliability of the assembly. This practice was challenged in the early 1990s by the elimination of a major class of cleaning materials, which had been used for flux residue removal. The targeted cleaning agents include chlorofluorocarbons (CFCs) and methyl chloroform (1,1,1—trichloroethane) that have been shown to destroy stratospheric ozone.<sup>1</sup> These were replaced by aqueous detergent cleaners and saponifying agents, and in some cases cleaning was eliminated by the use of low solids or no-clean fluxes.

Up to the mid-1970s, the predominant flux chemistry was rosin-based. Today, although rosin fluxes are still in use, great advances have been made in flux chemistries and a large variety of formulations with very different chemistries are being used.

The implementation by the European Parliament of Directive 2002/95/EC on the restriction of the use of certain hazardous substances (Restriction of Hazardous Substances [RoHS]) in electrical and electronic equipment, including lead in solder, has had significant

impact upon the manufacturing process. Traditional tin-lead solder melts at 183°C, whereas the most common lead-free alternatives have a much higher melting temperature, including tin-copper (227°C), tin-silver (221°C), and tin-silver-copper (217°C). This affects the substrate materials, the flux formulations, the cleaning materials and processes, among other things.

This chapter will review the assembly, soldering, and cleaning processes, briefly touch on choice of surface finishes for both printed boards and components, discuss the soldering flux in terms of its role in soldering, review the variety of flux chemistries available along with their advantages and disadvantages, and comment on the challenges for flux formulation and cleaning due to lead-free soldering temperatures.

## 43.2 ASSEMBLY PROCESS

---

The basic elements of an electronic assembly are the PWB, the components and the interconnecting metallization. The majority of PWBs are made of epoxy-glass substrate with copper or solder-coated copper metallization. In many cases, a solder mask covers most of the circuit traces, leaving exposed only those patterns where soldering will occur during assembly. Boards designed for through-hole components usually contain copper-plated through holes that may be solder-coated; those designed for surface-mount components will have metallized pads for interconnecting the surface-mount parts to form the assembly.

### 43.2.1 Assembly Process Issues

The assembly process for electronics includes wave soldering, reflow soldering, and vapor phase soldering as well as selective soldering. Components range from through-hole and surface-mount—BGA,  $\mu$ -BGA, CSP, and stacked packages—to chip-on-board (COB). The high density and reduced size of today's electronics has led to system-in-a-package (SIP), where the integrated circuit (IC) package contains several active devices, and system-on-a-chip (SOC), where all the functions of an electronic system are integrated on a single chip. These package types increase the complexity of the electronic assembly process, requiring adhesive attachment for bottom-side discretes, underfill for CSP, wirebonding and encapsulation for COB, and solder paste, paste flux, and liquid flux for various applications.

When manufacturing complex printed wiring assemblies (PWAs), the thermal process chosen must take into account the thermal mass of the assembly, the component density, the solder flux and solder paste characteristics, and the maximum temperature limitation of the components. Most of the components assembled to the board in the soldering process have a maximum temperature of 240°C for traditional Sn/Pb soldering. Some electronic components, such as electrolytic capacitors and plastic-encapsulated components, are not rated to experience the high temperatures required to process with lead-free solders. The resulting heat-induced degradation can result in early field failures. Also, the higher temperatures required for lead-free solders are not compatible with many optoelectronic components. The increased heat can cause a variety of conditions with these components, among them electrical variances, changes in silver-epoxy die attach properties, delamination between plastic and lead-frame parts, deformation of plastic encapsulants and plastic lenses, damage to lens coatings, and changes in the light transmission properties.

### 43.2.2 Assembly Temperature Profiles

IPC/JEDEC<sup>2</sup> has developed a recommended reflow profile for nonhermetic packaged semiconductor components. These recommendations are based on the temperature taken at the top side of the packaged device, and also based on package volume, excluding external leads,

or solder balls in the case of BGAs, and nonintegrated heat sinks. Table 43.1 lists the recommended range for Sn/Pb and Pb-free assemblies.

**TABLE 43.1** Reflow Profiles Recommended for Sn/Pb and Pb-free Assemblies Based on Temperatures Taken on the Package Body

Profile feature	Sn/Pb assemblies	Pb-Free assemblies
Average ramp-up rate	3°C/sec. max.	3°C/sec. max.
Preheat		
Temperature min.	100°C	150°C
Temperature max.	150°C	200°C
Time	60–120 sec.	60–180 sec.
Time maintained above melting Temperature	60–150 sec.	60–150 sec.
Time within 5°C of peak temperature ( $T_p$ )	10–30 sec.	20–40 sec.
Ramp-down rate	6°C/sec. max.	6°C/sec. max.
Time 25°C to $T_p$	6 min. max.	8 min. max.

The maximum recommended temperature for the package depends on the package thickness and volume. Table 43.2 lists the recommended reflow temperatures for Sn/Pb processing, whereas Table 43.3 lists the recommendations for Pb-free processing.

**TABLE 43.2** Recommended Maximum Package Reflow Temperatures for Sn/Pb Process

Package thickness	Volume <350 mm <sup>3</sup>	Volume ≥350 mm <sup>3</sup>
<2.5 mm	240 +0/-5°C	225 +0/-5°C
≥2.5 mm	225 +0/-5°C	225 +0/-5°C

**TABLE 43.3** Recommended Maximum Package Reflow Temperatures for Pb-Free Process

Package thickness	Volume <350 mm <sup>3</sup>	Volume 350–2,000 mm <sup>3</sup>	Volume >2,000 mm <sup>3</sup>
<1.6 mm	260 +0°C	260 +0°C	260 +0°C
1.6–2.5 mm	260 +0°C	250 +0°C	245 +0°C
≥2.5 mm	250 +0°C	245 +0°C	245 +0°C

### 43.3 SURFACE FINISHES

Surface finish is defined as the outerlayer metallization on a component or substrate being soldered. Both the type and quality of the surface finish have a major impact on surface solderability and on process soldering ability. Here, *solderability* is defined as the ability of the surface to be wetted by a solder, and the forming of an intermetallic layer between the solder

and the base metal. *Soldering ability* is defined as control of the soldering process parameters, such as a heating profile that produces that wetting action. The preference is always to have a surface that exhibits good solderability—that is, ease of wetting and formation of high-quality solder interconnections—for all soldering processes and materials to which it might be exposed. Soldering ability is best described as the quality of a solder process such that the operating window is wide, that is, the process is not overly sensitive to minor shifts in process parameters such as time and temperature. Thus a process with good soldering ability would be easy to control and would produce high-quality interconnections given that the incoming materials have good solderability.

### 43.3.1 Substrate Finishes

The substrate surfaces of choice are usually one of the following: electroless nickel/immersion gold (ENIG), immersion silver (ImAg), and organic solderability preservative (OSP). Two other finishes, hot air solder leveling (HASL) and immersion tin, are also in use, but HASL has declined in volume and immersion tin has not reached significant volumes due to concerns over reliability.

- **ENIG** This finish is widely used because it provides a very flat surface for surface-mount component placement. It has good solderability and a long storage life but is somewhat expensive compared to other finishes. Careful control of the gold plating process during board fabrication is required to prevent a defect known as black-pad. Black-pad is caused by galvanic corrosion of the nickel layer, creating corrosion products that affect the ability of the surface to be wet with solder. If severe enough, black-pad will impact reliability of the final solder joint.
- **ImAg** Immersion silver provides a flat surface with good solderability and storage life. It is also less expensive than ENIG. However, the ImAg finish is prone to tarnish under certain atmospheric conditions; in the presence of sulfur, it forms sulfides that darken the surface and reduce solderability.
- **OSP** Organic solder preservatives are inexpensive and also provide a flat surface for surface-mount technology (SMT) placement. Storage life for OSP is less than for the metallized finishes, and multiple thermal cycles cause it to degrade.
- **HASL** One of the oldest surface finishes, HASL is based on exposing the PWB to molten solder and then removing excess solder using hot-air knives. In the lead-free world, the processing temperature is higher than for tin-lead. HASL is inexpensive, has good solderability if the solder is sufficiently thick, but has the disadvantage of not being a flat surface.
- **ImSn** This finish is similar to immersion silver in most characteristics. However, because tin tends to form metallic whiskers that can cause electrical shorts, it is not widely used.

### 43.3.2 Component Surface Finishes

Component surface finishes, like those of substrate finishes, are intended to provide good solderability. In the past, the majority of component leads had a tin-lead solder finish. This finish was either plated on the base metal of the component or was applied by dipping the leads in liquid metal. Given the push for lead-free assembly, most of these finishes containing lead are being replaced by alternatives. The main contenders in replacement of lead containing finishes are based on noble metals (e.g., palladium or gold) or some form of tin plating. Palladium finishes have been in use for many years and are a known commodity. However, as noted previously, the tendency of tin to form metallic whiskers as a result of stresses in the plated layer is a matter of serious concern for the electronics industry.

## 43.4 SOLDERING FLUX

---

Soldering<sup>3</sup> is defined as the process of joining metallic surfaces with solder without melting the basis metal. For this joining to take place, the metal surfaces must be clean of contamination and oxidation. This cleaning action is performed by the flux,<sup>2</sup> a chemically active compound that, when heated, removes minor surface oxidation, minimizes oxidation of the basis metal, and promotes the formation of an intermetallic layer between solder and basis metal. The soldering flux has several functions to perform. It must:

- React with or remove oxide and other contamination on the surface to be soldered
- Dissolve the metal salts formed during the reaction with the metal oxides
- Protect the surface from reoxidation before soldering occurs
- Provide a thermal blanket to spread the heat evenly during soldering
- Reduce the interfacial surface tension between the solder and the substrate in order to enhance wetting

To perform these functions, soldering flux formulations contain the following types of ingredients: vehicle, solvent, activators, and other additives.

### 43.4.1 Vehicle

The vehicle is a solid or nonvolatile liquid that coats the surface to be soldered, dissolves the metal salts formed in the reaction of the activators with the surface metal oxides, and, ideally, provides a heat transfer medium between the solder and the components or PWB substrate. Rosin, resins, glycols, polyglycols, polyglycol surfactants, polyethers, and glycerine are among the major chemicals used. Rosin or resins are selected when more benign chemicals are required since their residues are less apt to cause reliability failures. Glycols, polyglycols, polyglycol surfactants, polyethers, and glycerine are used in water-soluble flux formulations because they provide excellent wetting of the board surface and dissolve the more active materials used in these formulation.

### 43.4.2 Solvent

The solvent serves to dissolve the vehicle, activators, and other additives. It evaporates during the preheat and soldering process. The solvent chosen depends upon its ability to dissolve the flux constituents for a given formulation. Alcohols, glycols, glycol esters, glycol ethers, and water are common solvents used.

### 43.4.3 Activators

Activators are present in the flux formulation to enhance the removal of metal oxide from the surfaces to be soldered. They may be reactive at room temperature, but their activity is enhanced as the temperature is raised during the preheat step of the soldering process. Among the common activators found in flux formulations for traditional soldering fluxes are amine hydrochlorides; dicarboxylic acids, such as adipic or succinic; and organic acids such as citric, malic, or abietic. Higher molecular weight activators are needed for lead-free soldering. Activators containing halide and amine give excellent soldering yields but may cause reliability problems if not properly removed in a well-controlled cleaning step. The halides may be present in either ionic or non-ionic form depending on the level of activation desired. Ionic activators provide, in general, a higher level of activation for a given halide content.

#### 43.4.4 Other Additives

Soldering fluxes often contain small amounts of other ingredients that serve a specialized function. For example, a surfactant may be added to enhance the wetting properties. This constituent can also assist in the foaming characteristics required for foam flux application. Other additives may be included to lower the interfacial surface tension between the molten solder and the PWB as it exits the solder wave, decreasing the chance for solder bridges to form. Solder paste formulations require the presence of additives to provide good viscosity or flow characteristics, low slump during the preheat step, and good tack characteristics for holding the component in place until reflow occurs. Finally, cored-wire flux used for hand-soldering contains a plasticizer to harden the flux ingredients that are present in the core of the wire.

#### 43.4.5 Flux and Temperature Issues

The flux becomes active as it is heated. In traditional flux chemistry for Sn/Pb solder, the assembly is preheated to around 100 to 125°C to remove the solvent and begin to activate the chemicals used to remove the metal oxide. After this plateau, the temperature is increased above the melting point of the solder (183°C) to 240°C for sufficient time to reflow the solder paste, and then the assembly is cooled, solidifying the solder and creating a metallurgical bond between the board metallization and the components. For lead-free soldering, the preheat plateau temperature is higher—150 to 200°C—and the peak temperature is 245 to 260°C. This requires solvents that evaporate at a higher temperature and activators that become chemically active at a higher temperature. In addition, new activators are needed to address the new metallurgy on board surfaces and new lead-free solders containing Ag, Cu, and much higher levels of Sn. The decrease in pitch for area-array packages has resulted in a need for finer solder powders. This is driving a change in paste flux chemistry since the higher surface area of these fine powders results in increased oxide formation and decreased paste stability.

### 43.5 FLUX FORM VERSUS SOLDERING PROCESS

---

Although one usually thinks of soldering flux as a liquid, in fact the soldering flux can exist in several different forms. *Liquid flux* is commonly used for wave-soldering or hand-soldering applications. *Paste flux*, a thick, viscous flux, is used to hold components to the board prior to reflow of the already present solder. Direct attachment of a solder-bumped chip or BGA packages to solder pads on a PWB is an example of paste flux's usefulness. Also known as *tacky soldering fluxes*, these materials are useful in repair of area-array devices. Solder paste contains *solder paste flux*, which is the solder paste without the solder particles. Solder paste is used in surface-mount attachment of components such as chip carriers, quad flat packs (QFPs), BGAs,  $\mu$ -BGAs, CSPs, leaded packages, and discrete resistors and capacitors. *Flux-cored solder wire* is used for hand-soldering, and *flux-coated or flux-cored solder preforms* are used as the solder/flux source in some applications such as backplane connector pin reflow soldering.

*Fluxing underfills* can also be considered as a new type of flux material. Many fine-pitch, low-profile array packages suffer from poor reliability due to their low standoff from the substrate, small area of solder interconnection and CTE mismatch with the substrate. Often, a reinforcing material is dispensed around the solder joints after assembly to improve attachment reliability. Fluxing underfills provide fluxing action for the solder process and cure into a hard supporting material during the soldering process, eliminating the need for a post-solder dispensing step.

### 43.6 ROSIN FLUX

Early flux formulations for electronics used rosin, which is a naturally occurring resin, obtained from the sap of a pine tree. Its exact composition varies depending on the part of the world from which it originates as well as the time of the year. Rosin contains a mixture of resin acids, the two most common ones being abietic acid and pimaric acid (see Fig. 43.1). Rosin has been a favorite material for soldering because it liquefies during the soldering process, dissolves the metal salts, and then solidifies when cooled, entrapping and for the most part immobilizing the contaminants. In addition, rosin has some innate fluxing activity since its molecular structure contains a weak organic acid. Finally, rosin-based fluxes work well in hand-soldering and repair operations because rosin provides good heat transfer characteristics.

The activity of a rosin-based flux will be determined by the activators and surfactants, which are part of the formulation. Some activators help to remove metal oxide but also leave residues that are essentially noncorrosive. Halide-containing activators leave residues that could be corrosive if too much is left on the board.

Military specifications<sup>4</sup> in the past have required the use of rosin-based fluxes. These were defined as pure rosin (R), rosin mildly activated (RMA), rosin activated (RA), and rosin super-activated (RSA), based upon the level of halide activators they contained. Typically only R or RMA fluxes were approved for high-reliability military applications.

In the 1970s, telecommunication companies in the United States and Europe predominantly used rosin fluxes for their wave-soldering requirements. These companies had their own internal set of test methods for selecting noncorrosive rosin flux formulations. Using their selection criteria, they believed the fluxes to be sufficiently safe. For their applications, they cleaned only the bottom side of the assembly, where rosin residues needed to be removed to ensure good electrical contact during bed-of-nails testing.

In the early 1980s, the IPC developed a flux characterization criteria based on the flux and flux residue activity. Thus, fluxes were classified as:

- L = low or no flux/flux residue activity
- M = moderate flux/flux residue activity
- H = high flux/flux residue activity

These designators were determined by a series of tests, including the copper mirror test, a qualitative silver chromate paper test for chlorides and bromides, a qualitative spot test for fluorides, a quantitative test for halides (chloride, bromide, and fluoride), a corrosion test for flux residue activity, and a surface insulation resistance test at accelerated temperature and humidity conditions.

The industry standard "Requirements for Soldering Fluxes" (J-STD-004A) includes a test for electrochemical migration and updates the earlier IPC-SF-818 solder flux specification to include some international elements from the International Standards Organization (ISO-9454). In addition to defining the flux categories L, M, and H, it notes the absence or presence of halides by a 0 or 1 that is added to the descriptor. In parallel the international standards, industry standards list the basic chemical constituents as RO (rosin), RE (resin), OR (organic), or IN (inorganic) (see Table 43.4).<sup>5</sup> The test methods for this specification are contained in the Test Methods Document (IPC-TM-650).<sup>6</sup>

**FIGURE 43.1** The two most common rosin isomers are abietic acid and pimaric acid.

**TABLE 43.4** Flux Constituents and Activity Levels

Flux materials of composition	Symbol	Flux activity level (% Halide)	Flux type
Rosin	RO	Low (0%)	L0
		Low (<0.5%)	L1
		Moderate (0%)	M0
		Moderate (0.5–2.0%)	M1
		High (0%)	H0
Resin	RE	High (>2.0%)	H1
		Low (0%)	L0
		Low (<0.5%)	L1
		Moderate (0%)	M0
		Moderate (0.5–2.0%)	M1
Organic	OR	High (0%)	H0
		High (>2.0%)	H1
		Low (0%)	L0
		Low (<0.5%)	L1
		Moderate (0%)	M0
Inorganic	IN	Moderate (0.5–2.0%)	M1
		High (0%)	H0
		High (>2.0%)	H1
		Low (0%)	L0
		Low (<0.5%)	L1
		Moderate (0%)	M0
		Moderate (0.5–2.0%)	M1
		High (0%)	H0
		High (>2.0%)	H1

### 43.7 WATER-SOLUBLE FLUX

Water-soluble fluxes have also been called “organic acid fluxes.” This name is misleading since all fluxes used for electronic soldering contain organic ingredients and many contain organic acid activators. The term “organic acid flux” probably originated from the designation of water-soluble fluxes as “organic” and those activated with organic acid activators as “organic acid.” Other activators for these fluxes include halide-containing salts and amines. Although the correct name for this category of fluxes is *water-soluble*, it should also be noted that the flux solvent is normally not water, but alcohols or glycols.

As the name implies, water-soluble fluxes are soluble in water and their soldering residues are also expected to be water-soluble. These fluxes are much more active than rosin fluxes, have a wider process window, and give a higher soldering yield with reduced defects. This means that the final assembly will require less touchup or repair. On the down side, water-soluble fluxes contain corrosive residues that, if not properly removed, will cause corrosion in the field and long-term reliability problems.

As indicated earlier, water-soluble fluxes usually contain glycols, polyglycols, polyglycol surfactants, polyethylene oxide, glycerine, or other water-soluble organic compounds as the primary vehicle. These provide good solubility for the activators, which are usually the more corrosive amines and halide activators. With the onset of highly efficient cleaning equipment, this type of flux became popular for computer and telecommunication applications.

F. M. Zado<sup>7</sup> raised concern in the late 1970s that water-soluble fluxes affect the electrical characteristics of the epoxy-glass laminate by reducing the insulation resistance. This reduction

was due to the dissolution of the polyglycols of the flux formulation into the epoxy substrate during the soldering process. Later work by J. Brous<sup>8</sup> indicated that some polyglycols were much more deleterious than others. In general, polyglycol containing fluxes (and fusing fluids used by board manufacturers to fuse tin-lead plating) can cause an increase in moisture absorbance of the epoxy-glass substrate.

The user must consider several factors when determining whether to use water-soluble fluxes in a given application. One important factor is the operating environment. If the assembly will experience extremes of temperature while under power, it is possible that localized condensation will occur and dendrites will form, shorting out some of the circuit elements. Assemblies of this nature should be conformally coated. A second critical factor is the use of a board design and cleaning process, which ensures that corrosive residues are removed. A third consideration is the voltage gradient in the electrical design of the circuit. Within reduced lines and spacings, a failure mechanism called conductive anodic filament (CAF)<sup>9</sup> formation has been associated with high humidity and high voltage gradients. This will be described in detail in a later chapter.

### 43.8 LOW SOLIDS FLUX

---

Until the mid-1980s, liquid soldering fluxes were formulated in 25 to 35 percent (weight percent) solids or nonvolatile liquid. Then flux chemistries changed and new formulations that were lower in total solids content came on the scene. These fluxes are composed principally of weak organic acids, often with a small amount of resin or rosin. Early formulations had 5 to 8 percent solids, but today's low solids fluxes are 1 to 2 percent solids composition. For lead-free soldering, weak organic acids with higher molecular weight are being used.

Nomenclature of these fluxes moved from "low solids flux" to "low residue flux" to "no-clean flux." The thinking was that the amount of residue left by these fluxes after soldering was so minimal that it did not need to be removed. This is only true if the residues are noncorrosive.

One challenge of low solids fluxes is the processing window. Unlike water-soluble fluxes that give very low defect levels and have a wide processing window, the soldering process for low solids fluxes must be carefully designed. To begin with, the recommended preheat temperatures are different from those for rosin flux and the preferred solder wave temperature is lower than that for rosin. Additionally, the solderability of incoming boards and components must be ensured. Although water-soluble flux can cut through heavy metal oxide layers, the amount of fluxing ingredients in low solids fluxes is not sufficient to accomplish the task.

Lower cost manufacturing can be achieved with low residue fluxes if the cleaning step can be eliminated. This assumes that the incoming components and boards are clean, and that operators handling the boards are careful not to introduce contamination. This requires a flux with noncorrosive residues that will not impede or contaminate the electrical bed-of-nails test probes.

A new category of low solids fluxes was introduced in the early 1990s to meet the needs of localities where volatile organic compounds (VOCs) are regulated. These fluxes are marketed as VOC-free or low-VOC fluxes. The solvent in this case is 100 percent water or at least greater than 50 percent water. Use of these fluxes requires special care in the preheat step where the water (solvent) must evaporate before the assembly reaches the solder wave. Failure to do this will result in excessive solder ball formation.

Solder fluxes and pastes have gone through significant evolution since the early 1980s. As of 2006, in North America about 70 percent of the fluxes were not cleaned, 25 percent were water-soluble, and 5 percent were rosin-based for military applications.<sup>10</sup> However, in the lead-free soldering world, more cleaning is required.

## 43.9 CLEANING ISSUES

---

Flux removal is motivated by several factors, and the importance of these factors varies with the end use of the product. In general, the purpose of cleaning is (1) to remove corrosive residues from the soldering process or handling operations (some fluxes have high levels of halide activators that would cause corrosion were they not removed); (2) to remove rosin, resin, or other insulating residues that would interfere with bed-of-nails electrical testing; (3) to remove rosin, resin, or other residues that attract dust, dirt, and other airborne contaminants; (4) to ensure that the board is free of residues and contamination prior to conformal coating.

In the early days of soldering, cleaning was either not done, because the flux was mostly rosin and noncorrosive (e.g., the telecom fluxes), or cleaning of rosin flux residue was done with solvents. Typically the solvent was a halogenated material, as such solvents were considered relatively nontoxic and were nonflammable. However, in the late 1970s, the Environment Protection Agency (EPA) listed some of these solvents, such as perchloroethylene and trichloroethylene, as suspected carcinogens and lowered the allowed level of these in the operator-breathing zone. This led to the application of CFC azeotropes with methyl alcohol, ethyl alcohol, and methylene chloride as replacements.

However, the CFCs were not without their own environmental problems. In September 1987 at the United Nations Environment Program Conference in Montreal, 24 countries signed the Montreal Protocol on Substances that Deplete the Ozone Layer. The protocol was the beginning of an international agreement on the reduction of CFCs that were shown to have a deleterious effect on the stratospheric ozone layer that protects us from harmful ultraviolet radiation. The initial protocol targeted CFCs and halons (bromine-containing CFCs) and proposed a 50 percent reduction in production by 1998 based on 1986 levels. Revisions to the protocol led to a ban on the manufacture of CFCs and other ozone-depleting chemicals effective by the end of 1995.

### 43.9.1 Solvent Cleaning

With the general elimination of the halogenated solvents, manufacturers have changed their flux and cleaning choices. The new cleaning materials must be capable of dissolving the particular chemical residues from a given flux formulation. Several detailed cleaning references are available.<sup>11, 12, 13, 14, 15, 16</sup>

Solvent cleaning options<sup>17</sup> have focused on semiaqueous cleaning, solvent defluxing using a blend of solvents, and vapor degreasing using a single or co-solvent mix. Semiaqueous cleaning usually involves a two-step process where the assembly is first cleaned in the organic solvent, then rinsed in a separate step. Terpenes have been widely used as the solvent with dibasic esters and non-ionic surfactants added to improve cleaning and rinsing. An alternative semiaqueous cleaning solvent is composed of high molecular alcohols. The solvent is usually sprayed under immersion onto the assemblies in its pure form. This step is followed by a rinse step that emulsifies the semiaqueous solvent and dissolves the ionic residues. Innovations<sup>18</sup> have shown that an aqueous emulsified solution of the solvent can also provide good cleaning.

Solvent cleaners may be inline or batch. Inline cleaning usually involves spray under immersion. The temperature of the solvent wash tank is set below its flash point, and several rinse tanks follow the wash tank to ensure good cleaning before the final drying step. Solvents such as glycol-ether blends are used for this process. Batch degreasers may use n-propyl bromide in specialized applications.

Traditional batch cleaning was performed in a vapor degreaser that has a wash sump of boiling nonflammable azeotropic solvent and a rinse sump. A vapor blanket forms above the sump and is contained using cooling coils at the mouth of the machine. The assembly is first placed into the wash sump, and then is transferred to a rinse sump that contains clean solvent from the condensation at the cooling coils. As the assembly is removed, it is held for a period in the vapor blanket for a final rinse and drying of the remaining solvent.

Co-solvent cleaning involves the use of a rinsing agent that is volatile and a solvating agent that is not volatile. The assembly is placed into the wash tank of boiling solvent where the solvating agent enhances the cleaning process. The vapor blanket above the wash sump contains only the rinsing agent. The assembly is moved from the wash sump into the rinse sump, which contains only the condensed rinsing agent. Finally, the assembly is removed from the rinse sump and held in the vapor blanket for a final rinse and drying step.

### 43.9.2 Aqueous Cleaning

Aqueous defluxing is performed using a high pH saponifying solution that is diluted to a 10 to 25 percent aqueous solution. The saponifier may be organic or inorganic, with additives such as solvents and surfactants to improve wetting and cleaning. The organic cleaning agent usually contains an amine, such as monoethanol amine, whereas the inorganic cleaners use buffered metal salts such as NaOH/sodium carbonate/sodium bicarbonate. The wash step is usually done in an inline spray machine, followed by a de-ionized (DI) water rinse with several spray sections to remove the more contaminated material, then by a final rinse and a final blow-dry step. The cleaning agents in the saponifier react with the rosin or resin from the flux to form a “soap” in the same manner that the detergent used to wash greasy dishes reacts with the grease and helps it dissolve, or at least be emulsified and removed in the rinse water. Once the rosin or resin is removed, the rinse water solubilizes the ionic residues that were on the surface of the board as well as those trapped within the solid rosin matrix.

Table 43.5 summarizes the possible cleaning agents for the various flux types.

**TABLE 43.5** Soldering Flux/Paste Cleaning Options

Flux/paste type	Possible cleaning agents	Comments
1. Rosin/resin	a. Detergent cleaning b. Semiaqueous cleaning c. Solvent cleaning	
2. Low-residue flux	a. No-cleaning step b. Aqueous cleaning c. Detergent d. Solvent	If flux is rated L0 or L1 in ANSI-J-Std-004 If flux does not contain rosin or resin If flux contains rosin or resin
3. Water-soluble	a. Water b. Detergent cleaning	

### 43.9.3 Flux and Cleaning Issues Related to Lead-Free Soldering

Solder flux residues are much more difficult to clean after lead-free soldering.<sup>19,20,21</sup> Fluxes formulated to remove oxidized metals (SnPb, Cu) for traditional tin-lead soldering must be modified to address the needs of different metallization for the solder, the board finish, and component terminations. Soldering flux formulations for lead-free soldering use higher molecular weight resins and activators for the more aggressive flux chemistry needed to achieve wetting. Also, the higher tin content of the alternative solders (SnAgCu, SnCu) requires more aggressive flux chemistries for good wetting.

The process window for lead-free soldering requires higher peak reflow temperatures and longer times above liquidus. Soldering in a nitrogen environment improves wetting and reduces oxidation of the flux residues and the solder. Due to the higher reflow temperature,

greater polymerization of the flux constituents can occur—producing residues that are more difficult to remove.

The cleaning challenge represented by lead-free soldering must be addressed by modifying the cleaning process to increase the wash time, wash concentration, and wash temperature.

Cleaning for fine-pitch components soldered under lead-free conditions requires an increase in cleaning time, the use of increased solution agitation (e.g., ultrasonic), and the modification of spray nozzles and impingement angle. Flux residues are more difficult to remove when they set. Thus, it is important to minimize the time between reflow and cleaning. Aqueous cleaning chemistries should include wetting agents, solvating agents, and reactive agents. Water-soluble fluxes that can be cleaned with water after lead-based soldering conditions may require the addition of some cleaning agent to remove the higher molecular weight organic acids and the tin salts created when the flux decomposes during lead-free reflow.

### 43.10 SUMMARY

---

This chapter has reviewed the processing issues and materials used for the soldering and cleaning processes. In the lead-free era, thermal profiles and component maximum temperatures require different reflow profiles. The various types of soldering fluxes, their constituents, and their role in the soldering process have been discussed and the formulation changes required for the higher temperature soldering examined. Cleaning materials and processes have been identified and the challenges with higher temperature soldering discussed.

## 44.1 INTRODUCTION

---

Soldering is a technology that has been used extensively for utilitarian and decorative purposes for thousands of years. In the last 100 years, soldering has been raised from art to science for joining electrical assemblies. By the late twentieth century, the tin-lead solder joint and properties of its constituent materials had been studied well enough that it could be modeled for purposes of predicting reliability.

Circuit board soldering has traditionally been accomplished with eutectic or near eutectic tin-lead (Sn-Pb). The eutectic alloy is approximately 63 percent Sn and 37 percent Pb by weight and is the mainstay of printed circuit board assembly. A binary alloy (composed of two constituent metals), its melting and solidification are well understood and predictable. Being a eutectic alloy, it has a distinct melting point of 183°C. This temperature is low enough that it is compatible with a significant set of materials such as circuit board laminates, integrated circuit (IC) package encapsulants, ceramics used for packaging, silicon devices, molded connector bodies, etc. Materials for these components were in part codeveloped for use with Sn-Pb solder for joining. Now the electronics industry is faced with tremendous change spurred mainly by the European Union's (EU) environmental initiatives to limit electronics waste and restrict toxic materials used in electronic manufacturing. The main thrust of the legislation is to limit or ban a short list of materials that the EU deems harmful to the environment. Lead (Pb) is most prominent on the list of restricted materials, and limitations on its use have the biggest impact to electronics manufacturing. Now the industry is forced to adopt Pb-free solder alloys. Most viable Pb-free alloys have a higher melting temperature than Sn-Pb solder. Most Pb-free alloys are composed of three or more metals.

All of this comes at a time when circuit board component density, layer count, and performance are higher than ever before. The complexity of printed circuit assemblies continues to increase in every sector of the electronics industry. The number of solderable contacts of IC components is on the rise as circuit board components both miniaturize and increase in body size due to ever-increasing input/output (I/O) count. Through-hole technology, although on the wane, is still prevalent. Motherboards for personal computers are more powerful than computer room servers that are only a few years older. Consumer electronics are highly sophisticated and internally complex. Mobile telephones are multifunctional incorporating still- and video-cameras, personal digital assistants (PDAs), wireless Internet, and localized wireless connection to user devices such as hands-free devices, all in smaller and smaller packages. Portable music systems such as MP3 and MP4 players have more memory than many

personal computers (PCs) in use today. They must be built small enough to fit in a pocket and be shock-resistant.

The ever-increasing demand for product performance drives increases in component density, the number of I/Os, increased board layers, and finer printed wiring board conductor trace spacing in order to make electrical routing possible. Higher density boards and higher layer counts result in more thermally massive assemblies, which are more difficult to solder during surface mounting and doubly difficult to assemble during wave soldering. When both surface mounting and wave soldering are used on the same assembly, it is referred to as *mixed-mount technology*. The proliferation of press-fit connections (force fitting compliant electrical contacts into a circuit board's plated through-holes) has alleviated some of the problems of mixed-mount assembly and has been driven largely by the difficulties faced in wave soldering large and thick circuit boards. See Chap. 49 in this book for an introduction to press-fit technology. Land grid arrays (LGAs) with separable pressure interconnect has become more prevalent especially for high-end motherboards for computing and telecommunications. LGA incorporation on a board has influence on layout and implications for soldering. This will be discussed in Chap. 50.

In the fifth edition of this handbook, there was a separate chapter on Pb-free soldering. Since Pb-free is now the primary focus of electronics manufacturing, its impact has been incorporated into the text of this chapter, which previously concentrated only on Sn-Pb soldering. The reader should understand that Sn-Pb soldering is still important, as many types of electronic assemblies will still be manufactured with lead-based solders until the year 2010 as per the new EU Restriction of Hazardous Substances (RoHS) legislation. Also, there may be problems associated with mixing Pb-free solders with leaded (Pb'd) packages and Pb-free packages with Pb'd solder. Since the latest EU legislative initiatives have profound effects on every aspect of electronics manufacturing, it is necessary to understand the impacts before delving into the technology of soldering.

---

## 44.2 ELEMENTS OF A SOLDER JOINT

---

There are three important constituents of a solder joint: the two materials or surfaces to be joined and the solder itself. Each has its own set of attributes and variables that contribute to the ease and quality of soldering. A delicate balance of material conditions and process parameters determine the solder joint appearance, resultant strength, and reliability of the soldered assembly. The composition of the solder, the surface finish on lead, pad or plated through-hole (PTH), environmental factors, chemical implications, and thermal conditions all impact the soldering process. Each will be discussed.

---

## 44.3 COMMON METAL-JOINING METHODS

---

Welding, brazing, and soldering are the three most widely used metal-joining techniques. Although this section does not provide a rigorous review of welding and brazing, a cursory comparison of these metal-joining processes is useful in setting the stage for an in-depth discussion of circuit board soldering.

Welding involves heating of two similar or dissimilar abutting metals to the point that they fuse into one another. Unlike brazing and soldering, there is considerable depth to the metallurgical changes at their interface that take place in the metals being joined during welding. Sometimes a filler metal is applied to lower the melting temperature of the weldment metals or for desired mechanical properties of the finished bond. As in brazing and soldering, sometimes chemical treatment is required to help dissolve surface oxides and also a cover gas may be applied to retard oxidation during the high temperatures of the bonding process.

There are three distinguishing characteristics that differentiate welding from brazing and soldering: the temperature of the bonding process, the depth of material dissolution from the bonding surfaces, and the reliance on surficial wetting and spreading of the filler material.

Brazing and soldering involve the use of a filler metal (brazing compound or solder), which has a significantly lower melting point than the basis metals associated with the two bonding surfaces. The filler material must be able to alloy with the surfaces to be joined. As the filler is heated to liquidus, there is near-surface metallurgical dissolution and mixing (alloy formation) with the contacted bonding surfaces. Continued heating above the liquidus temperature of the filler metal results in its further spreading and alloying via molten metal surface tension effects. As the bonding surfaces are cooled, the filler metal returns to solidus and a bonded assembly results.

There are only subtle differences between soldering and brazing, the primary distinction being the temperature required for joint formation. Brazing is generally accomplished at a relatively high temperature (>450°C) as compared to soldering. (There is no consensus in the literature, but values between 400°C and 500°C are commonly cited.) Brazing temperatures would be detrimental to most electronic components and PWBs. Since circuit board assembly is done almost exclusively by means of soldering at temperatures generally below 260°C, this chapter is devoted to that traditional joining method.

#### 44.4 SOLDER OVERVIEW

---

Solder is the cement that joins lead to pad, imparts the mechanical robustness required for a reliable assembly, and also possesses the electrical conduction needed for circuitry. Generally composed of an alloy of metals, it is chosen to melt at a temperature compatible with other materials associated with the soldered assembly. Once molten, the solder must wet the component lead and bond pad. Upon solidification, the resultant solder joint must provide bond strength to survive differences in thermal expansion rates of the associated component assembly. There must be compatibility of the solder alloy and related materials to requirements for assembly and service at elevated operating temperatures as well as resistance to mechanical shock and vibration.

Since the start of electronics, Sn-Pb has been the dominant solder alloy choice. Its eutectic alloy possesses a relatively modest liquidus temperature (183°C) and a working range typically about 205 to 230°C. This overage in temperature by about 20 to 50°C is applied to ensure that all parts have achieved a temperature commensurate with good solder wetting. It also may be necessary to reach such temperatures on thermally massive boards where the lightest parts may heat quickly while the most thermally aggressive parts may just barely achieve a temperature adequate for good solder wetting. Everything in the electronics industry has been tailored to working in that temperature regime. ICs and passive components, laminates, and process equipment associated with soldering have been qualified for use at those temperatures.

Now, due to the EU's RoHS directive and similar legislation elsewhere in the world, Sn-Pb is being phased out from mainstream electronics manufacturing. Only a small fraction of printed circuit assemblies (PCAs) will remain as Pb'd solder assemblies as permitted by RoHS exclusions and exempted military applications. As time progresses, it will become increasingly difficult to source Pb-bearing parts for use with RoHS Pb-exempt circuitry.

There are no drop-in replacement solders for Sn-Pb. Although there are many candidates, the most widely considered alloys require higher process temperatures and necessitate changes to components, circuit board laminates, and even process equipment.

#### 44.5 SOLDERING BASICS

---

Although these chapters will give great emphasis to Pb-free solders and soldering, it is best to demonstrate soldering process dynamics with Sn-Pb solder, for a couple of important reasons: first, it is our best understood metallurgical system, and second, it is a binary alloy with predictable bonding attributes. It will benefit the reader first to have a good understanding of this

relatively simple alloy system. The case presented will be based upon eutectic Sn-Pb solder (63 wt percent Sn and 37 percent Pb) in contact with solderable and non-solderable coatings on a basis metal.

Primary soldering steps include:

- Intimate contact of the solder to materials being joined
- Slow application of heat to warm the parts to be soldered
- Oxide removal from the joining surfaces and solder metallurgies
- Application of heat sufficient to melt the solder
- Solder wetting to joining surfaces and intermetallic formation
- Quenching of the solder liquidus

There are a few other materials that need to be covered for this discussion. The first is solder paste. This is a mixture of minute solder beads, flux, and other materials to give it specific rheological characteristics for dispensing and chemical agents for metal surface preparation. For surface-mount applications, it is typically stenciled onto PWB bonding pads, and then the electronic component is placed upon the solder paste deposit. The paste holds the component in place during the reflow process. The second is flux, which, as mentioned previously, is a key component of solder paste. The flux is a heat-activated chemical agent used to clean solderable surfaces. Both paste and flux will be covered in subsequent sections of this chapter.

#### **44.5.1 Intimate Contact of Solder to Surfaces to Be Joined**

This is the most basic of requirements. The solder has to be in contact with the materials to be joined. The contact area of the solder is not wholly important as long as the solder is in point contact with the surface to be soldered when it reaches liquidus. Surface tension effects and metallurgical wetting will complete the spreading of solder contact.

#### **44.5.2 Slow Heating of Boards and Parts to Be Soldered**

This is important for three main reasons. First, overly rapid heating can cause certain parts to experience thermal shock and subsequent failure as in cracking or may cause degradation of device electrical characteristics. Second, solder paste may spatter if heated too rapidly. Last, appropriate heating rate is crucial to good surface preparation through fluxing. Balance between time and temperature has to be determined so that the flux has enough time to accomplish its cleaning step and does not dry out prematurely or spatter. Prolonged heating cycles can also cause re-oxidation of flux cleaned parts. The following subsection covers fluxing more thoroughly.

#### **44.5.3 Oxide Removal from Bonding Surfaces and from Solder**

Most materials, when in equilibrium with our oxygen-rich environment, develop an oxide coating. Upon heating, solder surfaces as well as the bonding surfaces will more thoroughly oxidize in a normal air environment. If a silver-bearing surface is exposed to a sulfur-containing ambient (sulfur-tainted air), sulfidation occurs and that tarnish also inhibits soldering. Generally, the higher the storage temperature, the more oxidation is present unless oxide growth is self-limiting, as it is in some materials. The same holds true for soldering process temperature or process time. The longer and hotter, the more oxidation or tarnish is a problem if there is no flux or if the process renders the flux ineffective such as by overheating.

Oxides and tarnishes act as a physical barrier preventing alloy formation between the solder and the metal to be soldered. In the case of gold (Au), known to remain largely oxide-free, there is insufficient oxidation to degrade soldering. But unless oxidation is removed from the solder itself, solder alloying with the Au may not be possible or will be incomplete. Note that in most soldering processes, the ambient can be altered to mitigate the detrimental effects of oxygen or other airborne contaminants. This will be discussed later.

The most generally applied remedy for the effects of oxidation and tarnish as relates to the soldering process is the application of a chemical agent, flux. It is formulated to react with specific metallurgies and removes tarnish and oxidation. It also acts as a barrier preventing fluxed metal surfaces from re-oxidizing prior to and during the joining process. The word *flux* comes from the Latin *fluxus*, which means flow or flowing. Flux ensures that the solder, once molten, will flow over the surfaces to be bonded, unconstrained by oxide skins on the solder or the metals to be joined. Certain materials form oxides very rapidly, and some oxides are rather chemical-resistant. Nickel is one such element. Copper, like nickel, can also form resistant oxides and may necessitate the use of strong fluxing agents to achieve a bondable surface. Tin and silver oxides are easily attacked by even weak organic acids. Gold, which is known to remain oxide-free, can be applied as a thin, nonporous barrier over less noble, oxide-stripped metals such as nickel. During reflow, the gold dissolves quickly into the solder and the solder bonds to the underlying oxide-free nickel. Figure 44.1 shows the difference between a solder wettable surface and a flux-resistant oxide-coated surface.

#### Weakly Fluxed Sn/Ag/Cu Solder on Ni and Cu surface

**FIGURE 44.1** Comparison of soldering to copper (a) and nickel surface (b) with a weak organic solder flux. Note that in the case of the copper surface, the solder has wet and spread, characterized by a low wetting angle (the extent of wetting is indicated by the dashed outline). In the case of the nickel surface, the flux was ineffective in penetrating the oxide layer and solder was not able to wet to it. Instead, the solder beaded up on the surface of the nickel. (Courtesy of Hewlett-Packard.)

Several types of fluxes are available for soldering, but only two broad categories are in widespread use. The first is aqueous-clean, also known as water-clean flux. This is generally composed of relatively strong organic acids and may be fortified with halogens to increase its chemical activity. Aqueous-clean formulations are meant to be thoroughly washed from the surface printed circuit assembly after soldering. If left on the board, corrosion products will form and cause corrosion and electrical failure.

There are several electrical components that make aqueous-clean chemistry less attractive. These include dual inline package (DIP) switches, sealed switches (which are known to leak), high-density connectors, large area-array packages, micro-BGAs, and any other components with low headroom between the underside of the package and the surface of the PWB. It is for this reason, plus the opportunity to eliminate an expensive and vagarious process step (aqueous-cleaning) and associated equipment, that the vast majority of electronics manufacturers have widely embraced no-clean soldering fluxes.

The second is rosin-based, with additives to make it chemically active to varying degrees. Removal requires solvent, but it can be formulated so that the residue is inert and can remain on the board. This is termed no-clean flux.

#### 44.5.4 Heating to Liquidus

Once heated to melting, solder begins to form a metallurgical bond with contacted metals if wettable by dissolution and alloy formation. After the process starts, it progresses slowly, causing the solder to spread as it dissolves surfaces and alloys with it. The molten solder is drawn by surface tension to fill fine capillaries, and surface tension causes the solder to flow across wettable surfaces to some extent, forming webs of solder known as *fillets*. The solder fillet acts as a mechanical gusset imparting strength to the resultant solder joint.

#### 44.5.5 Solder Fillet Formation

The solder fillet is an overt manifestation of surface tension and wetting. Fillets are readily apparent in Fig. 44.2, which shows the fillet as a web of solder extending from the PWB bonding pad to the lead of the component.

Gull-wing leads rely on good heel fillets for solder joint strength. Toe fillets may be present or absent depending whether there is exposed copper or other oxidized or unsolderable exposed metal at the lead tip where the lead-frame was excised from its tooling strip. Toe fillets are of little importance, adding little strength to the soldered assembly. The bulk of the strength comes from the heel fillet and the solder wetted to the capillary between the bottom of the component lead and top of the bond pad. Similarly, side fillets may be present, but if the component lead width is on the order of the bond pad width, there may not be enough room to develop good side fillets. The wetting angle is also known as the *dihedral angle*. The lower the dihedral angle, the better the wetting.

For an example of a PTH solder fillet, see Fig. 44.2.

The fillet is a reasonable indicator of the degree of solder wetting and, therefore, of process goodness. It is generally believed that the higher solder fillet, the better the solder joint, but high fillets can be indicative of three problems: excessive overheating, which can result in brittle solder joints; excessive solder volume, and loss of component lead flexibility due to overly high fillet formation.

**FIGURE 44.2** Solder fillet formation: (a) Cross-section of an SMT solder joint; (b) a PTH solder joint in cross-section. In the case of the SMT solder joint, solder has wet to the pad and lead. The low wetting angles and good fillet formations are indications of good solder wetting. The PTH solder joint shows good fillet formation on the secondary side of the PWB. At the top, the primary side, the fillets are not as well formed, probably due to lower temperature at the top side of the board. (Courtesy of Hewlett-Packard.)

If too much solder wicks up the lead, it may cause solder shorting, particularly near the package body, where the lead spacing may be finest. Therefore, fillet examination alone is not sufficient to accurately assess soldering process performance. But, for a fixed set of process parameters, fillet appearance may provide a good means of first-pass comparative assessment of solderability and soldering results.

#### 44.5.6 Intermetallic Compound Formation

Intermetallic compound (IMC) formation is the key to soldering. IMC is the local alloying created at the boundary of the solder liquidus and the surfaces of the metal with which it is in contact. It is the essence of soldering. There is much misinformation about IMCs. One thing is certain: Without intermetallic formation, there is no solder joint. This is stressed because some erroneously claim lack of IMC in such processes as laser soldering. In the case of that technology, the IMC can be exceptionally thin immediately after soldering due to the short time of liquidus, but it is and must be present for soldering to occur. High temperature, time, and intimate contact of the liquid solder enhance the rate and volume of intermetallic compound formation.

The IMC is a crystalline intermediate alloy phase composed of some or all of the contacting metal constituents. This high-alloy concentration region generally has properties that are vastly different from those of either the solder or the contacted metals. It is a brittle material that is electrically conducting or even semiconducting. Solder is thought of as a soft, forgiving material of low melting-point and good electrical conductivity. It is ironic that the essence of soldering—the actual bond, or more correctly, the bond's anchor (IMC)—is in fact, a brittle, high melting-point composition of generally poor electrical conductivity.

#### 44.5.7 Cooling and Phase Change to Solidus

As the solder approaches its solidus temperature, the rate of intermetallic compound formation decreases significantly and the solder joint is formed. It is critical that the solder freezes prior to circuit board handling for two important reasons. First, accidental movement of the PWB may cause the components to move in the molten solder, which could result in defects such as solder joint opens (disbonds) or solder shorts (unwanted bridging of solder from one bond pad to the next). Second, a solder joint disturbance at the critical transition from liquid to solid may result in a bond of degraded reliability. This type of bond has an inherently grainy look and can even have microfractures within caused by motion-induced interruption of orderly crystal growth during solidification.

The cooling rate at the tail end of the process is as important as at the onset of heating. Extreme cooling rates may result in component cracking or electrical performance degradation induced by differential contraction of materials.

## 45.1 INTRODUCTION

---

Numerous considerations are crucial for successful circuit board assembly and useful product life. Assembly processes and materials that result in solder-joint formation can also have a profound effect on long-term solder-joint reliability as well as a product's environmental exposure and handling during its lifetime. Design and assembly engineers need to take into consideration temperature extremes and thermal excursion ramps that the product may endure as well as anticipated mechanical shock and vibration, the number of power (on-off) cycles expected over its lifetime, exposure to airborne particulates, gaseous pollutants, humidity, and handling. Such exposures may impact the printed circuit assembly (PCA) during soldering, when being handled on the factory floor, or while in the hands of the product's end user. These are but a sampling of variables that influence product reliability and should be considered in defining design and assembly attributes. PCA designs are most often driven by electronic device availability, electrical performance requirements, affordability, and the product's end-use environment and operating conditions.

This chapter will strictly avoid offering up generalized rules for all soldering process applications. The materials and requisite solder-joint reliability properties for a desktop computer are markedly different from those for the ignition system printed circuitry associated with the engine of a motor vehicle. Similarly, mobile electronics (mobile phones, laptop computers, PDAs, etc.) have the added requirements of mechanical shock-resistance as well as high-volume manufacturing needs, including low cost, ease of assembly, and high yields. In some cases, the cost to repair a PCA or an entire product may exceed the value of the combined material and labor content of the first-pass assembled product. It is also well understood that the reliability of a repaired assembly is not as good as a properly soldered first-pass printed circuit assembly due to additional board handling and solder-joint degradation as a result of re-soldering. The solder flux chemistry and how it is applied and heated may also impact product reliability. These points reinforce the need to understand PCA processes thoroughly and to solder properly the first time. There are fundamental rules that will become evident in discussions of metallurgies, fluxes, and processes. If these rules are heeded, the results are optimal soldering yield and the best reliability. However, the only way to know whether an assembly will endure its intended use and environment is to develop appropriate accelerated testing methods that can accurately gauge product field reliability.

It is incumbent on the PCA process engineer to understand the materials properties and phenomena that influence the soldering process and the reliability of the finished assembly. A basic understanding of mechanics, thermodynamics, metallurgy, and chemistry and how they apply to a finished solder joint is required for good PCA process engineering. The process engineer should influence product design for best manufacturability and reliability and also assemble boards with the highest reliability possible given the board design, materials variables (surface finishes, solder, solder flux, etc.), and components that comprise the bill-of-materials. Additionally, there are certain critical rules one could follow for incoming printed circuit board cleanliness, solder purity, etc. These are best described in standards documents, such as those published by the IPC.

There are also abundant pitfalls in soldering. Too much gold in tin-lead solder will cause solder-joint embrittlement. Too high a process time or temperature can have the same effect on solder joints. Contamination of tin-bismuth solder joints with lead (Pb) can cause joint failure. The residues left by some fluxes can be corrosive. Electrochemical migration induced by flux corrosion products is a common mode of circuit failure that is difficult to pinpoint by electrical testing. Dendritic filaments can form between two board features of differing electrical potential. Because these microscopic dendrites have limited current-carrying capability, they may act as miniature fuse links that may break and re-fuse, making the root cause of electrical failure quite difficult to diagnose and locate. Thus, there are many variables associated with circuit board assembly, and the process engineer has to rely on science and engineering fundamentals in order to contribute to intelligent PCA design and defect-free assembly.

## 45.2 SOLDERS

---

The properties of an alloy are dependent on its constituent metals and the ratio of the number of atoms of one constituent to the atoms of the other. Variations in these atomic ratios result in alloys of vastly different properties that are exploited to suit a particular application. Melting points can be adjusted, as can hardness, tensile strength, shock resistance, etc. In trying to achieve a suitable melting point, there are always trade-offs, and other material properties may degrade to the point that the alloy may not be suitable for its end-use application. Such is the case in the search for lead-free alloy substitutes. To date, no direct replacements approximate the properties of the well-understood standard of eutectic Sn-Pb (Sn63) solder. In most cases, liquidus temperatures (the temperatures at which a material goes from solid to liquid) of the Pb-free solder alloys are higher than that of eutectic Sn-Pb. As mentioned previously, this imparts many changes to process, process equipment, printed wiring board (PWB) laminates, and electronic components.

Families of alloys that are created from two or more metals in different ratios are called *alloy systems*. Tin-lead (Sn-Pb) is one such system, available in any number of compositions (50Sn-50Pb, 60Sn-40Pb, 10Sn-90Pb, etc.). Some solder alloys are composed of two elements. These are binary alloys such as tin-lead Sn-Pb or tin-bismuth (Sn-Bi). Others are ternary systems such as tin-silver-copper (Sn-Ag-Cu), which is also commonly referred to as SAC (for the *S* in Sn [tin], the *A* from Ag [silver], and the *C* from Cu [copper]). SAC305 is an abbreviation for Sn-3.0 wt percent Ag-0.5 wt percent Cu. Similarly SAC3807 is an abbreviated form of Sn-3.8 wt percent Ag-0.07 wt percent Cu.

Quaternary alloys are composed of four elements (e.g., Sn-Ag-Bi-Cu) and pentanary alloys (e.g., Sn-Ag-Cu-In-Sb) are composed of five. The latter is least understood; binary systems are best understood and easiest to formulate. Some of the small differences in compositions (0.5 wt percent) as seen in ternary, quaternary, and pentanary systems are difficult for solder vendors to control accurately during formulation. Also, in wave soldering, where the solder pot contents are in constant contact with metals from component leads and circuit board surface finishes, materials will be leached into the molten charge in the solder pot and will effect solder composition over the long term. Minor constituents of a solder may be depleted more quickly during wave soldering.

### 45.2.1 Tin-Lead Solders

Since these alloys have been the staple of PWB assembly and since Restriction of Hazardous Substances (RoHS) legislation exempts the alloy for certain applications until 2010, it is useful to understand this simple alloy system. A sound understanding of Sn-Pb will help in the intelligent selection of lead-free (Pb-free) solders and the mechanics of manufacturing reproducible and reliable solder joints. Until now, Sn-Pb solder was the alloy family of choice for electronics manufacturing with a long history dating back to the origins of circuitry.

**45.2.1.1 The Sn-Pb Eutectic Alloy.** Sn and Pb can be formulated into many alloys but its eutectic alloy is the most familiar to the electronics assembler. It is a ductile metal exhibiting a melting point below 200°C, a temperature range that has proven benign for most of the materials associated with or attached to a printed circuit board. Its fatigue resistance is sufficient for most commercial applications. Sn-Pb is easily fluxed by very weak organic acids and its shelf-life in terms of solderability is long lasting and generally not an issue. There are many solder alloys to choose from, but few as compatible as eutectic tin-lead when it comes to production assembly soldering of PWBs. There are also several metallurgical properties that make this alloy attractive as a solder, which explains why it is so widely embraced as the paradigm of solders. That is not to say that other metal alloys cannot be substituted, but this composition has endured the test of time and many searches for alternatives.

A eutectic alloy has several useful and interesting characteristics. Like all alloys, it has a melting point below that of its constituent metals (see Table 45.1)

**TABLE 45.1** Sn-Pb Constituent Melting Points Compared to Its Eutectic Melting Point

Material	Melting point (°C)
Sn	232
Pb	327.4
63wt% Sn:37wt% Pb*	183*

\* Eutectic alloy composition.

The eutectic composition has the lowest melting point of any other members of its alloy family. It has a discrete melting point rather than a melting range and its constituents are combined in a single, specific alloy composition. At the eutectic temperature, the eutectic metals coexist in a liquefied alloyed state as opposed to a state where there are some solids of one metal and liquid of the other.

When non-eutectic Sn-Pb alloys melt, phases of Sn or Pb precipitate out of the liquid solution and give rise to a solid-liquid mixture with broad melting range. The further from the eutectic point, the greater the band of the melting range for the alloy. This region of broad melting temperature is known as the “pasty” or “plastic” range. Non-eutectic compositions do not solidify as quickly as eutectic alloys. Because eutectic solders nucleate and crystallize very rapidly at the solidus point, fine grain growth and high mechanical strength in the solidified solder joint result. Upon solidification, non-eutectic compositions result in internal stresses and coarse, dull solder joints with perturbed surfaces. These are all points in favor of using eutectic or near-eutectic solders for circuit board assembly.

**45.2.1.2 High Pb-Content Solders.** High Pb content Sn-Pb solders are known for producing compliant solder joints owing to elemental lead’s high ductility. Due to high melting temperatures, these alloys are generally used to solder non-organic circuit board substrates such as ceramic. An organic laminate such as glass-epoxy is likely to incur degradation through a reflow cycle at such temperature extremes as required by alloys as 5Sn-95Pb (melting range = 301–314°C) and 10Sn-90Pb (melting range = 268–302°C). For these solders, the soldering

process temperature is generally chosen to be about 20 to 40°C higher than the melting point or the upper bound of the melting range for reflow and even higher for wave soldering. High-temperature solders are difficult to work with and are relegated to niche applications such as ceramic hybrid circuits or as a contact material for ceramic ball grid array (CBGA) and ceramic contact grid array (CCGA) packages and hand-soldering operations. Even in these applications, the solder ball or column is often soldered to the package using a lower melting-point formulation.

#### 45.2.1.3 Tin-Lead Additives

**45.2.1.3.1 Antiscavengers.** Occasionally a small fraction of silver (Ag) is added (up to 2 wt percent) to improve solder joint appearance and to retard Ag scavenging. Scavenging occurs when there is the propensity of one metal to dissolve rapidly and thoroughly into another upon reaching liquidus. A good example would be silver traces on a thin-film ceramic device and the use of Sn-Pb solder to bond to it. During soldering, the Ag would dissolve very rapidly into the Sn-Pb. If too much Ag is dissolved, then the bonding pad on the thin-film ceramic device may be rendered unsolderable due to the lack of a wettable solder surface. The addition of Ag to Sn-Pb solder would slow the dissolution rate of Ag from the thin-film ceramic bond pad and retard scavenging.

**45.2.1.3.2 Brighteners.** Sometimes Ag is added to solder to improve wetting, making the solder joint smooth and shiny. When not used as a scavenger, the addition of Ag should be avoided as it is not usually needed for most electronic joining applications with Sn-Pb.

**45.2.1.4 Sn-Pb Intermetallic Compound.** In addition to lowering the melting point of pure Sn (232°C), Pb retards Sn-Cu intermetallic formation by piling up at the intermetallic boundary, frustrating tin-copper intermixing. Sn-Cu intermetallic compound (IMC) is crucial for solder-joint formation, but if the intermetallic layer is too thick, the resultant solder joint will be brittle and subject to failure during thermal cycling or mechanical shock. Although Sn-Pb solder is known for its ability to wet well to a number of component lead platings and circuit board finishes, Pb actually inhibits wetting and keeps the solder localized to the targeted solder-joint area. Excessive solder spreading can be detrimental in three ways. First, if solder wicks away from the intended solder joint area, the resultant joint will be solder starved, and weaker than intended. Second, if the solder were too mobile, it could wick up connector leads and into the connector, decreasing inner contact flexibility, decreasing contact gap, and changing connector contact physics and resulting in a less reliable interconnect. Finally, if the solder wicks up too high on a gull-wing component lead, it inhibits the flexibility of the component lead and makes it more susceptible to mechanical failure.

## 45.3 SOLDER ALLOYS AND CORROSION

---

Just as some metals are more corrosion resistant than others, the same is true of solder alloys. When a solder corrodes on a circuit board, it is more than an aesthetic issue. Contaminants on the surface of the PWB between adjacent, oppositely charged conductors can result in corrosion dendrites. These are tiny conductive crystals—filament networks that may extend from one conductor to the other. They can have enough current capacity to cause electrical shorting or they may heat up to the point of fusion, melt, interrupt current flow, and return the assembly to normal operation. This can be a cyclical event with the dendrites growing, fusing, and regrowing, making diagnosis difficult. Finer-pitch surface-mount geometries are particularly susceptible to this phenomenon.

M. Abtew et al. published a chart of the electromagnetic force (EMF) of various metal couples present in some lead-free solder alloys.<sup>1</sup> As a rule, the lower the EMF, the more corrosion-resistant the alloy. Eutectic Sn-Pb, the basis of comparison, was by far the lowest value on the list at 0.010 volts. The next nearest, Sn-51In, was 0.201 volts or 20 times the voltage

as that of Sn-Pb solder. Other values reported were Sn-57Bi at 0.323 volts, Sn-9Zn at 0.624 volts, Sn-3.5Ag at 0.937 volts, and Sn-80Au at 1.636 volts. So tin-lead solder is significantly more resistant to corrosion and dendritic growth than the other seven alloys studied. This will be an area to watch as the world moves forward with Pb-free soldering.

#### **45.4 PB-FREE SOLDERS: SEARCH FOR ALTERNATIVES AND IMPLICATIONS**

---

The European Union's RoHS legislation has spawned widespread changes in electronic assembly. The biggest among them is the required move to Pb-free solders for most electronic products. Although this topic is a hotly debated, the use of elemental lead (Pb) in the electronics industry and more specifically in solders is a small percentage of the total industrial use of Pb worldwide. Accurate and current numbers are difficult to come by, but estimates range from less than 1 percent to as much as 10 percent worldwide. There are some excellent reasons, though, to find suitable substitutes for Pb where possible. Pb is toxic and governments worldwide spend large sums on abatement programs, education, and health care assistance to those afflicted with toxic levels of lead, mostly from peeling Pb-based paint, which is already regulated. Pb salts are sweet to the taste but toxic. The Romans purportedly added Pb salts to sweeten their wine. Electronic assemblies are rarely linked to toxicity through oral ingestion, but may be the source of contamination through improper disposal of the assemblies, components, raw materials, or their by-products. Purity of the water table may be affected by inappropriate land-filling of large quantity of Pb-bearing circuit boards; solder dross; spent solder pot contents; trace concentrations released as part of aqueous cleaning processes; and Pb-bearing ion exchange filters from aqueous cleaning units, plating baths, etc.

Replacement solders, while perhaps nontoxic themselves, may require deleterious raw stock or result in noxious by-products from processing or from ore refinement. It is wise to proceed cautiously and look at the impact of Pb removal from the electronics industry from all perspectives. There are many nonPb bearing materials associated with printed circuit board assembly, each with a set of material components and process chemicals that may be problematic in a public health sense. Products, by-products, raw materials, and their derivatives must be handled and disposed of in a conscientious and environmentally considerate manner. Attention to better reclamation and disposal methods of industrial and household waste streams, as well as adequate education concerning the same, probably holds more significance to public health than defining a quick substitution for Sn-Pb solder. However, it is the requirement and, therefore, a knowledge of alternatives is mandatory for design and process engineers.

The database for the material properties of widely used Sn-Pb solders is still incomplete. Needless to say, for a new Pb-free solder system, it will be much less complete and take several years to characterize the qualities and performance of a new solder. Since so many new solders are being investigated, this will further slow down solder development and characterization since efforts will be spread out rather than concentrated on a common solder alloy. As of this writing, several corporations have had product recalls associated with the changeover to Pb-free solders where there were unknown interactions with soldering system materials or lower-than-expected field reliability.

#### **45.5 PB-FREE ELEMENTAL ALLOY CANDIDATES**

---

Of the 90 naturally occurring elements, only 13 can be practically combined with each other to form a practical solder (see Fig. 45.1).

**FIGURE 45.1** Highlighted elements can be combined to form solders useful for circuit board assembly.

Of those elements that can combine to form solders, several have limitations that restrict their practical implementation for solder use (see Table 45.2). Gallium, gold, indium, platinum, and palladium cannot be mined or refined in sufficient quantity to satisfy the needs of the electronics industry and are prohibitively expensive, blocking their consideration as a major constituent of a worldwide solder supply. The Bismuth (Bi) supply, a by-product of lead refining, would be marginally sufficient. Mercury and antimony are too toxic. Both mercury and Pb are already on the EU’s RoHS list of restricted materials. Gallium and mercury possess too low a melting point to be used on their own. This leaves five metals for practical solder alloy consideration: bismuth (Bi), copper (Cu), silver (Ag), tin (Sn), and zinc (Zn). Due to

**TABLE 45.2** Elemental Candidates for Solders

Element	Symbol	Melting point (°C)	Comments
Antimony	Sb	630.5	Toxic, used as a minor constituent of some solders
Bismuth	Bi	217.5	Already in use
Copper	Cu	1084.5	Already in use
Gallium	Ga	29.75	Too expensive
Gold	Au	1063	Too expensive
Indium	In	156.3	Too expensive
Lead	Pb	327.5	Banned for use in EU
Mercury	Hg	-38.83	Toxic, restricted for use in EU
Palladium	Pd	1550	Too expensive
Platinum	Pt	1768.3	Too expensive
Silver	Ag	960.15	Expensive but already used in solders in small quantities
Tin	Sn	231.89	Already in use
Zinc	Zn	419.6	Already in use

its value, silver, too, can be used only in small proportions for solder and is already in wide use that way today. Given the four remaining metals (Bi, Cu, Sn, and Zn), there are many possible metallurgical permutations available for solder alloying, but there are few that either possess low enough liquidus to be useful for circuit board assembly or have attractive physical properties as a solder. Although Pb-free solders have been in use for many years (jewelry making, plumbing, brazing, etc.), few have been studied sufficiently for electronics assembly, most have too high a melting point to be useful, and none come with the well-documented properties database as is the case for Sn-Pb solder.

#### 45.5.1 Candidate Pb-Free Solders

Although many manufacturers completed the conversion to Pb-free soldering in time for the July 1, 2006, implementation of the RoHS directive in Europe, there was still no consensus across the industry for a single tin-lead solder replacement at the time. Pb-free alloy systems receiving the most attention include those listed in the Table 45.3.

**TABLE 45.3** List of Lead-Free Solders and Their Temperature Ranges

Alloy families	Most common compositions <sup>a</sup> (wt %)	Solidus temperature <sup>b</sup> (°C)	Liquidus <sup>b</sup> temperature (°C)
Sn-Cu	Sn-0.07Cu	227 <sup>3</sup>	227 <sup>c</sup>
Sn-Ag	Sn-3.5Ag	221 <sup>3</sup>	221 <sup>c</sup>
	Sn-5.0Ag	221	240
Sn-Ag-Cu	Sn-3.0Ag-0.05Cu	217	221
	Sn-3.5Ag-0.9Cu	217 <sup>c</sup>	217 <sup>c</sup>
	Sn-3.5Ag-0.7Cu	217	220
	Sn-3.8Ag-0.7Cu	217	220
	Sn-3.9Ag-0.6Cu	217	223
	Sn-4.0Ag-0.5Cu	217	225
Sn-Ag-Bi	Sn-1.0Ag-57Bi	137	139
	Sn-3.4Ag-4.8Bi	200	216
	Sn-3.5Ag-5.0Bi	208	215
	Sn-3.5Ag-1.0Bi	219	220
	Sn-2.0Ag-7.5Bi	191	216
Sn-Ag-Bi-Cu	Sn-2.5Ag-1.0Bi-0.5Cu	214	221
	Sn-2.0Ag-3.0Bi-0.75Cu	207	218
Sn-Bi	Sn-58Bi	138 <sup>c</sup>	138 <sup>c</sup>
Sn-Zn-Bi	Sn-8.0Sn-3.0Bi	191	198
Sn-Zn	Sn-9.0Zn	199 <sup>c</sup>	199 <sup>c</sup>

*Notes:*

<sup>a</sup>There are too many non-eutectic formulations composed of the same elements in varying ratios to list comprehensively here. Each variation in composition will have its own melting range. The ones listed in this table are examples only to show approximate temperature range and composition.

<sup>b</sup>There are discrepancies in the literature as to the exact melting point or melting range of alloys listed, but the table will be useful for approximating phase-change characteristics of the alloys listed.

<sup>c</sup>Eutectic alloys have a distinct melting point; solidus and liquidus temperatures are the same. Non-eutectic alloy melting is characterized by a melting range where the alloy is present as both solid phase(s) and liquid phase simultaneously (pasty range). At the upper temperature of the melting range, only the liquid phases exist.

**45.5.1.1 Characteristics of Pb-Free Solders.** Pb-free solders generally exhibit poorer wetting and spreading characteristics than Sn-Pb alloys, but may offer an advantage in tensile strength and creep resistance. In terms of the soldering process, a whole new understanding of the various Pb-free alloys is required. Propensity for solder void formation, solder paste shelf-life, solder

paste service-life (while on the stencil), printability and effects on stencil and squeegee life, fatigue characteristics, alloy interactions with board and component surface finishes, corrosion resistance, mechanical shock resistance, and numerous other properties will have to be understood, especially for the dense, high-end electronic assemblies that are expected to last many years in the field. It may be less an issue for consumer electronics that are considered obsolete within a couple of years. However, ruggedness, especially for portable consumer electronics, is a concern. Many of the lower melting point solders have precious elements, whereas some of the inexpensive alternatives wet poorly, are prone to oxidation during soldering, and tend to corrode. A few of the most favored alloy systems will be briefly discussed.

**45.5.1.2 Bismuth Alloys.** Bismuth (Bi), an elemental by-product of Pb smelting, is generally associated with lower melting point solder alloys. It is in short supply and Bi solders cost about twice that of Sn-Pb alloys. Bi is compliant like Pb and shares several of its properties, such as high specific gravity and ductility.<sup>2,3,4</sup> Pure bismuth melts at 271.3°C, about 50°C lower than that of Pb. Very easily oxidized, bismuth alloys are best soldered with the aid of highly activated fluxes or in a nitrogen environment.

Bi forms a binary eutectic with Sn in the proportions 58Bi:42Sn (m.p., 138°C). There are numerous bismuth alloys in use, many composed of two or more metals in addition to bismuth. The Sn-Bi eutectic, if contaminated with Pb, can be problematic as it is known to form a ternary alloy with a melting point of 96°C adversely affecting solder-joint fatigue characteristics. In some applications, solder joints will fall apart if the service temperature is high and the low melting point Sn-Bi-Pb alloy is formed. This becomes all the more critical with low-volume Sn-Bi solder joints. The Pb can come from solder predeposited on component leads, Sn-Pb hot-air solder leveled pads, or both.

Bismuth expands upon freezing, whereas tin contracts. A phenomenon called fillet lifting has been reported<sup>5,6</sup> (see Fig. 45.2). It is mostly associated with bismuth ternary alloys such as Sn-Cu-Bi and Sn-Ag-Bi used in plated through-hole (PTH) wave soldering, but has also been observed with Sn-Bi system.

**FIGURE 45.2** The expansion upon solidification in a bismuth-containing solder alloy can cause solder fillets to fracture and lift from the plated through-hole annular pads (right). Compare this to the schematic on the left, which is indicative of a conventional tin-lead solder joint.

As the board cools, it contracts at a different rate than the solder, and the fillets may lift, especially if cooled slowly or contaminated with Pb. Rapid cooling ( $\sim 3^\circ\text{C}/\text{sec.}$ ) has been advised but may not completely eliminate this phenomenon. Care must be taken not to exceed the component manufacturer's specified heating and cooling ramp rate. Too high a cooling rate may result in component cracking or degraded component reliability. Fillet lifting may also result in lifted PTH annular ring (bonding pad) if solder-joint strength is high and bond strength of the ring to the board is low.

Some Bi alloys have too low a melting point for many applications. Despite its excellent tensile strength and thermal cycling endurance (better than Sn-Pb), Sn-Bi eutectic (m.p., 138°C) would not be practical for use in most automotive applications or even for high-end computer assembly, where the service temperature may approach the melting point of this alloy. Bi also oxidizes rapidly, making Bi alloys difficult to maintain during wave soldering due to copious oxide (dross) production.

Bismuth soldering alloys are noted for their brittleness<sup>7,8</sup>; nonetheless, several bismuth solders are used commercially, the most popular alloys containing Bi as a minor constituent (in the 2 to 14 percent range). Aside from bismuth alloys' inappropriateness for high-temperature applications and Pb contamination, safety is an issue. According to C. White and G. Evans,<sup>9</sup> safety is particularly a concern when using alloys with high concentrations of bismuth. Cadmium (Cd), a poisonous metal, is a commonly associated bismuth contaminant. Care is recommended in handling of this solder, and special venting requirements may also be mandated for its use. On the other hand, the RoHS legislation has reinforced prior EU restrictions on cadmium, limiting it as a constituent or contaminant to less than 100 ppm by weight.

Bismuth and indium alloys are useful for *step soldering*, which refers to the use of two different solder alloys with two different melting temperatures used on the same circuit board. The higher temperature alloy (e.g., Sn-3%Ag-0.5%Cu, melting onset, 217°C) is used to solder surface-mount components and an alloy of lower melting temperature (e.g., 58%Bi:42%Sn, m.p., 138°C) is used for wave-soldered components. The temperature experienced at wave solder will not cause the Sn-Ag-Cu to reflow, thus preserving the integrity of surface-mount technology (SMT) solder joints.

In the case of repair or replacement of components, the use of low melting temperature solder will have no adverse thermal effect on adjacent or reverse-side solder joints. In fact, use of low melting point solder reduces the possibility of pad delamination or through-hole barrel cracking; failure mechanisms associated with localized overheating, especially at repair.

**45.5.1.3 Sn-Ag-Cu.** As previously stated, the Sn-Ag-Cu (SAC) family is receiving the most attention worldwide. Its tensile strength is superior to that of Sn-Pb, but its shear strength is worse. It is easily fluxed and moderate in melting temperature roughly 35°C higher than eutectic Sn-Pb solder. The elevated temperature regime makes this alloy more difficult to flux since the flux tends to dry up and activate too early in the process. This problem is overcome with higher molecular weight resin fluxes and volatile organic compound (VOC)-free flux formulations since there are no alcohols or other low boiling organics present to aid in evaporation. The SAC family has good compatibility with most Pb-free board surface finishes and Pb-free component platings. Its process window is narrower than that of Sn-Pb. It has been demonstrated that SAC can be used with parts containing Pb, but the reliability of the solder joint is less than if soldering Pb'd to Sn-Pb or Pb-free to SAC. SAC solders sell at about two-and-a-half to three times the price of Sn-Pb solder alloys. A comparison of Sn-Pb solder to SAC solder is offered in Table 45.4.

**TABLE 45.4** Comparison of Sn-Pb Solder with Pb-Free SAC Solder

Solder alloy	Tin/Lead Sn63:Pb	Tin-Silver-Copper Sn-(3.0-4.0%)Ag-(0.5-0.7%)Cu
Melting temp.	183°C	~217°C → ~221°C
SMT peak temp.	~215±10°C	~240±10°C
Wave solder pot temp.	250°C → 260°C	260°C → 270°C (with higher preheats and longer soldering dwells)
Solder reliability	Adequate	Collecting data
Process compatibility	Adequate	Collecting data

FIGURE 45.3 SAC solder requires higher process temperatures than Sn-Pb.

Figure 45.3 demonstrates the process temperature differences for Sn-Pb soldering compared to SAC.

A condition known as *sporadic brittle fracture* has been reported and may be related to the use of SAC alloy soldered to electroplate gold over electroplate nickel. It is most often associated with BGA solder ball-to-BGA package attach, but may also occur in board-level solder joints at the BGA ball-PWB interface. The root cause of failure is still unknown.

**45.5.1.4 Sn-0.7Cu Alloy.** Eutectic Sn-Cu (m.p., 227°C) is being used as a wave solder charge material. It is compatible with most board surface finishes and component lead-frame finishes. Its relatively low cost (about 50 percent more than Sn-Pb solder) makes it an attractive Pb-free alternative. It also has been demonstrated to be an effective alloy for Pb-free hot-air solder-leveled (HASL) surfaces on PWBs. One problem with Sn-Cu alloy, especially at wave soldering or fountain soldering, is that small amounts of dissolved copper will cause a dramatic rise in the melting point of the alloy. The high melting temperature of this alloy causes rapid material dissolution from PWB surfaces and component lead platings. Care must be taken to top off the wave solder pot with an appropriate amount of Sn or Sn-Cu to maintain proper Sn-Cu alloy proportions.

**45.5.1.5 Indium Alloys.** This metal and its effect on the solder joint is very much the same as for bismuth. Indium (In) is very soft and ductile in its elemental form and melts at about 157°C. In-based soldering alloys are much more expensive—about 25 times that of Sn-Pb—due to indium's scarcity, thus it is not suited as a dominant metal in solder. Price and supply make it unattractive even as a trace agent or a minor solder alloy constituent.<sup>10</sup> B. Allenby et al.<sup>11</sup> concluded that the world's indium supply would be depleted in about one year if indium were consumed at the same rate as Pb.

An In-Sn eutectic occurs at 58 wt percent In with a eutectic point temperature of 120°C. It forms intermetallic compounds with copper from the circuit board's bonding pad or copper-based component leads. Copper is highly soluble in indium.<sup>12</sup> Indium has been demonstrated to be of value in reducing the leaching of gold into solder. F. Yost<sup>13</sup> reported a lower Au dissolution rate for indium-based solders as compared to Sn solders. The use of indium allows soldering to gold films without thoroughly consuming the gold. The resulting solder joints are not brittle, as is the case of Sn-based solder joints exposed to too much gold.

Indium and some of its alloys can wet to glass, quartz, and other normally unsolderable inorganic substrates with the aid of an ultrasonic soldering tool. Ultrasonic soldering will be discussed in the chapter on soldering techniques.

**45.5.1.6 Zinc Solders.** Zinc (Zn) alloys, favored by some Japanese companies, oxidize rapidly. Solder paste shelf-life has been an issue even when these alloys are refrigerated at very low temperatures. Dross formation in wave soldering has also been problematic. Zn alloys are also known to have some corrosion problems.

## 45.6 BOARD SURFACE FINISHES

---

Most every circuit board consists of a stack-up of insulator material such as fiberglass and conductive layers composed of copper. Copper oxidizes quickly and its oxides are somewhat chemical-resistant, making it tough to solder without aggressive fluxing. Copper also corrodes in the long term from left-over process residues, fingerprints (body salts), or airborne contaminants. It is for these reasons that copper traces and solder lands on circuit boards are protected by solder mask, plating, or other surface treatments. The following section covers the most common board finishes. The process engineer needs to bear in mind that in addition to solderability, other surface finish-related issues may affect manufacturing or cost, including the following:

- **Probe-ability** This is the ease with which conventional in-circuit test probes are able to penetrate surface oxides or solder flux residue.
- **Tribology** The frictional properties of a material become important for press-fit connections.
- **Cost** Some surface finishes are significantly more expensive than others.
- **Shelf-life** This is the ability of a surface finish to resist oxidation or other surface conversion or corrosion and remain solderable.
- **Reliability** This refers to the resultant solder joint strength as it relates to long-term use and resistance to shock, vibration, and other environmental factors.
- **Corrosion resistance** Some surface finishes are more prone to corrosion than others. Immersion silver and copper are two such finishes.
- **Other surface finish-related defects** Immersion silver (Imm-Ag) sometimes exhibits linear arrays of microvoids at the intermetallic interface which detracts from solder joint strength. Electroless nickel/immersion gold (ENIG) sometimes results in brittle fracture if the plating chemistries are not maintained properly.

### 45.6.1 Hot Air Solder Levelled Surfaces

HASL coated boards have been the industry mainstay and the most common board surface finish worldwide. HASL is generally eutectic or near-eutectic Sn-Pb flowed onto exposed surface pads and traces on a finished PWB at the board shop prior to electronic assembly. It is inexpensive, eminently solderable, and easy to apply, and has excellent shelf-life/aging properties. There is the old adage in the industry that “nothing solders like solder,” which has made HASL a safe and preferred finish for many years. Previously it was thought that the HASL process could not deliver flat enough pads for fine-pitch surface-mount. Now it is a well-proven surface finish for component lead pitches down to at least 0.5 mm. Reputable board shops no longer consider HASL difficult to apply.

RoHS for the most part marks the impending demise of the Sn-Pb HASL surface finish. There are efforts to find other metallurgies to extend the useful life of HASL equipment.

Sn-Cu has been demonstrated to be one such HASL coating material. Studies are underway to determine long-term reliability impact of this change in material on the board and resultant solder joints.

### 45.6.2 Organic Solder-Preservative-Copper

Known as OSP-Cu,<sup>14,15</sup> organic solder-preservative-copper is a treatment and organic coating applied to the copper lands on the PWB at the board shop. The lands are first given a microetch to remove oxides and to increase surface area for OSP coating adhesion. The protective coating is an organometallic compound such as benzotriazole or imidazole, that chemically bonds with the freshly etched copper bonding pads and PTHs of the PWB. The coating retards copper oxidation and is meant to retain copper solderability through multiple reflow cycles. OSP-Cu is widely used and best for “just-in-time” board assembly strategies since its useful life is time-, temperature- and humidity-dependent.

During the soldering process, the organic coating degrades with each reflow cycle, allowing increasing levels of copper oxidation. The chemical-resistant copper oxide inhibits solder wetting, requiring ever stronger solder fluxes. This is particularly the case with thick [2.36 mm (0.093 in.) or greater], thermally aggressive boards with mixed-mount technology. Reflow results on the secondary side and primary side of such boards are generally satisfactory. But by the time such a board goes through wave soldering, the OSP coating has largely lost its effectiveness in preventing copper oxidation and incomplete barrel fill may result on PTH component soldering.

When solder paste printing goes awry and the PWB needs to be cleaned of the misprinted or smeared solder paste, most organic solvents used for removing the paste can remove, thin, or react with the OSP coating reducing its effectiveness in preventing copper oxidation. Care must be taken to ensure solvent compatibility with the OSP coating and its impact on the coating's ability to protect the copper after cleaning.

Another deficiency of OSP-Cu is found at in-circuit test (ICT). As the board is passed through top- and bottom-side reflow cycles and wave soldering, the unsoldered and unfluxed test points build up a layer of copper oxide. This oxide layer is difficult to pierce even with sharp pin- or blade-type ICT probes, resulting in open circuits and multiple fixture reseatings to attain probe penetration and electrical contact. Some have adopted coating the test points with solder; however, no-clean residues can also lead to ICT probe contact problems. The best strategy goes against modern PCA practices: reverting to the use of water-clean solder paste and wave solder flux and coating test points with solder paste. The post-soldering, aqueous cleaning cycle removes any flux residues, enhancing ICT probe contact on solder-coated test point on the finished PCA. Most large electronic manufacturers have worked diligently to remove aqueous cleaning from their factories—a move for improved process economics and significant environmental impact. Therefore, OSP-Cu is best used where ICT is not required, such as on low-end consumer products.

### 45.6.3 Electrolytic Nickel/Electrolytic Gold

This plating combination has been in use for many years and is considered a high-end surface finish but a highly reliable one in terms of solderability and product life. The amount of gold (Au) is small, but the plating process uses toxic and expensive materials that further increase the price of the plating. This plating system should not be confused with electroless nickel/immersion gold (ENIG). That surface finish will be discussed separately and does not have the reliable history of electrolytic nickel/electrolytic gold.

The electroplated nickel (Ni) serves as a barrier between the copper and the gold. Ni on its own is a poor candidate for a solder pad coating as it oxidizes rapidly and its native oxide is very stable—chemically tough to dissolve or react away. Unoxidized Ni can alloy with tin, which means that it can be soldered. Were the gold deposited over the copper directly, the gold layer would begin to interdiffuse with the copper even at room temperature forming an

intermetallic compound. The reaction rate is temperature-dependent. This intermetallic, like most intermetallic compounds, is difficult to solder, requiring a higher process temperature, a more active fluxing agent, or both. The Au-Cu system has poor solderability and the brittleness of this intermetallic results in diminished solder-joint strength.

Ni-Au coatings are in widespread use worldwide. Ni coating thickness is generally on the order of  $\geq 2.54 \mu\text{m}$  ( $>100 \mu\text{in}$ ). Au is a more difficult metal to plate. It tends to coalesce into islets, resulting in a porous coating. Any pores in the gold overcoat allow oxidation of the underlying Ni, rendering it locally unsolderable. To preclude this, the gold is liberally plated with a targeted minimum thickness greater than about  $0.127 \mu\text{m}$  ( $5 \mu\text{in}$ ) to ensure complete Ni coverage.

There are problems with the Ni-Au metallurgical system. First and foremost, it is well known that gold can cause solder joint embrittlement. When gold is introduced to tin as in tin-lead solder, it forms alloys with both the Pb and Sn. The Au-Pb alloy has two predominant intermetallic compounds:  $\text{Au}_2\text{Pb}$  and  $\text{AuPb}_2$ . Of the two, the latter is of greatest concern. It begins to form at the Au-Pb eutectic (85 wt percent Pb, m.p.,  $215^\circ\text{C}$ ), a temperature that encroaches into the normal reflow solder processing regime.  $\text{AuPb}_2$  is stable below  $254^\circ\text{C}$  and is characterized by brittle, plate-like structures. Regardless of the composition, size, and concentration of the intermetallic grains in the solder joint, they can either strengthen it (forming miniature reinforcing bars in a solder “cement”) or they can embrittle it, detracting from the solder’s inherent ductility.

Gold is non-oxidizing, like platinum and palladium, its noble metal neighbors in the periodic table. It readily alloys with most common solder alloy compositions, especially Sn-Pb and Sn-Ag-Cu. A. Korbelak and R. Duva<sup>16</sup> consider gold the most readily solderable material, but Sn-Au intermetallics are of even more serious concern than those of Au-Pb. The former is a characteristically brittle intermetallic that has been widely linked to solder-joint failure. Too much gold in a tin-lead solder imparts a dull, grainy look to the resultant joint—the only possible visual clue, although there are other conditions that can result in a similar appearance. There are marked differences in solder-joint integrity when it is loaded with Au. The embrittlement causes a reduction in the joint strength and fatigue life. Although there is much controversy over how much gold is too much, there is universal agreement that Au can be detrimental to the final assembly if its fractional weight-percent is not strictly controlled. The controversy is in part due to the type of product being soldered, its intended use, and its life cycle. If an electronic assembly is subjected routinely to high operating temperatures and/or frequent “on-off” power cycling, embrittled solder-joint fatigue problems will be evident. Although there is unanimous agreement that gold can be responsible for solder joint embrittlement and reduced solder-joint service lifetime, there is wide disagreement on the exact amount of gold permissible. Reported values generally fall between 2 wt percent and 10 wt percent, with most experts agreeing that less than 2 wt percent is a safe value.<sup>17,18</sup>

Ebneter<sup>19</sup> determined that Au as a thin, protective coating  $0.762 \mu\text{m}$  to  $5.84 \mu\text{m}$  ( $30 \mu\text{in}$  to  $230 \mu\text{in}$ ) does not pose an embrittlement problem. He also determined that the Au thickness required was a function of the plated grain size and porosity. Further, grain size is dependent on the type of plating bath (cyanide or acid) used. Hedrig<sup>20</sup> also concluded that  $>5$  percent Au in Sn-40Pb solder was problematic. Foster<sup>21</sup> reported a small net increase in solder-joint strength with a 2.5 percent Au addition to the same alloy, but when the addition was as high as 10 percent, there was a marked degradation in solder-joint strength. C. J. Thwaites<sup>22</sup> reported that 4 percent gold in a Sn-Pb solder joint is the threshold value above which there is a marked embrittlement and reduction in fatigue resistance.

There are three important Au-Sn intermetallics:  $\text{AuSn}$ ,  $\text{AuSn}_2$ , and  $\text{AuSn}_4$ . Eutectic points are at about 85 wt percent Sn ( $215^\circ\text{C}$ ) and 20 percent Sn ( $280^\circ\text{C}$ ). Gold can also form a ternary compound when joined with Sn-Pb solder, exhibiting a eutectic at about  $175^\circ\text{C}$ .<sup>23</sup> This can radically alter reflow characteristics and solder-joint performance. Au, like Pb, is poorly soluble in Sn, which means that it dissolves in hot Sn, Pb, or Sn-Pb solder and precipitates out of solution during the liquid-to-solid phase change of the solder. When it does, it forms brittle, plate-like crystals that appear needle-like in cross-section.<sup>24</sup>

When an intermetallic forms a distinct interfacial layer or otherwise high localized concentration, it is a rigid structural element, prone to cracking and brittle fracture failure on flexing. Therefore, even though the solder joint is composed of a ductile Sn-Pb composition, its overall strength and endurance is dominated by the brittle intermetallic composition and its thickness and structure within the solder joint.

As component lead pitch decreases, so does the amount of solder-per-joint contribution from the solder land metallurgy. Au concentration becomes increasingly difficult to control because its plated thickness cannot be easily regulated to accommodate the reduced surface area and lower solder volumes that accompany finer-pitch component requirements. After all, Au deposit thickness is dependent on its deposition grain size and plated porosity. The porosity must be overcome in order for the Au to serve its function in preventing oxidation of the underlying nickel on a Ni-plated substrate.

Another pitfall of Cu-Au or Cu-Au-Sn systems is that of Kirkendall void formation. Pores in the solder joint or at copper-gold interfaces occur through solid-state diffusion. Copper, which has a relatively high solubility and solid-state mobility in gold, diffuses into the gold. Transported by grain boundary diffusion at temperatures below 150°C and by bulk diffusion above that temperature, Au-Sn regions result along with atomic vacancies. When lattice vacancies are in profusion, voids can be observed, and this material depletion weakens the solder joint. Several references are available on this phenomenon.<sup>25,26,27,28</sup> Kirkendall voids should in no way be confused with voiding that results from entrapped gases, liquids, or residues from solder paste in the surface-mount process or from fluxes or from PWB laminate materials in wave soldering.

Although there is still much controversy on the subject of Au concentrations and effects on the solder joint, there is no doubt that this metal system is being widely exploited successfully in electronics manufacturing. It is, however, prudent to ensure that the Au levels are kept to a minimum via adequate vendor management and implementation of good process control methods for solder deposition. Note that because gold is a non-oxidizing material and therefore does not deplete the flux, more flux is available to work on the other components of the metallurgical system—namely, the underlying nickel (which must be kept from oxidizing), the solder, and the component lead.

The Ni-Sn intermetallic is more brittle than that of Cu-Sn, and this surface finish is generally not recommended for applications where the product may experience high mechanical stresses such as shock or vibration.

It has been stated that in the Ni/Au system, the soldering actually occurs on the Ni surface and the Au serves as a protective coating. Another intermetallic of this system, NiSn<sub>3</sub>, has been cited as a problem in long-term solderability degradation.<sup>29</sup> This IMC rapidly develops a platelet structure at low temperatures, with the greatest growth rate in the vicinity of 100 to 140°C. When intermetallic platelets grow large enough, they may penetrate the surface of the overlying tin, oxidize, and become a material difficult to flux and solder. The presence of elemental Pb was determined to retard NiSn<sub>3</sub> IMC formation.

Ni/Au surface finish is in use with Pb-free soldering, but there is currently a watch in the industry as sporadic brittle fracture has been observed on occasion. The exact nature of this fracture mechanism is yet to be understood and it is not certain that Ni/Au surface finish is at fault or just coincidental with some failures.

#### 45.6.4 Electroless Nickel/Immersion Gold (ENIG)

As the name implies, ENIG is not an electroplated surface finish. Still comprised of Ni with an overcoat of Au, ENIG is a lower-cost alternative than electrolytic Ni/Au. When the plating process is kept in control, it gives an excellent, solderable, and reliable surface finish. On the other hand, it is a finish that has caused many well-known reliability problems. Terms such as “black-pad,” “black line nickel,” and “mud cracks” describe some of the evidence of failed ENIG-related problems. Although these phenomena are most commonly observed on BGA packages plated with ENIG for package-to-ball attachment,<sup>30</sup> the failure has also been seen on solder joints on PWBs plated with an ENIG surface finish.

The main defect is brittle failure of the solder joint—a clean break beneath the intermetallic layer formed on the PWB bonding pad. Were the package completely pried loose from the board, a high surface area, dull finish on bonding pad would be evident—the well-known black-pad. Often the pad has an array of cracks visible on its surface reminiscent of mud cracks. Once the failed component is removed, the black-pad afflicted bonding pads is unsolderable or unreliable for further use and the board must be scrapped. Although the exact cause of ENIG failure is not well understood, it seems to be linked to low phosphorus concentration in the electroless nickel plating bath.

ENIG's appeal is its modest cost, flat topography consistent with all plated surface finishes, excellent solderability, excellent testability, and reasonable shelf-life if plated well. Unfortunately, the risk associated with this surface finish must be weighed alongside its benefits. In general, the assembler will find good results with ENIG. Unfortunately, there are no quick screening methods to weed out failure-prone ENIG plating lots.

#### 45.6.5 Immersion Silver (Imm-Ag)

This electroless silver-plated surface finish is in common use for Pb'd assembly and is also compatible with the most common Pb-free solders. Although it is highly solderable and known to be a good material for probe contact during in-circuit test measurement, it does bring with it some negative attributes. It has reasonable storage shelf-life if stored properly (air-tight bags), but is known to combine with sulfur contaminants in the atmosphere and tarnish or sulfidize. The silver sulfide is somewhat resistant to weak organic fluxes as used for no-clean soldering.

A new failure mechanism associated with this surface finish has been reported.<sup>31,32,33</sup> Referred to as “planar microvoids” or “champagne voids,” they are small voids in alignment atop the intermetallic layer of a solder-joint bond line (see Fig. 45.4).

**FIGURE 45.4** Cross-sectional micrograph of SAC BGA solder ball bonded to a silver surface finished PWB bond pad. Planar voids are clearly evident in the section and in the magnified inset. Voids in close adjacency above the intermetallic layer and the BGA ball can significantly detract from the solder-joint strength. (Courtesy of Hewlett-Packard).

Planar voids result in diminished bond strength and solder-joint fracture. This defect has been responsible for some product failures and recalls. The root cause of the microvoids is generally believed to be the result of volatile organics incorporated during Ag plating, but there also seems to be a correlation between Ag thickness and Cu topology on the bond pad.

**FIGURE 45.5** Ionic contamination on a board surface can adsorb moisture from the atmosphere. If an electrical charge is present, silver from bond pads may corrode and electrochemically migrate, resulting in a short circuit between bond pads.

Silver ions are known for their mobility in the presence of an electrical field (see Fig. 45.5). Ionic residues on a board with silver-coated surface finish together with adsorbed moisture from the atmosphere can result in electrochemical migration and corrosion dendrites originating from any exposed, unalloyed silver plating. These dendrites are most commonly seen on the board surface but can also occur under solder mask. If the dendrites are long enough, they may cause electrical shorting to one another or to adjacent traces. Since the corrosion dendrites are very thin, they are poor electrical conductors. If enough current is passed, the dendrites may fuse and the once-short-circuited circuit will become open again. If moisture and contaminant conditions are right, corrosion dendrites may form again and result in an electrical short. This cyclical growth-and-fuse phenomenon can complicate diagnosis of the source of the shorting.

Silver is an expensive metal. With its increased demand for solders (e.g., Sn-Ag-Cu), it is expected to rise in price, making it economically less attractive.

#### 45.6.6 Tin (Sn)

Tin deposited directly over copper, whether by electrolytic or electroless methods, should be avoided except for low-end/low-cost, short-field-life products. Sn alloys with copper, even at room temperature, form a brittle intermetallic compound, albeit slowly. It has limited solderable shelf-life at room temperature and the Sn-Cu intermetallic can inhibit soldering and may result in incomplete solder wetting or solder joints of inferior strength. For tin to be used effectively, an appropriate non-porous barrier metal, such as Ni, should be deposited between the Cu and the Sn. Immersion Sn can be plated only as a very thin layer since its deposition is by a self-limiting replacement reaction. When there is no more exposed Cu on the surface of the PWB during the surface-plating operation, Sn deposition will cease. Therefore, it is impossible to plate enough Sn by this method to extend the solderable shelf-life or reduce the brittleness of the solder joint.

When fresh, tin has reasonable solderability, but also tends to oxidize quickly. There are two important phenomena that are associated with Sn platings: tin whiskers and tin pest.

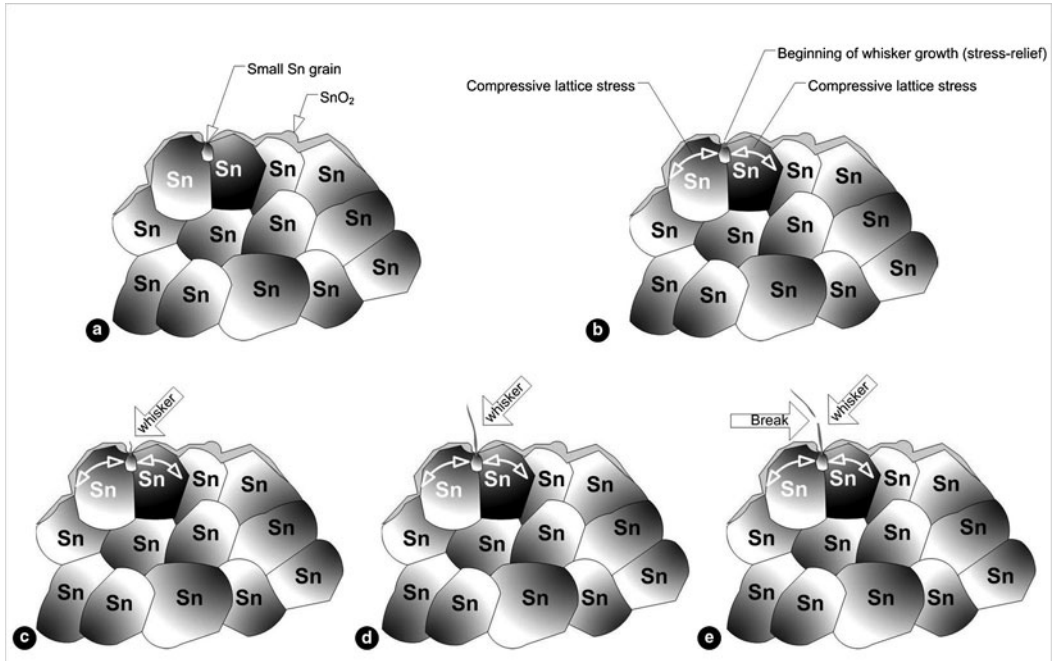

**45.6.6.1 Sn Whiskers.** Not to be confused with corrosion dendrites, whiskers are crystallites (see Fig. 45.6) that grow from pure tin surfaces into free space whereas corrosion dendrites grow on ionic contaminated, hydrated surfaces between two charged conductors. Although whiskers have been studied since the 1940s, their root cause is yet to be fully understood.

**FIGURE 45.6** Scanning electron microscope (SEM) micrograph of Sn whiskers growing from a pure Sn surface. When whiskers break, they pose danger of shorting between fine-pitch conductors. Whiskers can also grow long enough to bridge to a nearby conductor. (Courtesy of H. Hsu, Mitac Corporation, ShunDe, China).

The concern over whisker growth is related to electrical short circuits. If a tin whisker is long enough, it may break due to mechanical shock or vibration. The broken whisker may bridge two closely spaced contacts or traces on a component or PWB. Whiskers need not break to cause a short circuit, as they can grow long enough to bridge two adjacent, closely spaced conductors. In 1998, the Galaxy IV communications satellite failure was traced back to tin whiskers. Spare boards for that satellite stored on Earth clearly showed whisker growth. It is ironic that the first whisker issue occurred in 1946 on Bell telephone equipment, causing another telecommunications disruption.

Theories abound with regard to tin whisker formation. There are lattice dislocation theories and grain boundary diffusion theories. But the most prevalent theory for whisker generation relates their origin to compressive stresses within the tin lattice and perhaps weak spots in the overlying natural oxide on the tin surface (see Fig. 45.7). When tin grains are compressed against each other, and particularly when there are large compressive forces against a small, near-surface grain, the small grain may start to recrystallize or extrude in the least stressful direction, outward through a weak spot in the native oxide layer. Growth will continue until the lattice energy reaches equilibrium. Tin whiskers can grow to a diameter of approximately 1 micrometer and their length can reach tens of micrometers.

**FIGURE 45.7** Compressive stress within the tin lattice may cause whisker formation. The picture sequence depicts a likely mechanism for tin whisker growth and risk to printed circuit assembly: (a) A tin lattice with small, near-surface grain between two large grains. (b) Compressive stresses cause recrystallization of grain. A thin spot in the oxide layer allows rudimentary whiskers to penetrate the surface. (c) The whisker continues to grow. (d) The whisker continues to grow. (e) The whisker breaks due to mechanical shock or vibration. Whisker fragment poses a shorting risk to the PCA.

Now that Europe's RoHS legislation restricts Pb to a level of less than or equal to 1,000 parts per million by weight in electrical and electronic assemblies, there is much more focus on tin whiskers. Traditionally, many electrical components had tin-lead surface finishes, as did printed wiring boards (HASL). In cases where pure tin finishes were used on components, small additions of lead were added. The resulting lead-doped tin lattice imparted some compliance to the structure and reduced the risk of tin whisker formation. For the vast majority of electrical and electronic products, that is no longer an option for many classes of components.

Where tin and copper are in contact with one another, copper is found to diffuse into tin faster than tin into copper. The disruption to the tin lattice results in compressive strains, which sets the stage for whisker initiation. The solution is the addition of a thick, non-porous nickel barrier layer over the copper. Tin is then plated over the nickel. The thick nickel deposit is generally under tension and the tin diffuses into the nickel faster than the nickel into the tin. Since the nickel exerts no compressive influence on the tin lattice, tin whiskers are less likely to form.

Note that an added RoHS exemption allows the addition of Pb to Sn plated component leads if the component lead pitch is <0.65 mm (<0.025 in.). Besides metallic dopants, there are other ways to mitigate the growth of tin whiskers. Brighteners in tin-plating baths should be avoided and matte tin is preferred to minimize whisker growth. Annealing tin coatings is known to reduce whisker growth as recrystallization minimizes lattice stress. Ensuring that the reflow temperature during PCA soldering is above the melting point of tin (232°C) will reduce whisker risk. Additionally, the use of a barrier metal between copper and tin is recommended whether for circuit board or component surface finish.

**45.6.6.2 Tin Pest.** In addition to risk from whiskers, tin also poses another problem in some applications. At about 13°C, tin undergoes a crystalline structure transformation. The tetragonal crystal of white ( $\beta$ ) tin converts to the cubic allotrope, gray ( $\alpha$ ) tin. Since gray tin has less density than white tin, there is an expansion of the tin lattice upon transformation and the tin starts to fall apart, turning to a gray dust. So tin should be avoided as a surface finish for low-temperature duty. The transformation is most profound at -40°C but will occur, albeit more slowly, at temperatures below the allotropic transition threshold. As in the case of tin whiskers, tin pest has been combated with the addition of a dopant metal such as bismuth, antimony, or lead. Lead, however, is no longer an option due to the RoHS directive and similar mandates.

# CHAPTER 46

---

## SOLDER FLUXES

---

**Gary M. Freedman**

*Hewlett-Packard Corporation, Business Critical Systems, Singapore*

---

### 46.1 INTRODUCTION TO FLUXES

---

In a simplistic sense, the soldering process model is generally treated as solid and liquid metals interfacing with a gas (the soldering ambient). However, realities dictate a modified view. Nearly all metals oxidize when exposed to air and these oxides, whether on the solder itself or on the metals to be joined, always impede soldering. To keep the solder and surfaces to be joined bondable, the oxide must be removed and bonding surfaces must be kept oxide-free until soldering is complete. A chemical fluxing agent is used to this end and is indispensable to the process of joining. Fluxes are tailored to both the metals to be joined and soldering process temperature. Some metal oxides such as aluminum and nickel have chemical-resistant oxides, which make soldering difficult. Even copper oxides can be tough to dissolve. Most fluxes used in printed circuit assembly are acid-based and are formulated to be strong or weak depending on the metal systems to be joined, post-soldering treatments, and reliability needs.

Fluxes are typically composed of acids and high molecular weight materials that are slow to dry, slow to evaporate, and slow to decompose. They are often so acidic that they can etch, dissolve, or disrupt oxides and tarnishes on solder and surfaces to be joined. Both the absence and presence of liquid flux have an effect on the extent of solder wetting. Some fluxes can transition from a runny liquid during preheat to a viscous liquid or gel and ultimately to a gummy solid as it dries out, polymerizes, and decomposes during the soldering cycle.

#### 46.1.1 Flux Delivery Systems

Fluxes can be delivered in many different ways. For surface mounting, solder paste is used. The paste is a mixture of pure solder spheres, a fluxing agent, and other materials to adjust rheology for efficient stencil deposition of the solder paste on printed wiring board (PWB) solder lands. In wave soldering, a liquid flux is sprayed or otherwise applied to the secondary side of the board before the preheat and soldering steps. In hand-soldering, the flux can be an integral part of the solder wire, which has lumens within the wire filled with flux (see Fig. 46.1). As the solder melts, the flux is released to do its job.

It can also be applied as a flux paste with miniature artist's brush, with a pick, or as a liquid via fine-tipped flux pen. It has been shown that flux can also be delivered as a gas. This technology is rarely used, but will be discussed briefly.

### 46.1.2 Flux Functions

Selection of the flux type depends on the solder alloy, metal finishes on the board and components, condition of the surfaces to be joined, the type of soldering process selected, required solder-joint attributes, and the intended final use of the assembly. Some fluxes leave residues that are meant to remain on the board. Some fluxes are difficult to clean or may interfere with in-circuit test (ICT) probing or may hinder conformal coating or under-fill adhesion. Post-process flux deposits can cause corrosion, especially in the electric field between adjacent conductors on the surface of the printed circuit board (PCB). Fluxes may impart gas bubbles, or voids, which may be “frozen” into the solidified solder (see Fig. 46.2). The resultant voids may detract from the mechanical strength if they are large enough, are in abundance, intersect bonding surfaces, or are in close proximity to one another.

A) solder wire
B) flux-filled lumens

**FIGURE 46.1** Solder wire for hand-soldering showing flux-filled lumens.

When soldering is conducted in an air environment, once the flux reacts with the oxide layer on the solder and the metals to be joined, the metal surfaces are rendered chemically unstable and are quite vulnerable to reoxidation as they once again strive for equilibrium within the oxygen-rich ambient atmosphere. The flux residue coats oxide denuded, solderable surfaces as well as the solder and retards oxidation. If the solder flux is exhausted or fully evaporated before or even after oxide stripping and before the onset of solder reflow, oxidation would recur and solder-joint formation would be impeded. Solder fluxes

are generally formulated with high-boiling-point organic materials to slow evaporation, allowing overcoating of the cleaned metal surfaces. Further, if the flux residues were to become polymerized or charred prior to the solder melting temperature, this too could inhibit the flow of solder. It is therefore necessary to heed manufacturer solder paste or flux time and temperature guidelines from the flux or paste chemistry manufacturer, although some process optimization is recommended.

The presence of the hot liquid flux during soldering helps to promote thermal uniformity on the board. This is very important in mass reflow and may play an even more crucial role in some solder-in-place processes such as hot-bar laser. In some forms of laser soldering, the flow of hot flux may help to preheat leads and pads, readying them for solder joint formation. In the case of hot-bar soldering, a pool of liquid flux may help to even out thermal disparities over the length of the heated bar.

**FIGURE 46.2** A BGA solder joint rife with voids from flux-derived gases and improper soldering profile. These voids can detract from the reliability of the solder joint. The IPC-A-610 workmanship standard for printed circuit assemblies (PCAs) should be consulted on void acceptability. (Courtesy of Hewlett-Packard.)

## 46.2 FLUX ACTIVITY AND ATTRIBUTES

A flux’s ability to prepare a surface for soldering is dependent on its chemical strength or *activity*. Just like reagents on the chemistry lab bench, there are various concentrations available. A flux may be naturally strong or it may have additives to enhance its reactive power.

These additives are referred to as *activators*.<sup>1</sup> Activators accelerate the fluxing action either by direct chemical contribution or by catalysis. The activator can be an inorganic or organic material and combines with other ingredients in the flux, or decomposes with temperature to form an acid that is effective for oxide removal. Halogens, amino-halides, organic acids, and other materials are common activators. As the flux is heated, the activator begins its work. Flux heating for the soldering process has to be tempered for the particular type of flux formulation and solder system. Some activators may decompose if heated too quickly. Others may not be effective for a long enough time. Weaker fluxes (flux + activator) may require a longer preheat time and higher temperature in order to have sufficient chemical activity to remove oxidation and tarnish from parts to be joined as well as from the solder. Flux selection has to be appropriate for the solder alloy melting temperature as well as for the type of soldering process. The solder chemistry chosen will greatly influence the process time-temperature profile.

Like most chemical reagents, a flux's reactivity is in part a function of the exposure time and the temperature; many exhibiting Arrhenius-like behavior, where time-dependent chemical performance increases sharply with temperature. Some fluxes are weakly active at room temperature, but most require a significant thermal assist to enable them to be useful. Ultimately the only valid test of flux performance is whether the system works for the types and conditions of printed circuit boards and components encountered in the course of the required soldering process. A more active flux may be needed for low melting point solder, especially if manufacturing demands high throughput for this process step. In this case, the flux will not have the benefit of longer exposure times and higher process temperatures to assist in its job of oxidation removal. Higher-temperature alloys require fluxes that can withstand higher process temperature for reflow. It must not volatilize or decompose too rapidly nor polymerize or char at temperatures commensurate with soldering. Some metals are more prone to oxidation than others. Bismuth and zinc used in solder and copper on circuit boards are notable examples that may require a more active flux. A nitrogen-rich environment is helpful in augmenting flux performance. (See also Chap. 43, "Fluxes and Cleaning.")

### 46.3 FLUX: IDEAL VERSUS REALITY

---

The ideal flux would be one that is potent, requires only a small quantity, leaves little or no residue (and what residue does remain would be thin, transparent, nonreflective), easily penetrated by in-circuit test probes, electrically insulating, and chemically inert. If not inert, it should be easily and completely removable in an inexpensive solvent. However, this is far from actual materials and process reality.

Flux must be applied in sufficient quantity for thorough oxide removal and to avoid both metal reoxidation and flux exhaustion prior to solder wetting. Some post-soldering flux residues or form by-products may have deleterious effects on the circuit assembly since they may be chemically reactive and result in corrosion of exposed metals over the long term (see Fig. 46.3). The corrosive agents can be electrically conductive, resulting in electrical leakage (soft shorts) between closely spaced, oppositely charged conductors on the circuit board surface exacerbated by the residue's hygroscopic moisture uptake from the atmosphere. Corrosion may be augmented either by natural electromagnetic field (EMF) couples between two different metals or electrochemically driven by a charge between two adjacent conductors. The metallic ions, electrochemically driven, can plate out as metal dendrites on the surface of the board and produce intermittent or even persistent hard short circuiting (see Fig. 46.3).

Flux must be heated to a temperature to allow the best reactive conditions without drying out or denaturing. For the sake of economy and cleaning, a thin application is necessary and should be confined to the bonded site(s) of interest.

**FIGURE 46.3** Corrosion dendrites caused by corrosive, hygroscopic flux residues. (Courtesy of Hewlett-Packard.)

#### 46.4 FLUX TYPES

The 1989 adoption of the Montreal Protocol<sup>2</sup> imparted far-reaching changes to electronic manufacturing. In the circuit board assembly arena, it drove the elimination of chlorofluorocarbons and the reduction of volatile organic compounds for earth's ozone layer preservation. Many fluxes that used volatile organics such as alcohols were reformulated to use water as their solvent. Solvent-clean fluxes, which required non-aqueous cleaning chemicals (alcohols, chlorofluorocarbons [CFCs], hydrochlorofluorocarbons [HCFCs], etc.), were practically eliminated from the marketplace.

Today only two flux categories are in widespread use for PCB assembly: water-clean and no-clean. The former leaves a residue that must be removed from the PCA; otherwise, corrosion will set in. The latter, as the name implies, leaves a benign residue that is meant to be left on the circuit board. In fact, some no-clean residues perform as a conformal coating shielding the board from moisture and atmospheric contaminants. The choice between water-clean and no-clean has a profound effect on the process and may also affect subsequent process steps or long-term reliability. Both can be effective oxide strippers for soldering, but there are several considerations for choosing and using the proper flux.

#### 46.5 WATER-CLEAN (AQUEOUS) FLUXES

Also referred to as aqueous-clean fluxes or organic acid (OA) fluxes (a misleading term, because most fluxes are organic acid-based), this category contains the most aggressive fluxing agents used for large-scale commercial board assembly. It can consist of strong organic acids, inorganic acids, amines, amino salts, or often a weak organic acid fortified with reactive materials such as halogen salts ( $\text{Br}^-$ ,  $\text{F}^-$ ,  $\text{I}^-$ ,  $\text{Cl}^-$ ) that turn acidic during the flux decomposition process. For this reason, as the name implies, this type of flux requires an aqueous wash step to remove any reactive residue traces to avoid corrosion on the PCA.

Many of the water-soluble solder pastes are hygroscopic or leave hygroscopic, corrosive residues on the circuit board after soldering. This property can impact solder paste or flux shelf-life and the solder paste's physical attributes during printing and soldered assembly reliability. Most solder pastes are thixotropic; that is, they shear thin as they are being squeezed onto the board, becoming thinner with use. Generally, pastes are formulated to limit the degree of thixotropy. In addition to thixotropic thinning, some solder pastes, when exposed to a humid atmosphere, pick up moisture, which further thins paste rheology. Paste stenciling becomes more difficult to control and tack, and slump characteristics can be adversely affected. Ironically, some of these same organic acid solder pastes are prone to dry out in low-humidity conditions. Check paste manufacturer recommendations for optimal temperature and humidity regimes for storage and use. Localized environmental control of air temperature and humidity within the printer enclosure or factory-floor air conditioning can help to preserve solder paste rheological characteristics.

### 46.5.1 Cleaning Process

The cleaning consists of more than a dip in a tank of water. Generally commercially available, conveyORIZED wash tunnels are used for effective removal of the reactive residue from the soldered PCA. Such equipment can be many meters long and may have numerous zones consisting of cold-water spray nozzles, hot-water spray nozzles, and hot-air drying. Some systems may incorporate sumps where the board is briefly conveyed underwater for a short time to enhance residue dissolution. High-purity (de-ionized) water is recommended to enhance washing to eliminate or minimize corrosion. Saponifiers are sometimes injected into the water stream to target organic residues and convert them to water-soluble entities. Following the saponification step, thorough rinsing with pure water is required to remove traces of the saponifying agent.

### 46.5.2 Component Compatibility

Not all components are compatible with the water-wash process. Circuit board mounted switches are notable in this regard. Even some switches sold as "environmentally sealed" or "water-wash-compatible" have been found to leak during the high-pressure wash spray or submersion steps of aqueous cleaning. This can result in failure of the switch to work properly (the water causes an electrical short within the switch) or, if there is enough ionic content in the wash water or in the switch itself, switch contact corrosion may occur in the long term.

Many circuit assemblies are very dense with parts. The higher the part density, the less effective aqueous cleaners are. Like stones in a stream, the water swirls around them and eddy currents of relatively stagnant water form behind the stones. Components on a circuit board act in the same way, as they block the free flow of water and impede proper rinsing even in the most turbulent water spray systems. To counteract this, aqueous wash machines have multiple spray nozzles directed at board surfaces in several directions and angles. Many components have low headroom spaces beneath them, inhibiting rinsing effectiveness. In the case of PGAs, ball grid assemblies (BGAs), ceramic column grid arrays (CCGAs), ceramic ball grid arrays (CBGAs), etc., the water's path is further frustrated by the presence of solder joints beneath the component. Increasing I/O count, increased package size, and decreasing space between the PWB and component underside make water washing all the more difficult. The same issues hold true for chip-scale packages (CSPs) where the headroom is little more than a capillary and good wash-water exchange is unlikely. High-density, multirow connectors are also difficult to rinse. All of the preceding are equally difficult to dry. Water beneath components or within components may interfere with in-circuit test or functional test results immediately following aqueous cleaning. Water from aqueous wash has been known to enter integrated circuit (IC) encapsulant vent holes and cause shorts internal to the IC (see Fig. 46.4).

**FIGURE 46.4** If water enters an improperly sealed encapsulant vent/fill hole on an IC package, shorting or corrosion can occur. (Courtesy of Hewlett-Packard.)

### 46.5.3 Manufacturing Impact of Water-Clean Process

There are significant issues to consider when using water-clean fluxes, and the decisions are dependent on the specific parts and final product:

- **Expense** Aqueous washers are expensive and require a large footprint on the manufacturing floor. Generally, high-purity, de-ionized water is used instead of tap water to enhance rinsing effectiveness and to minimize corrosion or shorts caused by tap water particulates or ionic species such as chlorine or fluorine as found in treated public water supplies.
- **Additional process steps** Washing represents several additional handling steps, and with each handling step comes risk to the board. Due to the force of the water jets in the cleaning machine, boards, especially smaller ones, are put in baskets or carriers to go through the water-wash process. This involves additional materials (baskets/carriers) and handling. There is ample opportunity to knock parts off the board during loading or unloading of these baskets. Occasionally tall parts (such as surface-mount capacitors) are blown off the board by the force of the water blast. Boards that somehow escape the water-wash process will develop corrosion in short order.
- **Additional labor** Besides the need for additional operators to load and unload the conveyorized wash machine, increased maintenance is required for the aqueous cleaning machine, de-ionized water system, and waste-water treatment.
- **Environmental impact** The de-ionized water system requires frequent monitoring and filter replacement. Solder fines washed off the PCA must be filtered from the waste-water stream, and dissolved metals and other species harmful to the environment must be monitored and removed if of a high enough concentration before releasing spent water to the drain. This process is not suited to geographies with water shortages, water restrictions, or poor-quality water, or where the cost of water is high.

### 46.5.4 Benefits of Water Washing

There are significant benefits to using water-clean fluxes, but the decision involves trade-offs and must be made based on the specific needs of the parts and the product:

- **Unimpeded inspection** PCAs that have gone through a proper aqueous cleaning process are easy to inspect because there is no flux residue on the surface to interfere with solder-joint inspection by eye or automated optical inspection devices.

- **Best adhesion for conformal coating** Some boards that are intended for harsh environments rely upon a conformal coating process to enhance their resistance to moisture and airborne contaminants. The coating is silicone, epoxy, or other material. For good adhesion of these coatings, aqueous cleaning is usually prescribed for the boards.
- **Recommended for use with under-fill compounds** For added solder-joint reliability, epoxies or other adhesives are sometimes dispensed under certain critical components to anchor them to the PWB surface. Most under-fill compounds require a clean substrate for best bonding, so the underside of the component and board to be bonded in this method should be free of flux residues.
- **Possible electrical implications for RF circuitry** Flux residues can interfere with some high-speed circuit conduction by changing top surface dielectric properties and increasing parasitic capacitance. It is for this reason that radio-frequency (RF) circuitry is often specified to be assembled using water-soluble fluxes.

## 46.6 NO-CLEAN FLUX

---

Boosted largely by cost, floor space, and environmental concerns, no-clean fluxes now dominate printed circuit assembly. They are generally composed of rosins (e.g., natural acidic plant residues such as pine pitch) and/or resins. Often, but not exclusively, the term *resin* is used to denote a manmade rosin analog.

Historically, pine sap—*colophony*, as it is referred to in older publications—is the most notable natural product used as a flux. Once extracted from the tree, the pine rosin is purified and neutralized to remove excess acidity imparted by the extraction process and dissolved in alcohol. Termed *water-white rosin*, the key fluxing agents are a mixture of abietic and pimaric acids. Water-white used to be the basis for many commercial flux offerings.

Rosin is a solid at room temperature and can be dissolved or partially dissolved in alcohols. During the soldering process, the alcohol or other volatiles in the flux begin to evaporate and the rosin-based solids precipitate. The solids soften at low temperatures (50 to 70°C) and begin to flow, covering the surfaces to be fluxed. With higher temperatures come higher reactivity and oxides and other tarnishes are stripped, readying surfaces for solder wetting. The most widely used fluxes today are resins but act in the same fashion. Generally weak organic acid activators such as succinic, malonic, and adipic acids are added to increase the reactivity of the flux. These, too, volatilize or decompose during the reflow cycle and only a clear polymerized, non-corrosive residue is left on the board. The need for cleaning this residue is absent, hence the term *no-clean*. The best additives are ones that will not evaporate or decompose too early in the heating cycle but will completely volatilize or decompose at or near the peak temperature of the soldering process.

Halogenated activators should be avoided with no-clean chemistries. Some high-temperature organic acids may not completely volatilize or decompose, so reliability testing of the flux residues should be conducted to ensure that corrosion will not impact product reliability. Besides adding activators, one can boost a flux's chemical reactivity by increasing the rosin or resin content, but the higher the rosin/resin content, the heavier the post-soldering flux residue. Pure rosinic residues, especially from high-rosin-content formulations, are benign, hydrophobic, and electrically insulating, but they tend to be sticky.

### 46.6.1 Benefits of No-Clean

No-clean benefits include lower manufacturing costs through fewer process steps, less board handling, less maintenance, and reduced floor space than is required for board assembly via water-soluble fluxing. There are also environmental benefits of no-clean, as there is almost no waste effluent other than from the solvent within the paste or flux that evaporates during the process and from solvents used to clean the stencil, squeegee blades, and any misprinted boards.

This represents an extreme reduction in waste stream to the environment as compared to the use of water-soluble paste and flux. There are volatile organic compound (VOC)-free no-clean formulations that make no-clean even more environmentally friendly and attractive. These are generally compounded with a water or water-soluble solvent instead of alcohol.

### 46.6.2 The Negatives of No-Clean

Before talking about the negatives of no-clean, it should be understood that the no-clean approach to circuit board assembly is widely embraced and is the mainstay of the industry. Any negatives of this technology are counterbalanced by major benefits. No-clean is impractical for only a small number of niche applications.

**46.6.2.1 Difficulty of Inspection.** No-clean residues, especially from surface-mount technology (SMT) soldering, are generally hard, transparent polymerized deposits that interfere to some degree with solder-joint inspection. The deposit can crack and sometimes operators will mistake the cracked flux residue deposit for solder-joint cracking. The residue is also reflective, which can interfere with visual inspection or automatic optical inspection (AOI) methods.

**46.6.2.2 Decrease in Barrel Fill at Wave Soldering.** Since no-clean fluxes are weaker fluxing agents than water-soluble formulations, wave soldering is a somewhat less robust process. Poorer barrel fill is generally found with no-clean fluxes, although in most cases subtle changes to the wave solder machine configuration and wave solder time-temperature profile are sufficient to gain excellent or acceptable plated through-hole (PTH) barrel fill.

**46.6.2.3 ICT Probe Noncontact.** Much of the no-clean flux residue associated with wave soldering of the secondary side of the board is washed off by the molten solder during the wave solder operation. Generally, ICT is accomplished by bed-of-nails testing where pointed spring probes contact dedicated test pads located on the secondary side of the board (see Fig. 46.5a). Although these test points are masked off during wave soldering using selective wave soldering pallets (shields), sometimes the liquid flux, when dispensed to the secondary side for the wave solder operation, finds its way between the pallet and the board (see Fig. 46.5b). Flux-covered test pads may be difficult or impossible to probe, depending on the thickness of the solder flux deposit and type of flux used. Without cleaning, these residues will persist. Adjustments to probe tip style and spring force may be necessary to overcome the noncontact issue.

There are different types of test probes and different spring forces available. Generally, single-point probes rather than crown probes will have the best chance to penetrate the hardened flux residue. With a single-point contact, point force is maximized rather than spread out over multiple points. Using probes with high spring rates may cause the board to flex and damage solder joints or pierce through pads.

**46.6.2.4 Not Recommended for Conformal Coating or Under-Fills.** No-clean residue may inhibit adhesion of under-fills or conformal coatings. In fact, the flux residue may wick under a component and completely block an under-fill from entering between the board and the IC package. There are some new developments in this area and there are under-fill/flux combinations that may be effective.

**46.6.2.5 Corrosion from Repair.** Very often, even water-clean boards are repaired with no-clean formulations to avoid another aqueous cleaning step. Sometimes after a board is totally assembled, components of the board may not be suited for exposure to water. Although no-clean residues after soldering are generally benign, care must be taken to minimize the flux dispensed during board repair. There is a chance that the pooled flux will not be

**FIGURE 46.5** ICT probe noncontact: (a) If there is flux on a test pad, it will harden after soldering and may prevent the test probe from making electrical contact to the test pad. The test result may be interpreted as an “open” circuit. (b) As the board is fluxed in preparation for the wave solder process, the liquid flux may be drawn by capillary action between the wave solder pallet and the PWB. When this occurs, the in-circuit test pad (the target for bed-of-nails testing) may become fouled with solder flux. The flux residue inhibits probe contact.

fully heated and divested of its organic acids (activators). If this happens, the flux will remain acidic and promote corrosion. Therefore, it is important to ensure that:

- The smallest amount of flux is used for a repair
- Flux is confined to the area, that is, the lead(s) to be repaired
- The use of liquid fluxes is avoided, as they are prone to spreading
- The smallest diameter flux-core solder wire is used for repairs
- Ultra-fine, electrostatic discharge (ESD)–safe, felt-tip flux pens or paste flux is applied with an ultra-fine artist’s brush, fine pick, or pin
- All the flux dispensed has reached a near soldering temperature

## 46.7 OTHER FLUXING CAVEATS

Several general issues regarding fluxes must be considered before selecting one for a process and product.

### 46.7.1 Solder Paste Misprint Cleaning

When solder paste is printed in a manufacturing setting, occasionally the paste deposit is misprinted or smeared, requiring that it be removed before reprinting. Although this is not truly a fluxing issue, it does have ramifications to the process and reliability and is an important flux chemistry–related topic. Here are some guidelines for accomplishing this.

### 46.7.2 Aqueous-Clean Solder Paste Misprint Cleaning

A standard aqueous board cleaner or an aqueous stencil washer can be used for solder paste removal. Here are some simple guidelines:

- Ensure that all parts on the board are compatible with aqueous cleaning. Some surface-mount switches may not be compatible and may need to be removed from the board or masked in some way to prevent water or flux residue leakage.
- If SMD placement has begun, remove any high-value components from the paste on the side that is misprinted or smudged.
- Do not wipe solder paste off the board, as this will force paste into vias, PTHs, and solder mask clearance areas. Once reflowed, any solder residues may interfere with PTH component insertion or press-fit operations.
- If tape is used to mask gold fingers or other features, remove it before the commencing misprint cleaning to avoid entrapping solder beads or paste residue beneath the tape.
- Allow the paste to wash off during the aqueous cleaning process using a standard aqueous cleaning machine or an aqueous-based stencil washing machine
- Direct immersion of the board should be avoided. Immersion may result in water and diluted flux residues leaking into already mounted switches—even into switches that are specified as hermetically sealed and water-wash-compatible.
- Do not use solvents other than water to clean the board.
- Do not use a saponifer or solvent other than water unless the flux chemistry has been tested and qualified for compatibility and unless saponification or other solvent is in use with standard post-solder board cleaning.
- Do not use ultrasonic cleaners. Even random-frequency/random-amplitude ultrasonic cleaners may impact certain devices that may be already mounted on the board (e.g., on the secondary side). Crystal oscillators are notoriously sensitive to ultrasonic cleaning. Other components have been known to fail as a result of ultrasonic agitation and the consequential damage to internal bonds or die attach.
- After cleaning, use a microscope with as high a magnification as is needed to see individual solder spheres from the paste. Ensure that solder spheres are not present, or, if they are, ensure compliance with the workmanship standard in use. Also ensure that paste beads are not agglomerated in plated through holes. Generally a  $\geq 30\times$  stereo zoom microscope with good lighting is recommended for this inspection.
- If excess solder beads are still apparent, the board should be recleaned. Try rotating the board  $90^\circ$  or  $180^\circ$  for the repeat cleaning cycle.

### 46.7.3 No-Clean Solder Paste Misprint Cleaning

Cleaning boards printed with no-clean paste requires a little more care, but many of the same rules apply as for cleaning a water-soluble printed board:

- If placement has begun, remove any high value components from the side that is misprinted or smudged.
- If tape is used to mask gold fingers or other features, remove it before commencing misprint cleaning to avoid entrapping solder beads or paste residue beneath the tape.
- Do not wipe solder paste off the board. Instead, allow the paste to melt off in a stream of solvent recommended for the solder paste in the stencil washer or board washer. The solder paste vendor can provide a list of recommended cleaning solutions.
- Rely on the solvent in stencil or board cleaner to wash off the printed solder paste instead of trying to wipe it off.

- Do not use water to clean a no-clean soldered board unless the solder paste manufacturer recommends it, as it may result in a sticky, white residue on top of flux residues. This may impact electrical surface insulation resistance and corrosion.
- Do not use saponified water with no-clean unless the process has been tested for materials compatibility and subsequent corrosion. Surface insulation resistance (SIR) testing and electrochemical migration (ECM) testing are in order.
- Direct immersion should be avoided. Immersion can cause cleaning solvents and diluted flux residues to enter switch and other components. This, in turn, can result in an electrical short internal to the switch (from cleaning solvent conductivity), an open (from insulating flux residue), or corrosion (also from flux residue).
- Do not use ultrasonic cleaning. Even random-frequency or random-amplitude ultrasonic cleaners may impact certain devices that may be already mounted on the board (e.g., on the secondary side). Crystal oscillators are notoriously sensitive to ultrasonic cleaning. Other components have been known to fail as a result of ultrasonic agitation, which can damage or weaken internal bonds or die attach.
- After cleaning, use a microscope with as high a magnification as is needed to inspect for individual solder spheres from the paste. Ensure that solder spheres are not present; if they are, they should be in compliance with the workmanship standard. Also ensure that paste beads are not agglomerated in plated through holes, as they may interfere with PTH component insertion or press-fit operation. Generally a  $\geq 30\times$  stereo zoom microscope with good lighting is recommended for this inspection.
- If excess solder beads are still apparent, the board should be recleaned. Try rotating the board  $90^\circ$  or  $180^\circ$  for the repeat cleaning cycle.

#### 46.7.4 Do Not Use Aqueous Cleaning on No-Clean Repaired Assemblies

Very often, completed boards that are prepared with a water-clean flux formulation are repaired using no-clean flux. This strategy precludes the need for another wash cycle. In another situation, there may be parts that are on the board or associated with an assembly that are not compatible with a wash cycle (electromagnetic interference [EMI] shields, enclosure pieces, etc.); in such cases, a no-clean repair is necessary. However, once a board is repaired with a no-clean flux, it is important not to subject the board to an aqueous cleaning process for the reasons previously described. Conversely, aqueous cleaning must be used if a water-wash flux chemistry is chosen for repair.

#### 46.7.5 Test for Flux Compatibility

Certain no-clean fluxes are not compatible with each other. Their chemical interaction could result in corrosion on the PCA. To avoid corrosion issues, solder paste flux, wave solder flux, and repair flux should be tested separately and in combination for SIR and ECM with the board surface finish.

#### 46.7.6 Ensuring Full Flux Activation

As mentioned previously, it is important to heat the flux sufficiently to activate it (make it chemically reactive) and to burn off the activators by the end of the soldering process. This is true even of no-clean solder chemistries. If an unactivated, insufficiently heated no-clean solder flux is left on a board, the weak organic acids in the flux residue could cause long-term corrosion. Usually temperatures between  $80^\circ$  and  $150^\circ\text{C}$  (depending on the flux composition) are sufficient to activate a flux fully. Avoid pooling flux. To minimize the possibility of corrosion,

dispense liquid flux sparingly by using ultrafine artist paint brushes or fine-tipped, ESD-safe felt fluxing pens or a pick. Of course, the best practice will preclude the use of liquid fluxes. Instead, dispense paste flux with an ultrafine artist paint brush or pick, or use no-clean flux core solder wire to minimize flux deposition and for the best chance of reaching flux activation temperature.

### 46.7.7 Localized Solvent Cleaning

To remove excess flux on a board, cleaning solvents can be used locally. Sometimes these solvents are formulated specifically for flux cleaning and are sold as such. Sometimes pure chemical solvents, such as alcohols, are used. Very often solvents and flux cleaners leave gummy residues on the board. They can also dissolve the no-clean flux residue and redistribute it, leaving a messy-looking assembly. The dissolved residues can find their way into board mounted connectors via capillarity or direct dripping. This can result in electrically insulating flux residues on connector contacts or on board-edge gold fingers. Both can lead to interconnect electrical opens.

Methanol is a better cleaner than isopropyl alcohol (IPA) due to lower water content and it dries much quicker and more thoroughly than the latter. Care must be taken with methanol as it is flammable and its fumes are toxic. This is often true of other commercially available flux cleaners. Although sometimes flux cleaning is necessary or useful, it is best to avoid the need for cleaning by minimizing the flux dispensed and dispensing the flux only to the lead or leads to be repaired. Training, skill, patience, and practice are required for accurate flux dispensing and soldering.

## 46.8 SOLDERING ATMOSPHERES

---

The natural heat of the soldering process, combined with the oxygen in normal factory air, can inhibit soldering by creating oxides that compete with the action of fluxes. To avoid this problem, manufacturers can use inert or reactive gases for the local atmosphere at the solder site.

### 46.8.1 Nitrogen Soldering

Nitrogen ( $N_2$ ) as a cover gas for soldering processes has been in use for many years and is considered commonplace in today's electronic assembly.<sup>3,4,5,6,7,8,9,10,11,12,13,14,15</sup> Its role in reducing oxidation during the joining process ensures best solder wetting. Soldering in a nitrogen atmosphere has become increasingly important in recent years, driven by the rise of no-clean fluxes and solder pastes and the upsurge in the use of area-array devices such as BGAs, CCGAs, CBGAs, CSPs in reflow, and PGAs, along with complex, finer-pitch connectors in wave soldering.

Area-array devices have one thing in common: their solder joints are hidden by the package body and it is impossible to repair an isolated open solder joint beneath the package. Nitrogen provides added insurance that best solder wetting will result if soldering conditions and materials are process-appropriate.

The most recent increase in  $N_2$ -assisted soldering comes with the onset of large-scale lead-free soldering implementation around the world. Higher process temperature translates to higher oxidation rates during soldering. Also, as previously discussed, certain solder alloys are more prone to oxidation than conventional Sn-Pb solders.

**46.8.1.1 Use of  $N_2$  for Increased Fluxing Effectiveness.** The soldering environment is an important variable. Obviously the most common and least expensive soldering ambient is air, but many board assemblers introduce nitrogen to their reflow ovens, wave soldering

machines, or repair equipment.  $N_2$  is particularly effective when working with no-clean solder pastes or fluxes and it will gain increased importance with the conversion to Pb-free soldering. Most all of the Pb-free solders that are in widespread use for the electronics industry are slower to wet and require greater reflow temperatures than the old Sn/Pb standard. The introduction of nitrogen limits further oxidation of the metals to be joined, the solder, and even the flux. This in turn increases fluxing effectiveness and enhances solder wetting. Also, several of the Pb-free soldering alloys are prone to oxidation, such as solders containing Bi, Zn, or In. Reduced dross (oxides on top of liquid solder) production rates are generally seen when nitrogen is used to limit the oxygen content of the wave soldering atmosphere. Numerous citations have indicated that soldering can be effectively augmented by the use of an inert environment.

**46.8.1.2 Use of  $N_2$  for Lighter, More Transparent No-Clean Residue.** The yellow or brown coloration of some no-clean residues is absent when boards are soldered in a nitrogen atmosphere. Clearer no-clean residues make for easier inspection of solder joints on finished PCAs. It should be noted that the use of nitrogen even keeps the PWB laminate coloration looking the same as before it went through the soldering process.

**46.8.1.3 Nitrogen Negatives.** There are some negative points that must be considered when working with  $N_2$ .

**46.8.1.3.1 Cost.** There are some negative points that must be considered when working with  $N_2$ . First and foremost, nitrogen is an added expense for manufacturing. For factory usage, it is impractical and dangerous to store large numbers of gaseous cylinders or liquid dewars onsite; for this reason, bulk storage is needed. This comes with facility capital costs including: cement pad for outside storage tank and vaporizers to convert stored liquid  $N_2$  into usable room temperature gas. Pressure regulation is needed as well as piping and further pressure regulation for delivery of nitrogen to the soldering equipment. Then there is the incremental cost of nitrogen usage.

**46.8.1.3.2 Tombstoning.** It has been found that even modest flows of  $N_2$  are beneficial. However, too much nitrogen during reflow leads to passive component tombstoning (see Fig. 46.6).

**FIGURE 46.6** Passive component exhibiting tombstoning. Differential heating and surface tension effects have drawn the lightweight chip away from the surface of the PWB during reflow. On solidification, the component is frozen in the raised position and an open circuit results.

During reflow, solder may wet to one end of a chip before the other, usually due to one bonding pad heating before the other. As the solder continues to wet around the one end, the surface tension of the molten solder on that wetted end results in a lifting of the chip off the board before the solder paste goes molten and wets the opposite end. This results in an open solder joint. This defect, sometimes referred to as the “Manhattan Effect,” “standing proud,” or “drawbridging,” is most often seen on the smallest passive devices. The defect is exacerbated by excessive oven atmosphere inerting. Oxygen monitors can be used to sense the amount of nitrogen in an oven. Maintaining a reflow oven oxygen concentration level of about 1,000 ppm to 1,500 ppm O<sub>2</sub> will benefit reflow and minimize tombstoning. Inerting to this level is also significantly more economical since nitrogen consumption is less than when running at lower O<sub>2</sub> concentrations.

### 46.8.2 Fluxless Soldering

There have been many discussions and investigations into fluxless soldering, but often this term is incorrectly applied. Disruption of the integrity of oxides on the parts to be soldered and on the solder itself is a requirement for solder wetting. If a thermal or thermomechanical method is solely employed (e.g., as by ultrasonics), then it is truly a fluxless method. If a chemical agent is applied for oxide removal, whether it is in solid, liquid, or gaseous phase, it is still a flux-based process. Using cover gases alone does nothing to clean oxidized leads, bonding pads, or solder, but will limit further oxidation.

### 46.8.3 Gaseous Fluxing

It has already been discussed that flux can exist as a liquid or solid, but it can also be dispensed as a gas. There have been several investigations into the realm of fluxing with various gaseous species, including hydrogen, carbon monoxide, carboxylic acids, and others. Some have been demonstrated to be effective fluxing agents, but either their efficacy or economic impact, or both, is not yet sufficient to displace current liquid flux methods. Investigations continue in this area.

### 46.8.4 Hydrogen

There has been talk in the industry of hydrogen as a fluxing agent, but at soldering temperatures, hydrogen is predominantly a diatomic, unreactive gas; in fact, even at 1,730°C, it is only 0.33 percent dissociated at atmospheric pressure.<sup>16</sup> Therefore, it is relatively stable chemically, serving ostensibly as an expensive cover gas—an inerting blanket rather than a reactive fluxing agent. H<sub>2</sub> explosively combines with oxygen, so it is typically mixed with nitrogen or another inert gas when used for processing. This mixture, called *forming gas*, is susceptible to separation. Since hydrogen is lighter than air, it rises and may pocket in the upper recesses of the soldering machine or in the room. Its lower explosive limit in air is only 4.65 percent<sup>17</sup> so precautions have to be taken either to keep below this value or to preclude exposure to an ignition source. Its upper explosive limit is 93.9 percent, above which hydrogen is once again considered safe, but this is impractical economically and a gas containment vessel would rule out a reasonable continuous process and affordable equipment.

### 46.8.5 Carbon Monoxide

Carbon monoxide is an interesting choice. Very dense, it readily displaces air from the soldering environment, but since it is a heavier-than-air toxin with considerable public notoriety, it is unlikely that it will ever be considered an attractive assistive agent for reflow. Also, carbon

monoxide does not dissociate sufficiently well at soldering temperatures to be useful for effective fluxing, but does make an excellent, weakly reducing cover gas much as hydrogen does.

#### 46.8.6 Methyl Bromide

This material has been shown to be an effective fluxing agent but is toxic. In fact, it is now a banned pesticide.

#### 46.8.7 Carboxylic Acids

The idea of a gaseous fluxing agent has much merit. It could be inexpensive, eliminate post-solder cleaning, and leave no residue to impede inspection or test. Without residues, the prospect of corrosion would be minimized.

Carboxylic acids in gaseous phase have been demonstrated to be useful in this regard, but it has yet to undergo large-scale testing in a manufacturing environment. Of the carboxylic acids, formic and acetic have received some attention as fluxing agents. They are very simple materials, weak organic acids that decompose to water and carbon dioxide at temperatures above 160°C.<sup>18</sup> Acetic, in its dilute form, is vinegar. Both formic and acetic are widely used industrially and are inexpensive reagents. H. J. Hartmann<sup>19,20</sup> has shown that as formic decomposes, it is a good reducing agent for oxides of solder. The process produces meta-stable tin formate, which further decomposes, yielding elemental tin, water, and carbon dioxide. Acetic acid follows a similar reaction and decomposition cycle, forming meta-stable tin acetate and ultimately elemental tin. Especially attractive is the fact that there is no flux residue on the circuit board after the gaseous carboxylic acid reactive soldering process.

R. Iman et al.<sup>21</sup> have demonstrated formic and acetic to be especially effective for fluxing in the wave-soldering process in conjunction with a light application of adipic acid, a common food preservative and also a known fluxing agent. However, a water rinse was required to remove the adipic residue.

Work by G. Disbon and S. M. Bobbio<sup>22</sup> and K. Pickering, et al.<sup>23</sup> has demonstrated that a plasma can be used to strip oxides from circuit boards and components, and, if they are maintained in an inert environment, they can be soldered without the use of additional liquid fluxing agents. In these schemes, the plasma serves as the oxide-stripping flux.

# SOLDERING TECHNIQUES

---

**Gary M. Freedman**

*Hewlett-Packard Corporation, Business Critical Systems, Singapore*

---

## 47.1 INTRODUCTION

---

There have been many soldering methods devised over the millennia. The most ancient are the soldering torch and the soldering iron, but they are inadequate for assembling today's densely populated printed circuit boards. These are both directed-energy bonding methods, where the heating is localized to a specific small piece of board real estate to accomplish soldering of one or a localized set of joints. Oven reflow or wave soldering are examples of mass soldering techniques, where an entire circuit board is soldered simultaneously (or sequentially in the case of wave soldering). These techniques encompass a much larger area of heating than was possible by the iron. Thus, today's techniques can be divided into categories according to area of heating or number of joints formed simultaneously.

Soldering techniques must be judged by their applicability, cost, and end result. Mass soldering techniques are by far the most common for high-volume circuit board assembly. Some of the directed-energy soldering methods are now catching on in volume manufacturing.

---

## 47.2 MASS SOLDERING METHODS

---

The mass flow or reflow methods are suited for high-volume manufacturing. The entire board is heated and large numbers of components on the board are soldered simultaneously. The two most common of these methods are oven reflow soldering and wave soldering. A third technique, vapor phase reflow soldering, has dwindled in popularity due to environmental concerns regarding the use of the chlorofluorocarbon-based solvents that were key to this process. Now, however, perfluorocarbons are substituted and the technique is still in use.

The choice of soldering method is dictated by the types of components and boards being soldered, the required throughput rate, and requisite solder-joint properties. There are no clear-cut rules. Once the exclusive domain of wave soldering, some plated-through hole (PTH) components are being assembled along with surface-mount components in reflow ovens. Conversely, some surface-mount components are bonded by wave soldering.

### 47.3 OVEN REFLOW SOLDERING

Oven reflow is primarily used for surface-mount component soldering. To prepare a board for this process, solder paste is deposited and then forced through a metal stencil by either a metallic or polymeric squeegee. The paste contains both solder flux for preparing the metal surfaces for solder attachment and sufficient solder for joint formation. Components are placed in the solder paste on the board and the populated printed circuit board (PCB) is inserted into a conveyorized reflow oven. The oven is set to raise the circuit board and component temperatures gradually. Flux in the solder paste activates with the increase in temperature and strips metal surfaces on the components, board, and solder of oxides that inhibit solder joint formation. Finally, enough heat is imparted for the solder to flow (meaning to liquefy, also known as *reflow*). When built and implemented properly, the oven reflow process results in a controlled and predictable heating and cooling cycle and reproducible solder-joint formation.

Rapid heating of the paste is widely known to be a source of solder ball formation. Solder balls (isolated spheres of solder not necessarily connected to the solder mass of the joint) can be problematic for printed circuit board assemblies. They can induce electrical shorts, especially with finer-pitch components where solder ball diameters may be on the order of component lead or printed wiring board (PWB) pad spacing. Solder paste heating rates must be controlled to preclude solder ball generation. Similarly, the soldering time-temperature profile must be carefully adjusted to prevent excessively high temperatures that can cause flux charring or “caramelizing” and solder-joint degradation. The circuit board itself may also fall victim to the reflow process and deteriorate if temperatures are not maintained properly or evenly. It is for this reason that much equipment development has ensued.

#### 47.3.1 Reflow Oven Subsystems

Even the simplest reflow ovens consist of several subsystems: insulated tunnel, board conveyor, heater assemblies, cooling, and venting (see Fig. 47.1).

**FIGURE 47.1** Cross-sectional view of reflow oven with top and bottom heater assemblies, cooling module, vent stack, insulated tunnel, and printed circuit assemblies (PCAs) atop motorized conveyor.

Reflow ovens have reached a high level of sophistication, and there are many other items that enhance oven suitability for the manufacturing floor. Those items, beyond the aforementioned reflow oven subsystems, are niceties, accessories, and gimmicks offered by oven manufacturers, but are not discussed in this section; however, those subsystems previously listed are reviewed to impart an understanding of the basics of oven construction and operation as well as the most advantageous configurations.

**47.3.1.1 Tunnel.** The tunnel is a thermally insulated passage through the length of the oven where the board is heated and cooled for a continuous reflow process. It serves to insulate the

heaters and boards from the external (room) environment just as much as it is designed to preserve thermal conditions as prescribed by the process and demanded of the heaters. Boards are moved through the tunnel and past multiple heaters by an adjustable constant-speed conveyor permitting controlled and gradual preheating, reflow, and post-reflow cooling of the circuit board.

Consideration of tunnel dimensions is critical for the reflow application. Short tunnel ovens may not permit a profile adequate for attaining prescribed reflow temperature-versus-time profiles for larger, thermally massive PCB assemblies. Tunnel height dimensions must also be adequate to accommodate the tallest components or component heat sinks. Tunnel width will limit the size of the board that can be introduced to it.

**47.3.1.2 Conveyors.** There are two main conveyor systems used in reflow ovens: pin-chain and mesh belt. One is required and both are recommended for any reflow machine.

**47.3.1.2.1 Pin-Chain Conveyor.** The pin-chain conveyor, also known as an *edge-hold conveyor*, looks like a bicycle chain with a pin protruding inward from evenly spaced links, as shown in Fig. 47.2.

**FIGURE 47.2** Cross-sectional view of circuit board carried on a pin-chain conveyor.

There is one such chain on each side of the reflow oven. The circuit board rests on these pins on the inner aspect of the chains and is transported through the oven during the soldering process. The two chains are driven from a common motor, appropriately geared to ensure that the circuit board is conveyed through the oven evenly and to preclude angling and jamming of the board in the oven. Conveyor speed is adjustable and is one of the major factors of reflow soldering in the thermal (time-versus-temperature) profile development.

Pin-chain conveyors are best for circuit boards with components on both sides since the circuit board is conveyed by its edges. This edge-hold method prevents misregistration of parts to be reflowed and also eliminates movement of or mechanical interference with previously reflowed components on the bottom side of the board during transport through the oven.

Of course, an edge keep-out area must be designed into the board such that there will be no pin-chain or component interference.

When reflowing thin, large circuit boards, they may sag when held by the edges on a pin-chain conveyor. The sagging is due to thermal excursion above the glass transition temperature ( $T_g$ ) of the circuit board epoxy during the reflow process.  $T_g$  is the temperature at which a partially crystalline polymer will change from a hard structure to a rubbery, viscous state, as in the case of FR-4 and other such laminate materials. The  $T_g$  of most circuit board laminates is in the range of about 135°C to about 200°C, well below the peak reflow process temperatures of most solders. Sagging will be pronounced due to the fact that the board is unsupported at its middle as it surpassed its  $T_g$  during transport on the pin-chain conveyor. Copper ground and power planes within the board provide significant support, but may not impart enough stiffness to counter this problem. Sagging alone or together with rail-to-rail nonparallelisms at process temperature can even lead to boards falling off the conveyor. Most of the major vendors in the reflow oven market have conquered the rail twist problem, but hot testing an oven with precisely toleranced test vehicles or even aluminum plates should be performed prior to final acceptance of the equipment or reliance on it. Board sagging can be mitigated, to some extent, by means of mechanical stiffeners affixed permanently or temporarily to the circuit board or by reflowing the board on a pallet. It should be noted that stiffeners and pallets may affect the thermal mass of the board, making reflow more of a challenge. Care should be taken to ensure that the attachment of stiffeners does not interfere either mechanically or thermally with components that may be positioned close to the board edge. Design rules should preclude the use of reflow-challenging components or component fields too close to the circuit board edges. Additionally, some ovens are sold with an accessory steel cable strung the oven length that is meant to serve as an antisag support. An additional adjustable supporting chain is sometimes installed for the same reason and meant to be in contact with the bottom side of the board. The cable or support chain must not contact components on the bottom side of the board, as the chain could dislodge components; thus, clearance must be designed into the board or panel for the support cable or chain. The chain and its supporting rail can interfere with the reflow profile. The board will be cooler in the shadow of this additional rail as it blocks air flow from the bottom blowers.

In a properly designed oven, the pin-chain inflicts little thermal influence on the conveyor. However, some edge-hold systems have been known to impart a dramatic effect on the thermal transfer at board edges, resulting in overheating or heat sinking, depending on the oven's performance and rail position. Some vendors offer rail heaters to counteract this effect. It is best to avoid this type of system because it adds further complexity to the oven and makes the job of process control all the more difficult. This should not be a problem with the conventional pin-chain conveyor because in actuality the pin-chain is only in point-contact with the circuit board. Thermal transfer through these contact points is very poor. Further, most of the newest reflow oven manufacturers have replaced carbon steel chains with stainless steel chains. Stainless steel has better wear characteristics and is a poorer thermal conductor than other commonly available chain materials.

**47.3.1.2.2 Mesh Belt Conveyor.** Mesh belts used in reflow ovens are generally fabricated of stainless steel links. Some are wide open with large spaces, many centimeters from link to link. Others are more like chain mail armor (Fig. 47.3). The widely spaced links allow more air flow to the bottom side of the board.

**FIGURE 47.3** A large space mesh belt (a) allows more air flow than the “chain mail armor” mesh (b).

The mesh belt is close to the full width of the tunnel and traverses its entire length. Mesh belts offer exceptional versatility, as there is no need to adjust for various board widths and never a concern for board sagging or dropping.

The best situation, however, is a combination of conveyors with the pin-chain running above a mesh belt. In this case, redundancy can save boards, reduce maintenance time, and enhance personal safety. The mesh belt here serves as either an optional means of conveyance for boards populated on a single side or as a safety net to catch a board that may fall off the pin-chain conveyor. Dropped boards are a rare occurrence if the pin-chain conveyor is set properly and the equipment, process, and materials are properly specified and controlled. If the mesh belt were not used with the pin-chain, any dropped boards would “cook” on the heater assemblies, resulting in the release of noxious, irritating fumes. Additionally, the heater or heaters affected could become encrusted with the decomposed board laminate, which may impact their thermal performance. If a thermocouple, the sensing instrument for oven temperature control, is damaged or insulated by the laminate decomposition products, overheating of the zone could occur, causing oven damage and manufacturing downtime.

The biggest problem with mesh belt conveyors is that the bottom side of the board is in direct contact with the conveyor surface. Any components mounted on the bottom side of the board could be damaged or dislodged before or after reflow. While the board is at reflow temperatures, components could be forced into misalignment or nudged off bonding pads by contact with the conveyor mesh. Often, where there are components on both sides of the board, a carrier (pallet) is used to keep the board from contacting the mesh belt. The carrier adds thermal mass, so it is wise to clear unneeded materials or perforate it to allow good air flow during the soldering process. Time-temperature profile development should include such a carrier.

**47.3.1.3 Oven Heaters.** Each heater’s thermal output is sensed via a thermocouple, which is used to close the loop to the heater controller. In larger, production-worthy systems, heaters are located both above and below the plane of the circuit board and are at least as wide as the conveyor. Thermal uniformity across a 60 cm tunnel width can be better than  $\pm 2^{\circ}\text{C}$  on top-of-the-line ovens. This is a function of the tunnel insulation, heater performance, heater control, and convective mixing of the heated air or gas.

There are several heating schemes used in reflow ovens, the result of years of technological evolution. Focused infrared (IR) lamps have given way to secondary emission panel heaters and, finally, to the forced hot-air convective ovens that are the de facto industry standard today.

**47.3.1.3.1 Infrared Heater Types.** Alternative IR heater types are shown in Fig. 47.4.

**FIGURE 47.4** Three infrared heating schemes for reflow ovens: (a) IR lamp; (b) open resistance wire heater; and (c) resistance rod (calrod-type cartridge heater).

Early ovens utilized focused and unfocused IR lamps, mounted in the reflow oven tunnel. These bathe the solder paste-coated circuit boards and associated components with a broad spectrum of photonic energy heavily weighted to the IR end of the electromagnetic spectrum. The radiant energy absorbed by the printed wiring assembly (PWA) and related materials brings about the thermal increase needed to reflow solder. As the board travels beyond the last reflow heaters at the exit end of the oven, the absorbed heat is lost to the environment or the board is actively cooled by fans. The cooling results in resolidification of the molten solder and solder-joint formation.

Material such as plastic and ceramic component bodies, lead and pad metallurgies, solder, printed circuit board laminate, solder paste flux, and adhesives all absorb infrared radiation at different rates. Therefore, the direct radiative approach is known to cause overheating of some components and underheating of others. For this reason, direct IR heating is no longer the preferred method for reflow.

**47.3.1.3.2 IR Panel Heaters.** Better than direct IR heating is the secondary IR emitter panel (see Fig. 47.5). It is constructed out of metal or ceramic platens heated either conductively via attached resistance heaters or by direct IR irradiation on the back side of the panel.

**FIGURE 47.5** Secondary IR panels rely on radiant IR sources such as (a) lamps, (b) wire resistance heaters, or (c) heating rods/cartridge heaters. The primary IR is impinged on a baffle and the absorbed short-wave radiation is converted to longer wavelength radiation. This imparts more even heating of the PWB and components during soldering.

During reflow, the circuit board is shielded from direct short wavelength IR impingement from IR lamps or filament heaters. Instead, it is heated by blackbody emission of the heated platen. This results in much longer wavelength IR emission, slower heating rates, and more even heating—a significant improvement over the direct IR lamp oven reflow soldering method.

A variant of this method is the convective IR oven. This technique also relies on radiant or panel IR heating, but the air in the oven is stirred by fans to enhance uniformity of heating. However, techniques such as IR lamp, IR emitter, and combination convective units have been largely supplanted by a more favorable method: forced-air convection, where air is forced through the panel heaters at high velocity. This produces very even oven temperatures and rapid heating response and control. This method is the mainstay of oven reflow.

**47.3.1.4 Venting.** Oven venting is required to remove harmful fumes from the oven tunnel. If there is too little venting, fumes will not be removed effectively. Too much exhaust will pull in room air through the tunnel entrance, tunnel exit, or both, which can disturb thermal performance. If nitrogen is being introduced to lower oxygen levels, too strong an exhaust draw will negate the effect of the nitrogen or make it difficult to control the oxygen level within the oven. For a more detailed look at venting, see Sec. 47.3.2.

**47.3.1.5 Cooling.** Just as important as heating the solder, the solder must be brought back to solid state before the board is handled. Otherwise, components sitting in liquid solder could move. Also, as a material such as solder solidifies and crystallizes, mechanical motion can perturb the lattice structure. The resultant solder joints may be of poorer quality and lesser reliability. Some ovens rely upon passive cooling, whereas others have active cooling elements such as fans or even chillers (fans blowing over chilled radiators).

### 47.3.2 Forced-Convection Reflow Oven

This is the preferred tool for controlled and reliable reflow soldering dependent on heated air recirculated at high velocity in the oven tunnel. The only direct irradiation of the PCBs is by the longest IR wavelengths emitted by the hot surfaces within the tunnel.

**47.3.2.1 Forced-Convection Reflow Module.** Heating is accomplished primarily through heated air streams directed at the PWB's top and bottom surfaces. This method imparts greater thermal uniformity and controllability of the reflow process than any other reflow oven heating methods. It precludes overheating of the circuit board and/or components caused by preferential absorption common to direct IR heating methods. Although the combination IR-convective method has helped in this regard, it is no substitute for the hot-air forced-convection technology.

Top-of-the-line forced-air-convection ovens have heating modules mounted above and below the board conveyor. They accomplish heating by passing a high-velocity air stream drawn from the tunnel ambient over resistance heaters, through perforated platens. The heating elements are typically shielded from the board to mitigate the effects of any direct or indirect IR impingement on the circuit board. The high-velocity air flows are baffled and regulated to impart a uniform temperature across the tunnel width. Each module is quickly heated and highly controllable. Several heating modules are set side by side along the length of the oven. It is typical to duplicate the forced-convection module array on the bottom of the oven tunnel to impart controllability of the reflow time-temperature profile and to help in even heating of the board from both sides simultaneously. Fig. 47.6 depicts this arrangement.

**47.3.2.2 Cooling.** Some ovens rely upon passive cooling to lower the temperature of the PCB assembly below the solder liquidus point. In this case, the board traverses a region of the oven devoid of heaters cooling along the way. This is generally adequate for thin, low-thermal-mass boards. But the reality of multilayer, densely packed circuit boards necessitates some means of cooling to ensure that solder joints are solid prior to exiting the oven and before handling the board. To accomplish this, many ovens incorporate an area of active cooling after the last heating zone within the oven (see Fig. 47.7).

Active cooling comes in many forms. Forced-air cooling by fans is the most common. Fans can be deployed on top, on the bottom, or in combination for board cooling. Among the most exotic but the most efficient is the water-to-gas heat exchanger found in some ovens. This provides a stream of temperature-controlled cool air at the exit end of the oven for board cooldown and has distinct advantages in nitrogen atmosphere reflow systems. This method uses whatever process gas is in the oven, cooling it and redirecting it onto the circuit board. Thus, this method does not require additional nitrogen for cooling, does not draw any additional air into the oven that might degrade the nitrogen atmosphere, and precludes the need

**FIGURE 47.6** Forced-convection heating modules. Cooler air (a) is drawn across the resistance heater (b) by a fan (d). The heated air (c) is forced through a perforated plenum tuned for even heat distribution to the PWB (e), which is riding on the conveyor (f). A second set of forced-convection heating modules is directed at the underside of the PWB. Several such modules are arrayed the length of the oven for precise thermal profile control.

**FIGURE 47.7** Forced-convection oven with 12 top and 12 bottom heating modules (a). Each module is independently heated and controlled. The last two top and bottom modules on the right (b) are for active cooling of the soldered circuit board to ensure that solder has reached solidus before exiting the oven. In this machine, cooling zones are aided by fans blowing over water-cooled radiators. (Courtesy of Heller Industries).

for cooling fans outside of the oven adjacent to the oven exit. This approach minimizes air turbulence at that tunnel exit and air entrainment into the oven’s nitrogen environment. Water-to-gas cooling is efficient, but it must be included in the reflow profile to ensure that thermal ramp rate is correct. Some ovens use polymeric “muffin” fans. These must be kept on at all times to prevent overheating of the fan blades and the motors’ plastic fan support

structures. Other ovens use air rakes or even air amplifiers to direct a flow of cooling compressed air or nitrogen at the board.

In-oven cooling schemes often result in condensation of flux volatiles and flux decomposition products. As deposits build up on the coolest surfaces within the oven, they change the thermal transfer characteristics of the cooling system. This alters the thermal profile of the oven over a long period of time. Flux condensates may also drip onto circuit boards as they pass through the oven. Nitrogen atmosphere ovens running no-clean s face the biggest challenge in trying to control these condensates. No-clean pastes give off abundant volatiles during reflow. Ambient air entrainment is necessarily low for precise control of the nitrogen ambient within the oven, whereas nitrogen volume is minimized to keep board processing costs reasonable. The result is low gas exchange within the oven's tunnel and little dilution of condensable vapors. Condensates build up rapidly on the cooler surfaces and are baked on over time and difficult to remove. Oven manufacturers have devised many elaborate schemes for flux condensate management. Gas stream filtration in and around cooling zones, replaceable filters, cold traps, and cold fingers with self-cleaning burn-off cycles (kitchen oven-style) have been incorporated into some of the newest ovens. Several ovens have quick-change finned radiators that are swapped out, cleaned, and readied for the next change-out.

Many silicon integrated circuit (IC) packages or passive component devices have specifications for maximum thermal ramp rate. Exceeding this heating or cooling rate may damage die attach materials, crack packages, or otherwise alter electrical performance of the package. This is especially true of ceramic devices. Often the ramp is recommended in the range of 1–4°C per sec. Additionally, some solders like Sn-Ag-Cu (SAC) require cooling rates in this range to allow for quick solidification and to discourage solder alloy segregation. Cooling too slowly encourages redistribution of alloy constituents and silver platelets, or needles can form that may detract from solder-joint strength.

**47.3.2.3 Venting.** An often overlooked reflow oven subsystem is exhaust venting. This is most important from an industrial hygiene point of view, but it can also have a profound effect on the soldering process itself. During the soldering process, minute quantities of metal oxides accumulate in the oven atmosphere or coat oven tunnel surfaces. The dangers of prolonged exposure to microquantities of lead (Pb) or lead compounds are well documented. With the change to Pb-free materials, the risks are likely lower, but there should still be concern for inhalation of any metal particulates. As previously discussed, during reflow, solder paste volatilizes and releases paste reaction products. Since most solder pastes and fluxes are highly guarded proprietary formulations, the paste and flux vendors may neither accurately disclose the composition reagents nor report the decomposition products in the mandated Material Safety Data Sheet (MSDS). Additionally, if a PCB should fall off the pin-chain conveyor or a component should fall through the mesh belt, it may land on a high-temperature surface—either the heater itself, or, in the case of forced-air convection reflow machines, the perforated baffles above the heater assembly. Either the board or a plastic component will overheat, decompose, and release unpleasant or even dangerous fumes. A properly designed and implemented exhaust system will mitigate these hazards.

A high-velocity exhaust may influence oven performance. Too much exhaust will cause a significant net flow of atmosphere through the oven. This can result in unwanted turbulence within the oven, upsetting intentional forced-convection patterns and making temperature regulation more difficult, reducing zone-to-zone influence (zone separation), decreasing ease of profile establishment, and resulting in process variability.

Some ovens are set with one central exhaust flue, whereas others may be designed to have ports at both the tunnel entrance and exit. A dedicated manometer or other vent sensor should be installed in each exhaust line to monitor setup and routine exhaust performance. Blast gates in the exhaust line permit flow adjustment. It is customary to mount vent sensors after the flow damping device. Follow oven manufacturer's guidelines for exhaust requirements. Since the exhaust gases are laden with volatile materials, mostly from the solder paste, active exhaust systems should be checked routinely for performance. Impeller blades can foul

because of the condensates from these cooling volatiles. Exhaust stack monitors should help pinpoint such problems.

The smoke from a piece of smoldering cotton twine can be used to sense whether there is a net flow into or out of the oven. When venting is correct, there should be a lazy net flow into the oven at both the entrance and exit. Of course, the oven should be hot and fully operational for proper exhaust setup. Similarly, it would be instructive to perform this test using hottest and coolest reflow profiles to ensure that heater module settings do not affect the exhaust conditions for minimal net flow into the oven at entrance and exit. Once the exhaust properties are set, repeat the measurements with dummy boards in the oven and observe whether the properties' presence has an influence on net flow. Fine-tune the exhaust flows and repeat testing as needed. Proper exhaust setting will help achieve consistency in oven reflow soldering and protect plant personnel from exposure to noxious chemical or metal particles generated from the reflow soldering process.

### 47.3.3 Reflow Oven Requirements

**47.3.3.1 Multiple Heating Zones.** Reflow ovens are designed with multiple heating zones at the top and bottom along the tunnel length. Each heater or zone is independently settable to a different temperature and with sensor circuitry for stable temperature control. Note that a zone here is the top and opposing bottom heater pair, as shown in Fig. 47.6. Multiple heater zones allow the required adjustment and shaping of the time-temperature soldering profile necessary for successful heating, activating of flux, reflow of solder paste, and cooling of the soldered assembly. The number of heating zones required depends on the thermal mass of the product being assembled; the more heating zones, the more controllable the reflow process.

**47.3.3.2 Heater Independence.** Zone separation—the influence of one thermal zone upon another—is also essential for controllable and repeatable reflow soldering. One heating zone set to 250°C should have minimal affect on an adjacent zone set to 200°C. There are no set rules for zone separation requirements; however, the greater the zone separation, the more controllable the process. Testing this parameter prior to buying or deploying a reflow oven is necessary for proper process setup. To test, set one heater zone high and adjacent zones lower. Allow the oven to stabilize. Determine conditions that cause the higher temperature zone to influence the lower set-point zones. The lower set zones may rise in temperature above their set point; an indication that the hotter zone is causing uncontrollable temperature rise in adjacent zone(s). In setting the oven for circuit board assembly, avoid the large differential zone-to-zone thermal conditions and stay within the range of safe zone separation as previously characterized.

**47.3.3.3 Temperature Distribution.** Temperature distribution across the width of the tunnel determines the quality and uniformity of heating. Top-quality ovens have rail-to-rail thermal uniformity of about  $\pm 2^\circ\text{C}$ , even for large board widths. Such tight thermal distributions are necessary for controllable and consistent soldering.

**47.3.3.4 Heater Responsiveness.** Another important characteristic of an oven is responsiveness of the oven's heaters and accompanying thermal controller circuitry. As a board or multiple boards pass through the oven, the oven's heat is absorbed by those cooler boards on their way to reflow. The oven has to respond to that net heat loss absorbed by the train of PWBs with their solder paste and components. The thermocouples built into the oven should sense the thermal impact on the tunnel's ambient and the net loss in temperature from the flow of product in the tunnel. It is important not to space the boards too closely together, as doing so will fully segregate the top from the bottom heaters and alter oven performance. The spacing between the boards in a forced-air convection oven must be sufficient to obviate this top-to-bottom divisional isolation of the heater zones. The spacing is dependent on line

throughput requirements and thermal mass of the product design. Board separation may be as small as a few inches, but the effects of board loading and spacing need to be determined empirically and checked to detect any impact on the process time-temperature profile. Any assessment of new equipment ought to include load testing to ensure that the oven can handle anticipated process throughput and capacity. The oven's profile needs to be examined before, during, and after loading of the board train and compared to the performance with the same oven settings for a single board.

**47.3.3.5 Ovens and RoHS.** The onset of the Restriction of Hazardous Substances (RoHS) legislation and the move to Pb-free reflow has implications for reflow equipment. When using ovens set up for Sn-Pb soldering, there are five areas that the process engineer must pay attention to when making the move to Pb-free reflow.

**47.3.3.5.1 Heater Robustness.** Check with the reflow oven manufacturer to ensure that the heater and fan assemblies (heater modules) will be compatible with the rigors of the higher oven temperatures associated with Pb-free reflow. Although an oven may be able to reach the higher temperatures, the heater modules may degrade or fail as a result of running close to their maximum rated output.

**47.3.3.5.2 Over-Temperature Sensors.** Most good reflow ovens are equipped with bi-metallic switches or other over-temperature sensors to prevent catastrophic overheating of heater modules induced by a broken or faulty thermocouple or failing thermal control circuitry. When an oven is set up for Sn-Pb soldering, lower temperature bi-metallic switches are incorporated than when an oven is set up for Pb-free soldering. The lower temperature bi-metallic switches may trip the oven heater circuitry when used with the higher temperatures necessary for achieving Pb-free reflow. This will be most apparent in the highest temperature zone. Check with reflow equipment manufacturer that the bi-metallic switches in an older oven will be compatible with the higher-temperature regimes of Pb-free soldering.

**47.3.3.5.3 Firmware.** In some older reflow ovens, the computer control heater firmware does not allow the heater modules to be set high enough for Pb-free reflow. If the rest of the oven is compatible for Pb-free soldering, check that heater modules are settable for the higher peak temperatures required of Pb-free soldering. A firmware upgrade may be necessary.

**47.3.3.5.4 Seals and Others.** Check with the reflow oven manufacturer that soft seals and other oven components in older reflow equipment will be compatible with the higher temperatures of Pb-free soldering.

**47.3.3.5.5 Vent Stack.** Since vent gases are much hotter when running with most Pb-free solders (due to the higher melting point or melting range of these solders), ensure that all elements of the venting system are compatible with this increase in temperature. This is particularly necessary closest to the oven itself, where vent stack gases are hottest. Check flexible vent ducts, duct seals, flexible vent stack couplings, and stack monitors (manometers, velocimeters, etc.) to ensure that they are compatible or not overheating.

#### 47.3.4 Elements of Reflow

The reflow time-temperature profile is of greatest importance in the oven soldering process. It is the relationship of temperature with respect to time required to bring a PCB assembly to solder liquidus and back to solidus before exiting the oven.

**47.3.4.1 Profile Dependencies.** The solder paste composition, circuit board lay-up (number of layers, board material), component types, component count, and the number of components per unit area on the board will dictate or influence reflow profile characteristics. Oven performance such as heating characteristics (number of heater zones and responsiveness of each module) will dominate the process and profile. Although the requirements of the in use determine each profile, how well the profile is maintained depends on the materials to be reflowed, the heating characteristics, repeatability health of process equipment, and the attention to detail by the process engineer.

**47.3.4.2 Solder.** The solder alloy chosen dictates the peak temperature and time required for reflow and wetting. It may also influence the post-reflow cooling rate chosen, as some solders, especially Pb-free compositions, have preferred cooling ramps.

**47.3.4.3 Flux and Other Solder Paste Components.** As discussed previously, solder paste is typically composed of three main ingredients: solder alloy, flux, and other materials added to help with rheological properties critical for solder paste printing on the PWB. As mentioned, the solder alloy dictates the peak temperature regime, whereas the flux and other constituents dictate the pre-reflow heating ramp rate. Heating too rapidly may prematurely dry out solder paste components. Overly rapid heating may cause the solder paste to spatter. Too little heat may not allow proper activation of the flux. There is no universal profile recipe for reflow for a given solder alloy. The solder paste manufacturer will provide guidance for the time-temperature profile for each solder paste formulation. The reflow characteristics should be consistent from batch to batch for a given paste formulation.

### 47.3.5 The Reflow Profile

There are four distinct steps in the reflow profile that must be accommodated by the reflow oven for successful soldering. Each step must be tailored for the solder paste composition and must be accomplished in proper, controllable, and repeatable reflow equipment. A misstep at any of the four stages of reflow can result in product loss. Refer to Fig. 47.8 for this discussion on thermal profile.

**FIGURE 47.8** Schematic of a generic reflow profile for Sn-Ag-Cu solder paste. Time-temperature values are not precise and are shown for illustrative purposes for a discussion of reflow soldering.

**47.3.5.1 Initial Ramp.** In this step of the reflow time-temperature profile, preheating of the boards, components, and solder paste is initialized. The solder paste begins to lose some of its volatile components and the flux becomes chemically active (activates). If the ramp gradient is too steep, volatiles will be given up too rapidly, boiling will result, and the solder paste will spatter. This can cause explosive solder ball formation and decrease local solder volume, and thus impair bond reliability. Unattached solder balls may form solder bridges between two closely spaced conductors and produce an electrical short circuit.

Overly rapid heating is known to cause component cracking. This is particularly true of ceramic components. To be safe, restrict the ramp rate to between 2 to 4°C/sec., but investigate component manufacturers' specifications as well as the solder paste vendor's recommendation for the maximum allowable heating ramp.

**47.3.5.2 Thermal Soak.** During this step, the solder, board, and components are further heated. The flux from the solder paste flows onto all metal surfaces in which it is in contact, continues to react away surface oxides, and also acts as a barrier to prevent oxidation. The soak is designed to provide the requisite time and thermal energy for the flux's prolonged chemical reaction with oxides and tarnishes on metal surfaces and the solder. Were the flux to activate fully too early in the process, it could dry out or be spent too soon. If its potency is lost, fluxed metal surfaces will reoxidize in the critical moments before the onset of solder liquidus, and solder wetting (alloying) would be inhibited.

### 47.3.5.3 Spike

**47.3.5.3.1 Onset of Solder Liquidus.** In this step, the solder undergoes a phase change from solid to liquid. The liquid metal solder wets onto fluxed metallic surfaces and flows along the component lead-to-PWB pad interfaces drawn by surface tension, capillary forces, and convective flows within the liquid metal. This is the essence of soldering and effective solder-joint formation.

Characterized by a rapid thermal rise, the spike's peak temperature is chosen to be well above the solder's melting point to ensure that all parts of the board, all components, and all solder paste deposits have surpassed solder liquidus onset. As examples, for eutectic Sn-Pb solder, the peak temperature is generally 25 to 40°C above the melting point. For Sn-Ag-Cu solders, the peak is a more conservative 15 to 30°C above the onset of liquidus. The lower temperature coverage for SAC solder as compared to Sn-Pb is due to the higher melting range of the SAC alloy family and the potential damage to components and the circuit board due to the higher-temperature regime needed for reflow. Also, since the temperature is higher than for Sn-Pb, oxidation of heated metal surfaces is more likely, as is solder paste decomposition or charring.

**47.3.5.3.2 Surface Tension Effects.** While the solder is molten, surface tension effects draw component leads into best registration with circuit board pads if the component is light enough to float upon the molten solder. Passive devices (resistors, capacitors, inductors, etc.), most components with formed leads, and plastic or laminate BGAs self-align during this step. Solder surface tension is typically not strong enough to effect self-alignment of heavy ceramic components such as ceramic ball grid arrays (CBGAs) and ceramic column grid array (CCGAs).

**47.3.5.3.3 Intermetallic Compound Formation.** As previously discussed, intermetallic compound (IMC) formation occurs when the molten solder wets to metal surfaces of component leads and PWB pads. IMC thickness is dependent on the temperature and time at or above liquidus. The longer the solder is heated, the thicker the intermetallic layer, and thick IMCs result in brittle bond lines and degraded solder-joint reliability. For this reason, overheating the circuit board during the spike should be avoided. Time-above-liquidus (TAL) should be in accordance with the solder-paste manufacturer's recommendation, which is typically 30 to 60 sec., although there are no hard and fast rules for TAL. A longer TAL for some components may be evidenced on large thermal mass boards that are slow to heat and heat unevenly. In this case, some devices may overheat while others barely reach soldering temperature. Similarly, some component or board metallurgies may be slow wetting and a longer TAL may be necessary.

Hot air solder leveling (HASL) or reflowed tin on copper bond pads possess a thin intermetallic layer between the applied surface finish and the pads. During surface-mount technology (SMT) reflow, the addition of molten solder on top of this preexisting intermetallic layer will further its growth. Therefore, the TAL should be limited to minimize IMC but sufficient for good solder wetting.

**47.3.5.3.4 Materials Degradation.** During spike, board laminates, component bodies, etc., can degrade, so trials should be performed to ensure that all materials are compatible with chosen reflow parameters. If connectors are being applied during SMT reflow, make sure that normal contact force has not been jeopardized by distortion or softening of the connector body during the spike. Inspection of connector contact gaps before and after reflow and comparison to the connector manufacturer's specifications will provide clues as to whether the connector is truly compatible with the reflow process. This is most important during the

transition to Pb-free soldering due to the novelty of materials and questions of compatibility with higher reflow process temperatures.

### 47.3.6 Cooling

The fourth and final stage is cooling. It is here that the board's temperature is lowered beyond that of solder liquidus prior to exiting the oven. Once again, recommendations for device heating-and-cooling ramp rates should be heeded. Most electronic packaging and board materials are reluctant to shed heat quickly. If the board is thick, the laminate, a relatively poor thermal conductor, will remain hot. It must be cooled to below solder liquidus prior to exiting the oven to preclude dislodging of any soldered components or disturbing the solder-joint solidification process. On the other hand, with the trends toward thinner circuit boards, slimmer components, and hot, fast-soldering profiles (to keep up with high-volume product demand), it is wise to ensure that the negative thermal ramp requirements are considered for this step also.

As mentioned previously, the solder paste manufacturer will provide recommended profile guidelines, but those are only a starting point. The process engineer should optimize the reflow oven profile with product profile boards and analysis based on actual product runs. Board profiling will be covered in a subsequent section.

Older textbooks and industrial references cite completeness of fillet formation and solder reflectivity as typical hallmarks of a good reflow process, but these are subjective measures that may not be true indicators of solder-joint quality. As mentioned previously, overheated joints will be brittle although they may appear to be well wetted. SAC and other Pb-free solder alloys have a naturally grainy-looking solid structure as compared to that of Sn-Pb, so a dull solder joint is not necessarily indicative of a poor solder joint. Tests such as tensile pull-peel, shock and vibration, thermal cycling, x-ray for solder void content, and metallographic cross-sectioning are much better means of assessing solder-joint quality. There is yet another implication with the move to SAC solders. If not quenched quickly, this alloy is known to result in some constituent separation. Silver may precipitate out as platelets or needles. This can be minimized by using a fast-cooling ramp. Check with component manufacturer's specifications so as not to jeopardize component integrity.

### 47.3.7 Successful Oven Reflow

Successful soldering is dependent on several factors including suitable, well-maintained, and controlled reflow equipment; good-quality solderable parts; a thermally balanced board designed for the reflow process; a well-tested and reliable solder paste; a proven time-temperature profile; and good thermometry techniques.

**47.3.7.1 Adequately Maintained and Controlled Reflow Equipment.** The oven should have small thermal differentials across the width of the tunnel and should be capable of adequate heating and cooling ramps as well as adequate zone separation characteristics. It should be stable for a given zone setting, not varying by more than a couple of degrees centigrade. Similarly, the conveyor speed should be stable, not varying by more than 1 cm to 2 cm/min.

**47.3.7.2 Good-Quality Solderable Parts.** The best reflow equipment, profiles, and solder paste will not make up for inadequacies in part quality or restore solderability. Good solderable parts and boards are a must for successful reflow.

**47.3.7.3 Coplanarity.** Coplanarity of component leads, BGA balls, or CCGA columns is a must. All component leads should share a common seating plane within the specified tolerances associated with the component vendor's specification. The coplanarity requirement also depends on the dispensed solder paste height and paste deposit uniformity, as the solder paste accommodates some small differences in lead-to-lead coplanarity both as a paste and also as the solder assumes the characteristic dome shape upon melting.

**47.3.7.4 Component Storage.** Extended storage should be avoided and parts should be kept cool and dry prior to use. Sufficient quality control methods should be established to ensure that the solder and components are solderable. Plastic molded parts such as plastic quad flat packs (PQFPs) and plastic ball grid arrays (PBGAs) can absorb moisture from the atmosphere over time. When moisture-laden plastic packages are subjected to reflow soldering, the entrapped vapor may expand to the point where the package fractures, often damaging the silicon die and associated wires internal to the package. This phenomenon is commonly known as *popcorning* throughout the industry. Ensure that plastic packaged components are stored in unopened bags as supplied by the component vendor until time of use. Once the components are removed from the manufacturer's packaging, follow IPC/JEDEC guidelines<sup>1</sup> for useful shelf-life in the unbaked state and any bake-out requirements prior to soldering.

Parts must be suited for the temperature required by the reflow process. Lastly, ensure that component contact or surface finish is compatible with the solder being used, be it leaded or lead-free.

**47.3.7.5 Board Design for Oven Soldering.** Thermal balance of the board design is important for reliable and adequate reflow. Ensure that a design for manufacturing (DFM) review of the board has been done and that thermally massive components are not relegated to one portion of the board. Also, it is desirable to distribute smaller components rather than to create component fields to permit uniform thermal balance across the board. Components should be spaced adequately to prevent shadowing of smaller devices on the board by larger, neighboring components. This is particularly important in IR ovens without the forced-convection option. If the oven is characterized by poor uniformity across the tunnel width, the board should be oriented, if possible, to take advantage of the imbalance; i.e., the board edge with greatest thermal mass should be aligned to the oven edge with the highest recorded process temperatures. Board components should be designed far enough away from board edges to preclude any mechanical interference with the pin-chain conveyor. Since the oven rails can have an influence on the reflow or damage of bottom-side components, leave enough edge clearance on the board to accommodate the pin-chain pin length plus some additional margin in case the board is moved from one reflow oven to another.

**47.3.7.6 Paste and Profile.** The profile provided by the solder paste vendor is only a recommended starting point that needs to be optimized for the reflow conditions and process time requirements. Solder paste with finer solder particles are more troublesome to flux owing to their greater total surface area and corresponding greater surface oxide volume per unit volume of solder.

It is important to limit exposure to high temperatures and particularly time above liquidus, as it is in this regime that the intermetallic layer growth is most vigorous. The thicker the intermetallic layer, the more brittle and less reliable the solder joint will be.

### 47.3.8 Impact of Pb-Free on Reflow Soldering

Although the move to Pb-free soldering represents a major change for the industry, its impact on the reflow process and reflow equipment is minimal. In many cases, reflow ovens used for Pb-bearing solders can be used for Pb-free reflow. There has been concern that Pb-containing dust collected on the tunnel walls, fans, and such could contaminate Pb-free solder, but it is unlikely that the small number of Pb-bearing particles in a properly vented oven will provide enough contamination to exceed the RoHS limit for Pb of 0.1 percent by weight.

As mentioned previously, to permit Pb-free reflow, reflow equipment may require some oven modifications. There is little impact to the reflow process and most of the changes are material related. Because many of the Pb-free solders are slower to wet out on leads and pads, extended wetting times may be required. Many Pb-free solder pastes are more prone to solder void formation. Extended soak (pre-heat) times and slightly higher peak temperatures are known to help with void reduction.

### 47.3.9 Good Thermometry Techniques

Understanding the thermal impact of the oven on the board and the board on the oven is critical for a controlled and reproducible reflow process. Thermometry is the only practical method for validating these influences by means of oven profiling. Oven-and-board interactions are explored in this presoldering step and the oven is adjusted for proper time-temperature profile of the PWB with the parts to be soldered. Some of the most important process points determined through board and oven profiling are:

- Heating-cooling ramps and ensuring that they are within the recommended bounds prescribed in the surface-mount device (SMD) component and solder paste specifications
- Peak process temperature and duration
- Dependency on the heater types, quantities, cooling methods on board, and component materials
- Conveyor speed
- Heat distribution along the oven's width
- Heating characteristics of the PWB and the SMD components upon it
- Rate at which the oven reacts to the board's presence

### 47.3.10 Product Profile Board

All of the preceding and many more variables have dramatic impact on the soldering process. The only way to assess these is to gauge accurately the thermal energy distribution in the oven in the presence and absence of the board. Most process engineers trust their favorite profiling board to determine the health of their reflow oven or assess the performance of a new oven prior to purchase. The profiling board is simply a thermocouple-instrumented product board or test vehicle that is run through the oven for the purpose of determining the oven's effect on the board for given heater and conveyor speed set points. The thermocouples trace the temperature profile of the oven as seen by the component lead or package as the board is conveyed through the oven for reflow.

However, reliance on a product board to determine oven performance may mask some inherent problems with the reflow oven. If the board is not thermally balanced in terms of components or board innerlayers, it may not be able to detect a strong transverse (rail-to-rail) thermal differential. It is for this reason that a balanced oven diagnostic profiling device should be made and run to assess oven performance independent of a product board. That is not to say that the oven diagnostic board is a direct replacement for the product profiling board. The latter is to verify that the critical sectors of the board or, better yet, device leads are heating per set profile. Thermocouples for this board are deployed at the leading edge, trailing edge, center, and sides, with the thermocouple beads ideally embedded within the solder joints of disparate component types. Additional thermocouples can be placed on unusually massive components as well as on adjacent smaller components to determine whether a large component is thermally shadowing its diminutive neighbor. The number of thermocouples deployed depends on the package types, known oven characteristics, board thickness, board layout complexity, etc. The following sections describe good thermometry practices and the oven diagnostic board, as well as some of the thermocouple measuring innovations that are now a routine for large-scale mass reflow manufacturing operations.

**47.3.10.1 Oven Diagnostic Board.** The oven diagnostic board can be a very simple or a rather complex device. Its job is to probe the normal operating conditions of the oven and determine whether all the heaters and forced-convection fans are working properly. It is useful in assessing not only the oven's time-temperature profile parallel to the tunnel's long axis, but also perpendicular to it at the rail edges. The data recorded from this board are not necessarily be translatable to the establishment of a product time-temperature profile, but are more suited

**FIGURE 47.9** Schematic plan view and detailed side view of an adjustable oven characterization fixture (oven diagnostic tool) composed of pairs of thermocouples, shielded from one another by a rigid, heat-resistant insulator. The thermocouple positions are adjustable in width and length for investigating temperature distribution along the tunnel width.

to determining oven performance. The diagnostic board, whether a product board or a separate test board or other device, should be thermally symmetrical. It should be made from a low thermal conductivity material, or better yet, a thermal insulator. It should also be of low thermal mass. Attached to this are thermocouples mounted top-side and bottom in an evenly spaced array across the width of the material. They should be mounted close enough to the conveyor rails to gauge their influence on the thermal profile. Thermocouple beads should be identical in size and spacing from the insulating material. Furthermore, they should also be mounted slightly off the insulating material such that the heated oven environment can freely swirl around them. Measuring with such a device provides a true picture of the oven's thermal environment. Figure 47.9 shows a schematic of one such device developed for oven diagnostics.

**47.3.10.2 Printed Circuit Board Thermometry.** Knowledge of good thermometric practices and thermocouple use is critical to acquiring accurate and useful board time-temperature profiles and oven thermal performance information.

**47.3.10.2.1 Good Thermocouple Practices.** A thermocouple is composed of two atomically disparate metals or alloys in contact with one another. The wires are joined by twisting them tightly together or preferably by welding (Fig.47.10a,b).When both legs of the thermocouple are held at the same temperature and joined at a discrete point, an electronic difference between the two metals results in a measurable voltage. This electromagnetic field (EMF) is temperature-dependent and once calibrated can be used for accurate temperature measurement.

**FIGURE 47.10** Thermocouples: (a) twisted couple; (b) welded couple; (c) welded couple with an inadvertent couple (see arrow).

Thermocouples are simple to make. The two different wires need only touch one another to form the couple. This simplicity in construction can also be problematic. If the two wires inadvertently contact (see Fig. 47.10c), thermocouple output will be related to the temperature at that accidental juncture.

In the case of a thermocouple sandwiched between a component lead and PWB pad (see Fig. 47.11) and an accidental junction formation nearby, the thermocouple will register the oven air temperature rather than the conducted temperature of the component lead, the solder, and the PWB. Since the oven air temperature is generally much hotter than the PWB traveling through it, the resultant soldering time-temperature profile (based on the false thermocouple reading) may be cooler than desired and cold (under-reflowed) solder joints may result.

**47.3.10.2.2 Welded versus Twisted.** A thermocouple wire pair should be welded to help preclude noise-induced measuring errors from intermittent wire pair contact. Small, inexpensive bench-top welders are available for this purpose. The two halves of the thermocouple pair should touch at only one point—that closest to the area desired for temperature measurement. The welded pair has a significant advantage in that the resulting weld bead can be made small and uniform in shape. As a rule of thumb, the weld bead diameter can be made as small as about 1.5 times the diameter of the individual conductors that compose the couple. The temperature will be sensed only at the weld bead. Regardless of whether the couple is made or bought, always check with a magnifier or microscope to ensure the integrity of the bead and that couple wires are only touching at the bead and not at any point below it. During manufacture of a thermocouple assembly, the usual practice is to twist the thermocouple wires together prior to welding. Upon welding, the twisted material will fuse and melt back. After welding, it may be necessary to untwist the pair just behind the bead. Of course, this is risky because many of the thermocouple materials are brittle before welding and are even more so afterward.

**47.3.10.2.3 Most Common Couple.** The most common thermocouple used for PWB soldering application is the “K” type, Ni-Cr/Ni-Al (chromel-alumel) couple, as it possesses a

**FIGURE 47.11** Arrows indicate impinging forced-convection flows from oven blowers. The inadvertent thermocouple junction (crossed wires) will record oven local air temperature rather than the intended measurement target—the solder-joint area.

thermal measurement range best suited for soldering of circuit boards regardless of alloy type. There are two main devices in use for measuring the output of the thermocouple: the reflow tracker and digital thermometer.

**47.3.8.2.4 Measurement Instrumentation.** One of the two most primitive measurement devices is the electronic (digital) thermometer with output hand-recorded or tied to a chart recorder. The other (though much more sophisticated) device is the reflow profiler or tracker, an electronic package that can not only output the time-temperature plot of multiple thermocouples but can also make certain assessments of the data, such as heating ramp rate, pre-heat time, time above liquidus, cooling ramp rate, and other attributes. Tracker systems are computer-based and battery-powered and can generate detailed reports and graphs of a reflow cycle. Most are sold with a thermal protective cover that enables them to travel through the oven, thus eliminating the resistive losses and thermal heat-sinking effects of excessively long thermocouple wires. Some even output temperature by wireless transmitter so that measurement data can be observed in real time.

Once a selected above-ambient threshold temperature has been reached, such as 30°C, the tracker begins recording the experienced thermal environment per unit time. It samples and

records the circuit board's thermocouples at short, programmable time intervals (several times per second) for the entire trip through the oven's tunnel. When the tracker emerges from the exit end of the oven's tunnel, it is removed from its protective thermal barrier and docked to a computer. The data stored in the electronic tracker are uploaded to the computer, conditioned, displayed, reported, and printed for analysis. The user defines the reporting format, including the type of data sought, thermocouple plots, and other relevant, run-related data. Some systems are capable of making predictive corrections to the profile based on current measured conditions and recorded oven settings. This can further enhance the ease of adjusting a complex multizoned reflow oven to meet the requirements of a particular job. Whether a simple or complex model is selected, the reflow tracker is invaluable for setting up the oven and checking process repeatability.

When an electronic tracker is used, its presence in the oven may have an impact on the resulting profile data by affecting the local aerodynamics within the oven. The trackers also have thermal mass, but all trackers are sold with an insulating cover to protect their electronics. It is best to check the influence of the tracker's presence as it traverses through the oven tunnel. To do this, use long thermocouple wires and, once the oven has warmed to a steady-state operating condition, run the profile tracker with the tracker a fixed distance behind the profile board. Note that the tracker is usually placed to follow the board in reflow. Were the tracker to precede the thermocoupled profile board, it might cause the heaters to ramp up as the oven attempts to compensate for the thermal mass of the tracker or compensate from the disrupted or deflected air flow. Although that is what happens during a reflow cycle as a cooler board enters a heated zone of the oven, the oven would attempt to adjust for the board's thermal mass. The added thermal mass or disruption of the air flows from the profile tracker would not be a factor in the normal reflow process.

Rather than assessing the reflow tracker effect on the profile, if you maintain the tracker one board length away from the instrumented board, you can eliminate the likelihood of the tracker having any influence on the measured profile.

**47.3.10.3 The Profile Board.** The profile board is the keystone for any soldering process. It is a board loaded with its complement of appropriate components. Thermocouples are attached to critical locations to ensure that proper soldering temperatures are reached during the bonding cycle. Typically thermocouples are embedded under BGAs (innermost joint and outermost joint) and on fine-pitch and even some passive components. The idea is to ensure that the most difficult, thermally challenging parts are receiving enough heat and that the lightest components are not overheating at the same time. Sometimes it is impossible to achieve the perfect balance, and in such cases the thermal edge is given to the area array components to ensure good soldering beneath while slightly overheating the lighter components.

It is good practice to attach thermocouples to components on the leading edge of the board, the trailing edge of the board, the sides, and the middle. It may take more than one trip through the oven to collect data for all these locations. There is no substitute for a profile board. Some have tried weighing the board for an estimate of thermal mass. Generic profiles with overly hot peak temperatures have been applied and other supposed short-cuts have been attempted. None of these approaches can be 100 percent successful. There is no replacement for preparation and proper thermal assessment with a profile board.

Typically for oven reflow soldering, one profile board is prepared for the secondary-side reflow profile (in which only secondary-side components are mounted), then another for primary-side reflow profile (in which both secondary- and primary-side components are mounted). Another board is prepared for wave soldering (all SMDs loaded plus PTH parts). These boards also double as rework profile boards.

It is wise to attach thermocouples to power and ground pins if that information is readily available. These connection points are the most thermally challenging points for a particular device. This is especially true on thick motherboards where there may be multiply interconnected, thick ground, or power planes embedded within the board, which are slow to heat and slow to cool.

Always allow the profile board and the reflow profile tracking instrument to cool to room temperature before attempting another profile check. Cooling with a fan greatly decreases the wait time.

**47.3.10.3.1 Thermocouple Deployment.** The size and position of the thermocouple are critical for accurate and reliable thermometry. There are many methods for securing the thermocouple bead to the PWB and some simple rules for proper thermocouple use:

- The junction must be in contact with the object to be measured.
- Each of the thermocouple legs must be kept at the same temperature.
- There should be only one junction (the bead) between the two legs of the thermocouple.
- The measuring technique must not interfere with the outcome of the measurement.

**47.3.10.3.2 Thermocouple Contact.** The thermocouple bead must be in intimate contact with the lead and pad combination of the solder joint to be measured. Therefore, the thermocouple bead must be inserted between the device lead and the circuit board bonding pad. It is good practice to tailor the size of the thermocouple wire and, thus, the bead, for the scale of the solder joint to be measured. Flattening the thermocouple bead also helps in positioning it between lead and pad. Flattening can be accomplished with smooth-jaw pliers, a smooth-jaw vise, or a hammer. After flattening the bead, check to ensure that it is neither cracked nor broken (see Fig. 47.12).

**FIGURE 47.12** Checking the quality of the thermocoupling: (a) A good thermocouple deployment. The bead is secured beneath a single lead and held in place with high-temperature solder. (b) The thermocouple is held in place by high-temperature solder but the solder has bridged to multiple leads. Temperature indicated will be that of the entire thermal mass of leads and solder rather than a single lead as in (a).

For BGAs and other area-array devices, it is necessary to drill a very small diameter hole through the board and into the BGA ball or column. This procedure is done with a very fine drill bit slightly larger than the BGA ball. The drill bit should be kept short (slightly longer than the board plus ball thickness) to avoid breaking the bit. It helps to drill the hole location before assembly and then re-drill to remove solder for thermocouple insertion after reflow. An overly hot thermal profile can be used for assembly of the thermal profile board. Drilling into the ball at that time completes the path for thermocouple insertion. As long as the hole diameter is kept small, there is no need to add solder to retain the thermocouple within the BGA. If the hole is kept slightly larger than the thermocouple bead, the radiated air temperature within the hole and around the thermocouple bead should be the same as the ball temperature. A high-temperature adhesive or heat-resistant tape should be used to anchor thermocouple leads to

**FIGURE 47.13** Thermocouple embedded into BGA ball. Leads are anchored to the board with a high-temperature adhesive or high-temperature tape.

the board to keep them in place and to prevent dislodging of the bead from its intended measurement target (see Fig. 47.13). Note that there is no need to seal the drilled hole into which thermocouple is inserted. It is a miniature blind hole largely filled with thermocouple wires. Air transfer within this hole will be negligible.

**47.3.10.3.3 Thermocouple Size.** Many factors can confound the solder-joint temperature measurement process, regardless of whether the thermocouple bead is properly deployed between lead and pad. Among these are the size of the bead and the thermal mass of the thermocouple assembly. In general, the use of finer-gauge thermocouples such as 30 to 36 American Wire Gauge (AWG) (see Table 47.1) is recommended. This will permit insertion between lead and pad even at very fine lead and pad pitches. Ideally the thermocouple bead will be completely within the solder joint to be measured.

**TABLE 47.1** AWG versus Wire Diameter and Anticipated Thermocouple Bead Diameter

AWG	Wire diameter (in.)	Wire diameter (mm)	Bead diameter (in.)	Bead diameter (mm)
20	0.032	0.81	0.048	1.22
24	0.020	0.51	0.030	0.76
30	0.010	0.25	0.015	0.38
36	0.005	0.127	0.0075	0.19

Strive for the shortest possible length of thermocouple wire pair that is practical for the application. Long, large diameter wire may conduct heat away from the solder joint to be measured, altering its true heating nature.

**47.3.10.3.4 Securing Thermocouples: Thermally Conductive Adhesives.** If an adhesive is to be used to hold a thermocouple bead, its thermal conductivity must be taken into account. Most thermally conductive adhesives are not nearly as conductive as metal or solder. The best are filled with high thermal conductivity materials such as aluminum, boron nitride, or other

thermally conductive ceramics. If the thermal conductivity is not high enough, a false thermocouple reading will result. Thermally conductive adhesives are meant to be applied thinly and conductivity depends on bond-line thickness. It is wise to baseline a conductive adhesive against a soldered thermocouple to ensure that it is not insulating and affecting measurement results. Also ensure that it survives multiple reflow cycles and still maintains its thermal conductivity. Were the adhesive to release the thermocouple bead during the process, then measurement data would be useless. Many adhesives will not tolerate the high-temperature environment of soldering or the continuous thermal cycling encountered in trying to adjust a soldering profile. This is especially true with the onset of Pb-free soldering and the higher soldering temperatures associated with the move away from lead-bearing alloys. High-conductivity adhesives are also expensive.

**47.3.10.3.5 Securing Thermocouples: Adhesive Tapes.** Tape should be avoided for holding the thermocouple bead to the board as it is known to be an unreliable technique. Problems arise as the tape heats up and stretches, expands, or even releases from the board, allowing the thermocouple bead to float off its measurement target. The tape also shields the thermocouple and target solder joint from the oven ambient, which is contrary to the task at hand—measuring the effect of the oven environment on the intended solder-joint location.

**47.3.8.3.6 Securing Thermocouples: High-Temperature Solder.** Best practice is to use a high-temperature solder to secure the thermocouple bead to its measurement site. The bead is not really soldered, as the K-type thermocouple wire is not easily wettable. Instead, the solder bead is positioned under a component lead, and the lead is soldered with the high-temperature alloy, merely encasing the bead in the solder.

The chosen high-temperature solder should have melting range or melting point well above the intended peak reflow temperature. An alloy such as 10Sn/Pb (melting range near 300°C) is appropriate as SAC solder melts in the vicinity of 220°C and the peak soldering temperature is generally less than 255°C. Before applying the high-temperature solder, it is advisable to use a fluxed copper wicking braid to remove any solder associated with normal manufacturing assembly of the board, such as SAC or Sn/Pb, as these may depress the melting range of the high-temperature solder.

**47.3.10.3.7 Profile Board Components.** The profile board can be populated with dummy or electrically failed or reject components. The board can be used over and over and should be saved. Once the oven profile has been established and data recorded, a quick check of the oven with the profile board before a soldering run is useful to ensure that the oven is working properly and reproducibly.

**47.3.10.4 Profile Board Spacing.** In ovens with pin-chain conveyors, it is common practice to place the profile logging device (reflow tracker) on a dummy board that is trailed behind the profile board. The distance between the profile board and the dummy board or data tracker carrier should be at least one board length. Thermocouple wire length beyond the thermal profile board should slightly longer than one board length (see Fig. 47.14).

**FIGURE 47.14** The thermal profile board should be kept a distance of about one board length from any dummy board or carrier for the data tracker. This enables the heaters to function properly for a board of a given thermal mass.

Were the two boards abutting, the heaters would try to compensate for a much larger thermal mass and overheat. Heater performance would be much different than during steady-state manufacturing and not give a good picture of heater performance during thermal profile. This rule also applies to thermal profiling at wave soldering.

### 47.3.11 Pin-in-Paste Soldering (Intrusive Reflow Process)

An adjunct to the surface-mount process, this method, sometimes referred to as *intrusive reflow*, allows the soldering of some through-hole (solder-tail) parts into plated-through holes on the circuit board during SMT oven reflow. This process can eliminate or reduce the need for wave soldering—a step prone to defects.

The through-hole components (axially leaded parts, pin-grid arrays, solder-tail connectors, etc.) are inserted into their respective PTHs before or after surface-mount component placement. Once the surface-mount components and the solder-tail parts are placed, the paste-bearing board is then passed through the SMT reflow oven. During the reflow process, the molten solder coalesces around the through-hole pins wetting between the pin and barrel. Surface tension and capillary action draws the solder down the barrel to complete the solder joint.

**47.3.11.1 Solder Paste Deposition for Pin-in-Paste Soldering.** To prepare a board for pin-in-paste soldering, you deposit generous amounts of solder paste over or adjacent to the circuit board's targeted PTH sites. This is done during solder-paste stenciling in preparation for SMD component placement and reflow (see Fig. 47.15).

**FIGURE 47.15** Solder paste stenciling in preparation for SMD component placement: (a) a PWB cross-section prior to solder paste deposition; (b) the same PWB after solder paste deposition. Note that SMD pads and PTHs have received solder paste deposits. In the case of (b), paste has been forced into the PTH by the squeegee during solder paste printing.

Of course, stencil apertures have to be created in the surface-mount stencil to accommodate paste deposition on PTH sites for pin-in-paste soldering. If solder volume is not a concern, it is desirable not to dispense paste into the PTH. This is discussed later in this chapter.

**47.3.11.2 Solder Volume.** The inability to apply enough solder paste to meet standard through-hole solder-joint acceptability criteria is one of the major shortcomings of pin-in-paste reflow. That is why this technique is usually relegated to boards  $\leq 1.6$  mm (0.063 in.) thick. Requisite solder volume is dictated by component pin pitch and the available printing space between component leads; stencil thickness, which is generally limited by the smallest or finest pitch components on the PWB; and PTH volume and associated component lead displacement volume.

Since requisite solder volume for pin-in-paste reflow is a function of the ratio of PTH volume to component lead displacement, it follows that reducing PTH barrel size is advantageous,

especially in the case of thick PWBs. But as the volumetric annulus between lead and barrel is reduced, there is a tendency for excessive void formation. Solder pastes formulated for surface-mount applications consist of solder spheres in a creamy matrix of organic chemicals composed of soldering flux and other materials to help with printing and component placement as required for SMT processing. Voids in the solder are caused by vaporization of solder paste organic components during the reflow process. In an unlikely twist, enlarging a plated-through hole in a thicker board may also benefit the pin-in-paste technique. The paste printing process drives solder paste into the PTH, effectively increasing the solder volume available for joint formation. A double-print cycle forces more paste into through holes. If solder paste is in the PTH, some quantity of it will be displaced as the component's lead is inserted (see Fig. 48.16a).

Upon reflow, the solder generally wets back up the pin (see Fig. 47.16b). Sometimes, though, the solder will form a bead on the pin tip, as seen in Fig. 47.16c). Although electrically it is of no

**FIGURE 47.16** Board sections illustrating pin-in-paste process: (a) A PTH component pin inserted through solder paste squeegeed in and around PTH. (b) At reflow, the solder has melted and wet to pin and component leads. If solder volume is correct, surface tension effects will draw the solder between pin and barrel and a good solder joint will form. (c) The solder paste displaced by the pin insertion has melted into a ball around the pin tip. So much solder was displaced that voids are apparent between the pin and the PTH barrel.

consequence and well adhered since it is soldered, it can interfere with critical clearances (such as aboard to chassis) or impede proper board seating at in-circuit test or in other fixtures.

A solder paste stencil can be made to occlude solder deposition on top of or in the board's PTH, as can be seen in Fig. 47.17.

**FIGURE 47.17** A<sub>0</sub>, B<sub>0</sub>, C<sub>0</sub>, and D<sub>0</sub> are solder paste apertures cut into a conventional stainless steel stencil. Apertures B<sub>0</sub> and D<sub>0</sub> are designed to prevent solder paste from being forced into through holes. Corresponding paste deposits are indicated as A<sub>1</sub>, B<sub>1</sub>, C<sub>1</sub>, and D<sub>1</sub>. C<sub>0</sub>/C<sub>1</sub> and A<sub>0</sub>/A<sub>1</sub> are usual round and square apertures and deposits, and solder paste is allowed to enter corresponding PTHs.

**FIGURE 47.18** Solder-joint defects can result from uneven solder distribution: (a) A solder-starved pin-in-paste solder joint showing large void; (b) a good pin-in-paste solder joint showing nearly 100 percent barrel fill and no voids. (Courtesy of Hewlett-Packard).

Stencil designs that preclude solder paste from entering the PTH also result in a significant reduction of solder paste on the top surface and in the PTH. These reductions may make the pin-in-paste technique impractical for some boards. If the solder volume is too low, the available solder distributes unevenly around the PTH pin and the PTH barrel, resulting in voids and inferior solder joints (see Fig. 47.18a, b).

A normal incident x-ray will highlight circumferential voids in PTHs, as evidenced in Fig. 47.19.

**47.3.11.3 Pin-in-Paste on Thick Boards.** Since the solder volume increases proportionately with increasing board thickness, pin-in-paste soldering is best suited for thin PWBs ( $\leq 1.6$  mm). The technique is limited by available solder and required solder volume for proper barrel fill. There are two ways to deal with the added volume.

**FIGURE 47.19** A normal incident x-ray photo of a connector. The light spots around the pins are areas of no solder or voids (reduced solder thickness). (Courtesy of Hewlett-Packard).

**FIGURE 47.20** Application of solder pre-form foil washer to augment pin-in-paste solder volume. Note that the flux from the solder paste is sufficient for pre-form soldering.

**47.3.11.4 Addition of Solder through Pre-Forms.** Solder foil pre-forms (stamped solder foil) can be added to through-hole parts to augment solder volume (see Fig. 47.20). This approach is expensive and application of the pre-forms is tedious and time-consuming.

**47.3.11.5 Buried Intrusive Method.** There is a new method for formation of a somewhat nonstandard solder joint in thick PWBs.<sup>2</sup> A foreshortened pin, on the order of that used for a board 1.6 mm in thickness, is used in the thick board. So, too, solder volume is treated as if for a board 1.6 mm thick. When the solder melts, it coalesces and wets to the pin and barrel as in any through-hole soldering process. Conventional thinking would have the molten solder running through the barrel and out the bottom side of the board. Instead, nearly all the solder is retained by surface tension forces around pin and barrel. If the solder volume is calculated properly and aptly delivered, there is 100 percent pin wetting both longitudinally and circumferentially (see Fig. 47.21). Accelerated thermal cycling followed by tensile testing has shown that resultant solder-joint reliability is sufficient and equivalent to conventionally formed pin-in-paste or wave-soldered joints of twice the pin-wetted length.

**47.3.11.6 Temperature Compatibility.** If pin-in-paste soldering is to be used, check that components are temperature-compatible with the oven reflow process. The high temperatures and long exposures associated with oven reflow soldering may cause unsuited molded component bodies to melt or warp. Connector contact normal force may be affected if the molded connector body softens or distorts. Solder joints or wire bonds internal to some devices may become disbonded, and some, such as electrolytic capacitors, may leak or even explode as a result of an oven reflow cycle. Check the component manufacturer's specification for thermal limits and compatibility with oven reflow soldering.

**FIGURE 47.21** Cross-sectional micrograph showing pin-in-paste buried intrusive soldering. Note that very little solder has drained.

## 47.4 WAVE SOLDERING

Once the predominant method for mass assembly of circuit boards, wave soldering has taken a back seat to oven-based reflow soldering. The ease of surface mounting led to a rapid rise in popularity of oven-based technology, and proliferation of surface-mountable packages has led to a decreased reliance on wave soldering. Nonetheless, through-hole componentry persists and mixed-mount (surface-mount plus through-hole) technology still may be the only alternative for some assemblies, and it is unlikely that wave soldering will disappear from PWB manufacturing in the short term. Since wave soldering, compared to reflow soldering, is fraught with defects, it behooves the designer and assembler to minimize the number of PTH components on a board.

### 47.4.1 Wave-Solder Process Basics

Wave soldering utilizes a reservoir of molten solder pumped and circulated to form a standing wave. The circuit board is prepared with devices for wave soldering in one of three ways:

- Coarse-pitch surface-mount components, especially passive devices, are affixed to the bottom side of the PWB using surface-mount adhesive. The adhesive is cured prior to wave soldering. The adhesive is in contact with the body of the component, which is aligned with its respective pads on the circuit board in preparation for wave soldering.
- Solder-tailed components—such as connectors, PGAs, or other through-hole devices—are inserted into PTHs from the top side of the board.
- Solder-tailed components such as axially leaded devices are inserted from the top side of the circuit board, whereas the leads are clinched on the bottom side of the board.

The circuit board is placed on a motorized, edge-hold conveyor where it is fluxed, then preheated both to activate the flux and give the PWB a thermal boost. The board is next skimmed over the crest of the molten solder wave. Only the bottom of the circuit board is exposed to the molten solder (see Fig. 47.22).

**FIGURE 47.22** Schematic of a board going over a solder wave. The board is conveyed over the pumped standing wave of molten solder. Only the secondary side of the board is exposed to the wave. The wave height is set to contact the bottom of the board very slightly.

When exposed to the wave, the adhesive-attached surface-mount devices pick up solder on their metal contacts and the solder bridges from the contact to its corresponding bonding pad on the bottom side of the PWB. In the case of solder-tail components, the molten solder is drawn by capillary action between the lead and the PTH barrel. If the barrel and lead are hot enough and well fluxed, the solder fills up the barrel and wick to form fillets from pin to barrel. As the board continues past the wave, it cools, solder solidifies, and joint formation is complete.

One attribute of this process is the speed at which solder joints are formed. Much quicker than oven reflow soldering, the wave-solder process allows little time for preheating, fluxing, and solder-joint formation, which also explains the variability of this process.

#### 47.4.2 Wave-Solder Machine Subsystems

There are five basic subsystems of a wave soldering machine, including conveyors, fluxers, preheaters, solder pots with pumps and heaters, and ventilation. If alcohol-based fluxes are being used, it is wise to install a fire suppression system also.

**47.4.2.1 Conveyor.** As for the reflow oven, the wave solder machine is generally equipped with a mechanized, speed-controlled conveyor to transport the board through the soldering process. In the case of wave soldering, the board is always held by a width adjustable edge-finger conveyor, which grabs the board by its edges and neither occludes solder exposure nor interferes with wave dynamics. The stainless-steel edge fingers need to be cleaned routinely to avoid flux build-up.

**47.4.2.2 Fluxer.** The fluxer is responsible for delivering a uniform application of soldering flux in a sufficient quantity for solder-joint formation. The short preheat and liquidus times characteristic of the wave-soldering process dictate the use of slightly stronger fluxing agents

than are used in reflow soldering. Although this is the case, the vast majority of wave solder applications have migrated to the use of no-clean fluxes. For the flux to do its job, it must be heated to an ample temperature to permit best reactive conditions without drying or denaturing it. For the sake of economy, the thinnest flux application is deposited. The flux quantity has to be sufficient to remove oxides from the PTH barrels, solder, and component leads. On the other hand, since post-wave solder no-clean flux residues can confound in-circuit test probe contact, the thinnest application that still permits adequate fluxing is recommended.

Flux quantity may also be of concern in the wave-soldering process for yet another reason: fire hazard. Flux-laden boards are preheated going into the wave. If the flux application is too heavy, the flux may drip onto preheater elements. This may cause the flux to volatilize rapidly, combine with oxygen in the atmosphere, and provide the right conditions for flame initiation. Even if there is not direct exposure of the liquid flux to preheaters, if the quantity of volatile, flammable components is high enough to be an ignition source, then an explosive condition may develop. With the advent of more eco-friendly, water-based fluxes, fire hazard is less of a concern.

Foam and wave fluxing have given way to spray fluxing as the predominant flux application method. All three techniques are discussed here.

**47.4.2.2.1 Foam Fluxer.** Foam fluxing is accomplished by pumping and aerating a stream of liquid flux through a porous metal nozzle, a fritted glass, or porous stone. The nozzle, also called a *chimney*, shapes the flow of the aerated flux. The board to be soldered is run over the foaming flux and then heated to activate the flux before reaching the solder wave. As it moves past the solder wave, the solder wets to solderable metals and solidifies to complete the soldering process. Foam fluxing is particularly effective for soldering of PTH assemblies. Surface tension draws the foam into the PTH barrels, just as is the case with solder. The resulting flux deposit on the pin and barrel is thin and uniform.

**47.4.2.2.2 Wave Fluxer.** The wave fluxer works much as the solder wave itself. The printed circuit board is moved over a standing wave of solder flux. The height of the wave and depth of the board penetration into the wave are adjusted to allow for proper flux application thickness. Capillary action, as in all the fluxing methods for through-hole components, draws the flux into interstice between component lead and the barrel. As with foam-fluxing, it is difficult to control the amount of flux delivered. For the most part, flux applied for wave soldering is largely removed by the turbulence of the solder wave; however, it is possible to bake on the flux if the preheater temperatures are set to too high. This may impede fluxing, and the residues can even preclude otherwise solderable contacts from the solder during initial contact with the wave.

**47.4.2.2.3 Spray Fluxing.** Because of its economy and accuracy, spray fluxing has grown to be the predominant technology. Precise amounts of a low-solids flux can be applied generally to a board or can be selectively delivered to small areas of the board to be soldered. There are two principal methods of spray fluxing: air-spray and ultrasonic. Both are effective and well tested. Ultrasonic methods minimize flux volumes consumed in manufacturing.

If not set properly, spray fluxing may result in a flux-laden airborne mist that deposit wherever the air or process gases carry it. Flux contamination of edge-card gold fingers and connectors is most notable. This can disrupt proper electrical contact when a daughter-card is inserted into a connector. It is wise to cover any exposed gold fingers with an acrylic adhesive polyimide tape<sup>3</sup> or other shielding to prevent contact fouling.

**47.4.2.2.4 Fluxer Maintenance.** As fluxes are exposed to the atmosphere, they are vulnerable to evaporation of the volatile constituents. This is the case even with water-based fluxes. Evolution of volatiles is significantly enhanced in systems such as wave-fluxer or foam-fluxer, where the flux is open to the atmosphere or processing environment, has significant exposed flux surface area, and is constantly being recirculated. Therefore, the flux needs to be monitored and maintained. Although some automatic systems are now available, most require routine measurement and adjustment of the flux's specific gravity with a hydrometer. Flux thinner must be added to restore the specific gravity to compensate for evaporative losses. In addition, the volume of the flux in the system must be adjusted to the proper level. The fluxer must be maintained to prevent impact on process yield. The flux manufacturer can

provide information as to the specific gravity-per-flux target and also recommend an appropriate thinning formulation.

The flux reservoir should be emptied, cleaned thoroughly, and refilled with a fresh charge of flux periodically. Sometimes the flux develops a residue that changes the flux's surface tension characteristics, clogs nozzles, or dispenses pores in foaming systems. In addition, flux may become contaminated with debris conveyed by the PCB to be soldered, which may impact assembly quality. Since the PTH relies on a minute capillary to be filled first by flux and ultimately by solder from the solder-wave process, any small particulates entrained in the flux or the solder may impede PTH barrel fill. Also, while the flux reservoir is empty, it is a good idea to inspect it to ensure that the materials of construction are holding up to the rigors of system operation and prolonged contact with fluxing agents that may prove corrosive in the long term. An inspection of the materials of construction for the entire system should be made prior to committing to the purchase of a wave-soldering machine. Unfamiliar or untested materials should be avoided unless there is sufficient literature, test results, or customer experience to ensure compatibility with fluxes that will be used in that system.

### 47.4.3 Preheating

Preheating the PWB and components serves three purposes in the wave-soldering process:

- Helps the board and components reach a temperature sufficient for the flux to activate and clean surfaces to be joined in preparation for wave soldering
- Lessens thermal differentials and decreases the likelihood of components cracking due to thermal shock when impacted by the intense heat of the molten solder wave
- Allows the board to ramp quickly to solder-melting and -wetting temperatures when it comes in contact with the solder wave

A component's resident time in the solder wave is 10 to 30 times shorter than for a comparable solder joint formed during reflow oven soldering, so everything in wave soldering has to happen very rapidly. On the other hand, heating time-temperature ramps must be observed in accordance with the component manufacturer's specifications. Components and PWB bonding pads must be fluxed sufficiently to allow adequate solder-joint formation, yet there must be enough flux left on the circuit board after preheating to protect the newly fluxed surfaces until the assembly reaches the solder wave.

Just as in the reflow soldering oven, there are multiple solder-wave preheater styles, but only two are in prevalent use: radiant preheaters (direct and indirect IR) and forced-air convective preheaters. Both are effective and both have their advantages. In fact, the best configuration is a combination of the two. Some wave-soldering machines can be equipped with both top and bottom preheaters. This can be advantageous for thermally massive boards.

### 47.4.4 The Wave

Numerous solder-wave configurations are available. Rather than provide a detailed discussion of each, this section offers a basic overview of the elements of the process in relation to the wave. As previously mentioned, the molten solder is pumped to form a standing wave. This is accomplished by a spinning impeller on the bottom or side of the solder reservoir. Once the solder is molten, the impeller motor is activated and the solder wells up between baffles and nozzle that reside within the solder reservoir. A combination of impeller speed and baffles-and-nozzle configuration dictates overall standing-wave characteristics. The nozzles and baffles are generally adjustable, as are impeller speed, molten solder temperature, board introduction angle, and board conveyor velocity. These, along with preheater settings, define the profile parameters or process variables that must be tamed to accomplish high-yield wave soldering.

Since the solder is a molten, turbulent liquid, theoretically it can make intimate contact with the underside of the circuit board. Therefore, thermal uniformity is generally not difficult to control as long as the wave contact area along the width of the PWB's underside is uniform. Since the solder is in contact with the underside of the PWB and since the underside of the PWB is coated with flux, the molten solder has the opportunity to wet to PWB lands and component leads. As the process progresses, the solder wicks between the pin and barrel. After leaving the wave, the board cools rapidly, liquid solder solidifies, and solder joints result.

#### 47.4.5 Wave-Soldering Accessories

Solder-wave manufacturers have devised a number of options that may be helpful to the process. Some of these have extended wave-soldering capability to allow finer-pitch soldering or have permitted wave soldering of thicker PWBs.

**47.4.5.1 Gas Knife.** The gas knife—more commonly called the air knife—directs a high-velocity stream of heated air or nitrogen at a glancing angle to the bottom side of the board directly after the board emerges from the wave. It can be effective in relieving solder bridges from tight interstitial pin fields or closely spaced passive device fields. When the gas knife is used with air instead of nitrogen, increased rates of dross formation may result. Also, if the angle is wrong and the velocity is too high, the exit gases could disrupt the solder wave, resulting in solder opens or shorts. If it is set too cool, the knife will have little effect or may exacerbate solder bridging. Since the advent of the air knife, there has been less dependence on the teardrop-shaped trailing pads used to minimize trailing edge solder bridges.

**47.4.5.2 Sonic Assist.** Although not in common use, another accessory imparts high-amplitude sonic pulses into the solder wave. This can help drive solder into PTHs and increase wetting, especially on thick printed wiring boards. Care must be taken during setup, as very high amplitudes may pump so much solder up the barrel that it may result in topside solder bridging or solder splashing. This feature can help with barrel fill on thick PWBs. Its value is limited, since it does not affect board heating, which is the primary factor in barrel fill.

#### 47.4.6 Wave-Solder Diagnostics

As in all cases of mass soldering, the use of a product-specific, fully populated time-temperature profile board is necessary to ensure that critical areas of the board to be soldered are maintained at proper temperatures for each stage of the process. Topside SMT component solder joints must be kept well below the melting point of the solder used to join them to the PWB. At the same time, PTH barrels and PTH components must surpass liquidus temperature to guarantee sufficient wetting and capillary rise of the molten solder. With the complexity of today's mixed-mount boards, this is more of a challenge than ever. A profile board should be constructed and instrumented just as for oven reflow soldering, but thermocouples should be attached to both sides of the board and monitored simultaneously during the wave-solder profile run. Topside SMT solder joints should be monitored to ensure that they stay beneath the reflow temperature of the solder alloy being used. Connector bodies should be monitored to ensure that they are not overheated. Generally, for 63Sn/Pb solder, a temperature of approximately 120°C is chosen for maximum preheat to preclude reaching reflow temperature (183°C) on the top side of the board when the board touches the molten wave. Of course, this thermal limit varies greatly with board size, thickness, component type, number of board layers, number of connections to inner planes, thickness of inner planes, component layout density, etc. In the case of Pb-free solder, the preheat temperature should be about 50 to 70°C less than the liquidus temperature of the soldering alloy used for SMT. The use of wave pallets (shields) in the context of selective wave soldering will be discussed later.

In addition to the profile board, there are numerous useful diagnostic tools commercially available for dynamically measuring the wave height and wave contact area and assessing resident time in the wave for a given conveyor speed.

#### 47.4.7 Dross

Hot solder is prone to rapid oxidation at the air-liquid solder interface. Although the wave is in constant motion, the solder is actually flowing beneath a thin, stationary, plastic film of solder oxides. In Sn/Pb, Sn-Cu, or Sn-Ag-Cu systems, the skin is composed chiefly of tin oxide but also contains oxidized traces of other alloy constituents or contaminants. The oxide skin on the surface of the wave and atop the solder in the reservoir is called *dross*. The dross has a beneficial aspect in that it helps to limit oxidation of the recirculating solder in the solder pot, but it also interferes with solder-wave dynamics.

When adjusted properly, the board meets the crest of the wave and disrupts the oxide skin. In doing so, the fluxed components and board are immersed in the flowing, oxide-free molten solder. If all steps are carried out properly, the solder alloys with the fluxed, oxide-free component leads, component pads, and PTH barrels. Upon exiting the wave solder machine, the assembly cools below the solder liquidus temperature and solder joints are formed. The more the system is used to solder boards, the faster the contamination and dross build-up.

**47.4.7.1 Impact of Dross.** Dross is of concern from three points of view:

- **Dross's impact on the process** Dross is solder lost from the manufacturing process.
- **Economics of dross** In high-volume manufacturing, the amount of solder lost to dross can mean hundreds of dollars of lost solder per week per machine. Of course, the actual cost depends on machine use, solder alloy, and quantity of boards soldered. However, the dross can be returned to some solder foundries for recycling.
- **Sn drift** Excessive dross on the surface of the solder can disrupt normal wave dynamics. In the case of Sn/Pb solder, Sn oxidizes more easily than Pb. The solder can become Sn depleted over the long term. This is known as Sn drift. The same is true of Sn-based Pb-free solder alloys, but since some alloys are nearly all Sn (SAC305 with 96.5 percent Sn by weight), this effect will be less dramatic. However, other Pb-free alloy perturbations such as dissolution of Cu become much more important. For example, in the case of the eutectic Sn-Cu alloy, the copper content is only 0.7 wt percent. Small changes in the copper content by means of copper dissolution of copper pads on the board can have a dramatic effect on the melting temperature of the solder.

**47.4.7.1.1 Dross-Related Process Defects.** Dross can generally change the dynamics at the wave-land-lead interface, discouraging adequate pull-back of the solder and encouraging defects. Molten solder droplets can become entrapped in the dross as a result of wave turbulence and mixing of the oxides with the molten solder. Once oxidized, they are unable to rejoin solder in the reservoir. As the dross passes through a PTH pin field intended for soldering, it is raked by the pins; the pins acting as a strainer. The dross containing liquid solder can hang up on the pins and cause shorting (an effect known as *drossy shorts*). This dross-thickened layer can also block the solder wave from effectively contacting PWB land and component lead, and opens (skips) result.

**47.4.7.1.2 Taming Dross.** Various schemes have been devised to control dross, such as co-mixing the pumped solder with a mineral oil, which floats to the surface, blanketing the solder from the atmosphere. Liquid reducing agents can be added to the solder as well as fluxes. In the long term, none of these has proven popular. The most popular method of dealing with dross is manually scooping dross from the surface of the solder reservoir with a ladle. Machines that vacuum dross are also available.

Inerting is effective in reducing dross formation and ensuring best fluxing from no-clean or other weakly activated fluxes. Nitrogen as a cover gas has become the most effective method

of dross management. R. Iman et al.<sup>4</sup> have explored the use of formic acid in gaseous form as an additive to the nitrogen atmosphere for the soldering process. The fundamentals of this process were demonstrated by H. H. Hartmann,<sup>5,6</sup> who had shown formic acid to be an effective gaseous fluxing agent for soldering. Dross forms when the solder is exposed to the atmosphere, so limiting atmospheric contact limits dross production. As mentioned previously, nitrogen blanketing of the solder pot and the wave will help in this regard. Another simple but effective method is to turn off the wave pump(s) when the solder wave is not in use.

#### 47.4.8 Metal Contaminants

Metal contaminants can also affect wave soldering. These stem from two sources: contaminants from the bar solder used to charge the solder pot, and, to a greater degree, from the materials joined during the soldering process. As the hot, circulating wave washes over component leads and PCB through-hole lands and pads, materials are dissolved into the solder. Even if leads and pads are solder-plated or solder-dipped, there is the opportunity for adulteration of the solder in the reservoir, dependent on coating composition, thickness, and underlying basis metals and impurities within surface finishes as well as resident time in the wave and wave temperature. Copper, gold, silver, additional tin or lead, and intermetallic compound precipitates are all common contaminants derived from the slight dissolution of component lead and pad or coatings thereon during soldering. See Chap. 46 for discussion of these metals in the solder process.

Solder reservoir contamination can have significant process impact, eventually altering melting range of a solder, injecting particulates into solder joints, and altering wetting characteristics. This may lead to an increase in shorts or opens or even result in solder-joint embrittlement. The composition of the wave reservoir can be assayed by a testing service to determine its impurity content by scooping a small amount of solder and checking its solidus and liquidus points (melting range) against a pure standard. This method is less accurate than chemical analysis for contamination assessment and will not be adequate for detecting the presence of some impurities such as intermetallic precipitates that may not affect the solder alloy composition.

Excessively high temperatures in the solder reservoir and low speeds through the wave should be avoided to limit dissolution of component leads, PWB pads, and PTH barrel materials.

Note that the solder wave is maintained at fairly high temperatures, generally 245 to 265°C, depending on the solder alloy, but board exposure is short (2 to 10 sec.). Compare this to oven reflow, where time above liquidus is typically 30 to 90 sec. As in oven reflow, thermal shock in wave soldering can lead to component cracking or degradation problems, so the preheating rate should be tempered to match component vendor recommendations—sometimes to as little as 2°C per sec.

Bar solder impurities such as aluminum, gold, cadmium, copper, and zinc can increase surface tension of the solder and make the process more prone to bridging. D. Bernier<sup>7</sup> reviews some of these contaminant effects and describes empirically derived impurity limits.

#### 47.4.9 Hygiene

Airborne tin, lead oxide fumes, and other metal particulates are unhealthy to breathe. Risks associated with lead oxide intake are well documented, but inhalation of any particulate should be considered potentially hazardous. The health risks associated with working with Pb-free alloys are not as well known as those of the Sn-Pb system. With any alloy, precautions should be taken, especially during wave-solder system maintenance procedures, to preclude particulate inhalation. Donning a personal particulate mask and washable or disposable outer garments (contamination suit) is recommended. Proper hygienic venting of the work area, not only during maintenance procedures but for normal soldering operation, is necessary.

#### 47.4.10 Design for Wave Soldering

In most factories, defect levels at the wave step are higher than those for the oven mass reflow process. The defects are related to poor process setup, poor process control, inadequate PWB design, or any combination of the three. Although wave soldering has been around for a long time, it is still not very well understood, due mainly to varying machine configurations and number of process variables.

Many wave designs are available from the various wave-solder machine manufacturers. There are wave machines that provide multiple smaller, turbulent wave(s), which are best for leadless components such as surface-mount passive devices (resistors, capacitors, etc.). Smoother-flowing waves are recommended for components with leads and through holes as well as coarse-pitch surface-mount devices. Wave dynamics are dictated by process values as well as the materials in contact with the wave. As the solder wets to the circuit board materials, solder wetting contact angle and solder viscosity imposes wave peel-off characteristics (see Fig. 47.23).

**FIGURE 47.23** PWB passing over a solder wave. Note the tendency to pull a web of solder from the wave as the board passes over. The solder-wettable lead-pad combinations become one with the wave as the board passes through it. Good soldering relies on flux-aided wetting and the ability of the solder web to break cleanly from the wave when surface tension forces are exceeded as the board moves away from the wave. (Courtesy of Alpha Metals, Inc).

The hot-air knife, as previously described, is sometimes useful in removing unwanted solder bridges from between component leads while the solder is still molten. This is especially useful in connectors and PGAs with interstitially arrayed pin fields (see Fig. 47.24).

As the wave moves through this frustrated interstitial pin field, areas in which fluid flow stagnates may occur and opens or insufficiently soldered pins may result. In addition, the interstitial pin field may not drain solder well enough in other areas, causing solder bridge formation. Numerous wave designs are aimed at improving the soldering yields of these large packages, but there is no clear choice in wave style for all applications.

In designing circuit boards for the wave-soldering process, it is important to anticipate the flow of the wave over the bottom surface of the board. Placing tall components in front of short component fields should be avoided and component spacing should be maximized; otherwise, solder from the wave may be blocked from washing over the targeted joining area. The taller component may shadow the flow of the wave, causing areas of flow eddying or stagnation in the vicinity of shorter components behind it. Also, via placement should be as far away from the leads as is practical to avoid the aforementioned problems of re-reflow.<sup>8</sup>

**FIGURE 47.24** Circuit board segments with (a) an orthogonally arrayed connector PTH pattern and (b) an interstitially arrayed connector PTH pattern.

Component spacing from the edge of the board is dictated by wave flows and the surrounding structure. F. W. Kear’s review<sup>9</sup> of the thermal aspects of through-hole solder-joint formation offers a glimpse of the physical phenomenon of the wave-soldering process.

**47.4.11 Wave-Solder Pallets**

The pallet, selective soldering pallet, or shield is a masking device meant to shield certain secondary (bottomside) components or features of the PWB during the wave soldering process. On its topside are a recessed nest for the PWB and retention features to hold the PWB within the nest. There are cutouts that expose those areas to be soldered to the flux and the standing solder wave (see Figs. 47.25 and 47.26).

**FIGURE 47.25** (a) A wave-solder pallet: (1) a PWB with PTH connectors; (2) PTH axially leaded resistors; (3) BGAs. (b) A pallet with cutouts for PTH components. It also shields BGA via pattern and other components and features on the bottom side of the PWB. (c) A PWB nested in a pallet. Dashed lines indicate areas in the pallet that were cut out to expose the bottom side of the board to the wave. (d) A masked board passing over the solder wave, showing open and shielded areas.

**FIGURE 47.26** A wave-solder pallet for a PWB. The light areas are cutouts that allow the component solder-tails to come into contact with the solder wave. The dark areas shield the board, component vias, and critical components from the wave. (Courtesy of Hewlett-Packard).

The typical wave solder pallet is made of a nonwetting, electrostatic discharge (ESD)–safe, thermally insulating material such as Delmat or another high-temperature epoxy-glass composite.

**47.4.11.1 Pallet Uses.** A pallet may serve several purposes, including the following:

- Bottomside SMD solder-joint protection
- Via and via field shielding from solder<sup>10</sup>
- Edge card finger shielding from solder
- Press-fit connector site shielding
- PWB distortion prevention
- Test-point protection
- Plated chassis hole protection

**47.4.11.2 Wave-Solder Pallet Design.** Although the wave solder pallet can prevent damage to a board, if not designed properly it can also interfere with soldering. There are only a few rules governing wave pallet design:

- **Limited pallet thickness** The pallet must not be too thick. The design must not hold the board so high as to preclude the molten solder wave from contacting areas to be soldered.
- **Largest possible pallet openings** Pallet openings should be as large as possible for good PCA preheating and to permit free access of the molten solder to the targeted areas of solder-joint formation.
- **Clearance between cutout walls and component pins** Clearance must be provided between the edge of the pallet opening and the component pins to be soldered. If the pins are too close to the pallet opening wall, the wave may not contact the pins. Further, the pallet is somewhat of a thermal sink and inhibits the thermal rise necessary for soldering.
- **Board locks and overclamps** Board locks to clamp the board into the pallet are useful. If none are included, the PWB will float up when contacted by the wave. Overclamps may be

needed to keep the board tight against the pallet during the wave-solder process. Over-clamps are also useful to hold connectors and other nonclamped parts from buoying up when contacted by the wave. Care must be taken that the overclamps and board locks are not so massive or otherwise interfere with preheating of the board.

- **Pallet support** The pallet design should include enough areas of support under the board so that a thin, large PWB will not sag as it traverses the wave.
- **Bevel cutouts** Cutout openings should be beveled to aid in the hydrodynamics of the wave, ensuring that the wave smoothly enters and exits each cutout.

#### 47.4.12 No-Clean Flux Residue and In-Circuit Test

During wave soldering, most of the flux from that process is consumed or washed off the bottom side of the board when in contact with the molten solder wave. However, if no-clean flux residue seeps between the pallet and the board, it will not be removed by the wave process. Any remaining residue, if covering in-circuit test pads, may be an impediment to proper in-circuit test probe contact. Care should be taken to minimize flux deposition for wave soldering. In terms of board design, test pads should be moved as far from intended wave-solder pallet openings as possible.

#### 47.4.13 Designing PWBs for Wave Soldering

Complex PCAs with BGAs and fine-pitch SMT components on boards thicker than about 2.36 mm (0.093 in.) may be difficult to wave-solder if care in layout is not observed.

- **Use appropriate heat relief** It is good design practice to use appropriate heat reliefs (e.g., spoked pads) to provide electrical conduction but limit thermal conduction from the PTHs to ground or power planes internal to the board (see Fig. 47.27). This will enhance heatup of the PTH and limit thermal sinking to the ground or power planes and thus also enhance PTH barrel fill if process parameters are correct.

**FIGURE 47.27** Schematic of a thermal relief feature within a PWB. The spokes connect to the PTH to the conduction plane and limit thermal transfer. The limited thermal path enhances heating of the PTH for soldering.

- **Limit the number or plane attachments** Where possible, limit the number of ground or power plane attachments to a PTH barrel. Each attachment point will result in thermal dissipation into the copper plane. This lost heat will detract from the soldering process making the job of pre-heating and solder wetting all the more difficult.
- **Cluster components and provide clearance** Group wave-soldered PTH components together. Avoid interspersing nonwave soldered SMD components within PTH fields. Conversely, avoid designs that place an isolated PTH component amid a field of SMD components. Such a placement requires a small wave pallet opening that inhibits solder-wave fluid flow, pre-heating, and wave contact.
- **Place the components properly in relation to edges and use selvage edges** When possible, avoid placing PTH components directly against the edge of the board. There must be clearance from the board edge to the pallet to allow the board to nest within the pallet. A selvage edge (a removable and disposable board edge extension that is part of the board itself) can be designed into the PWB (see Fig. 47.28). After wave soldering, the selvage edge can be removed by rotary cutter or routing. Note that post-solder routing is not preferred, especially for no-clean soldered assemblies. The abrasive router dust may remain within connectors and scratch connector contact surfaces or mating connector contacts. The vibration from routing may also affect the reliability of certain components.

**FIGURE 47.28** Board schematic showing a removable selvage edge, a disposable edge to enable wave soldering of the PTH connector near the true edge of the board.

- **Avoid double-sided wave-soldered PTH components** Double-sided wave soldering is generally fraught with defects. Determine whether SMT or press-fit technology can be used to replace a second wave-soldering operation. The industry-standard preference is to restrict all wave-solderable components to one side (components inserted through the primary side) of the PWB.
- **Do not place components near gold fingers** Clearance from gold fingers is required so as not to contact the gold fingers with solder. The gold finger should be away from the pallet nest edges. Covering the gold fingers with an acrylic-based high-temperature adhesive tape will help to keep solder and flux from the gold fingers. The tape is not an effective mask if exposed directly to the solder wave.

## 47.5 WAVE SOLDER DEFECTS

There are many types of wave-soldering systems, each with its unique advantage as claimed by the manufacturer. The soldering engineer has to assess these improvements as they relate to the type of assembly being soldered. The technology has matured significantly, but the degree of equipment complexity attests to the complexity of the process. There are many process variables associated with this operation. If these are not understood or properly controlled, wave-soldering defects such as skip soldering (electrical opens) and bridges (electrical shorts) will occur as in any other soldering operation. Another important defect is the influence of secondary-side wave soldering on primary-side surface-mounted components. If parameters are not controlled properly, it is possible to cause primary-side SMDs to reach reflow temperatures. This can induce

solder opens, shorts, or solder-starved joints. This phenomenon is most commonly associated with thin, densely populated, double-sided PWBs with fine-pitch surface-mount devices such as quad flat packs and BGAs soldered to the primary side of the board. Thermal conduction from the wave through the board itself, through electrical vias and along electrical traces in and on the board, may provide enough heating to cause previously soldered parts to reflow again. Solder can be drained away through vias or wicked-up surface-mount component leads, resulting in opens or weakened soldered joints with an extreme hourglass-shaped attachment of solder from the bottom of the lead to the bonding pad.

A common defect associated with no-clean wave soldering is the seepage of flux between the pallet and the board. The resulting flux residue may inhibit in-circuit test probe contact. Care should be taken to ensure that the board fits well into the pallet nest, is rigidly indexed within the nest of the pallet, and is adequately retained against the pallet surface. As a pallet ages, it may shrink, take on twist, or bow and even delaminate. All of these may interfere with proper board seating.

If a component is seated tight against the PWB, it may block the flow of solder into the PTH. A gas pocket may form at the primary side of the hole. Gas pressure may force liquid solder out of the hole, preventing adequate PTH hole fill. This can be remedied by applying a small spacer under the component as shown in Fig. 47.29.

The spacer must be made of a heat-resistant material such as silicone.

**FIGURE 47.29** A component body tight atop a PTH can seal the hole: (a) The resulting gas pocket in the PTH can exclude liquid solder; (b) this situation can be remedied with silicone or other heat-resistant spacers applied beneath the component body.

### 47.5.1 Wave Soldering in the Pb-Free Context

The advent of lead-free solders has brought with it several issues:

- **Solder pot temperature** In wave soldering with eutectic Sn-Pb, the solder pot temperature is typically in the range of 240 to 260°C. Surprisingly, the move to Pb-free soldering has not necessitated a big change in solder pot temperature. For SAC305 (Sn-3 percent Ag-0.5 percent Cu), solder pot temperature is typically maintained between 255 and 265°C. It is wise to use the lowest practical solder pot temperature to reduce solder oxidation (dross formation) and to limit dissolution of PWB or component materials. In many cases, major assembly houses are using the same solder pot temperature for Pb-free solder as was used for Pb-containing solder, and conveyor speed is slightly reduced for better preheating and to compensate for the lower wetting rate characteristic of most Pb-free solders.
- **Oxidation** Some of the Pb-free solder constituents—such as copper, zinc, and bismuth—are notorious for oxidizing. When using alloys in which such constituents are major components, nitrogen inerting is mandatory to ensure good soldering and to conserve solder composition by retarding oxidation and excessive dross formation.

- **Flux** Both alcohol-based and water-based (volatile organic compound [VOC]-free) fluxes are compatible with most Pb-free alloys. The longer preheat times and slightly higher wave temperature are more of a challenge for alcohol-based fluxes, as dry-out is a concern. Higher flux solids content will help in this regard. Water-based fluxes are the direction in which the industry is moving, and a higher boiling point is widely used for Pb-free soldering.
- **Pb-free wave-solder joint appearance such as duller solder joints** Just as in reflow soldering, wave-soldered joints tend to be duller than those obtained from eutectic Sn-Pb. This is not a defect but a reality.
- **Fillet lifting** This has been previously covered, but it is worth noting that the effect is more prevalent in Pb-free alloys than in Sn-Pb alloys. Fillet lifting occurs when the solder cools at a different rate than the board. The Sn-Bi system is notorious for resulting in lifted leads. Bi expands upon freezing and can rip itself off the bonding pad or rip the bonding pad from the laminate. Fillet lifting is generally controllable by optimization of the cooling ramp rate after soldering.

When associated with the primary side of the board, fillet lifting is not considered a defect. If found on the secondary side (bottom) of the PWB, it is considered a workmanship defect with reliability consequences.

- **Hot tears and shrink holes** Most solders shrink upon solidification, and this is true of SAC solder. This alloy is known to form microcracks (see Fig. 47.30) on its surface during the phase change from liquid to solid. These cracks are called *hot tears* or *shrink holes*. They are generally benign as long as the crack is shallow (that is, the bottom of crack can be seen) and the crack neither extends to contact component lead nor PTH features (annular pad or barrel).

**FIGURE 47.30** Hot tear (shrink hole) on an SAC wave-soldered PTH joint. (Courtesy of Hewlett-Packard).

## 47.5.2 Equipment

There is little difference between wave-solder equipment set up for Sn-Pb and that configured for Pb-free soldering. There are two points to consider before converting equipment. First, the level of Pb contamination will be high in the Sn-Pb equipment. This can be remedied by draining the system of Sn-Pb solder and purging the system with a charge of pure tin. The tin scavenges any Pb from the solder pot, delivery lines, and nozzles. Good cleaning of the wave machine will take care of any trace Pb contaminants, but proper protective gear (respirator and clothing) should be donned for this cleanup.

Sn is known to dissolve many metals. With the high Sn content of the SAC solders (SAC305 is 96.5 wt percent Sn), check to ensure the machine is compatible with the higher tin content. The solder pot, impeller, delivery lines, and nozzles are all subject to iron leaching. This can interfere with the process by changing the composition of the solder. It can also be dangerous if a leak develops in the system allowing molten solder to leak from the solder pot. Some coated steels (such as ceramic and nitride) and cast iron are generally compatible. Changing over older systems to Pb-free compatibility can be an expensive proposition.

## 47.6 VAPOR-PHASE REFLOW SOLDERING

---

Because of safety and environmental concerns and compliance with the Montreal Protocol for the reduction of ozone-depleting chemicals, this soldering technique had fallen out of favor. With the advent of Pb-free soldering, there is increased interest in vapor-phase soldering for SMT applications, but it is likely that it will remain a niche application. Due to its continued diminished status, vapor-phase reflow is covered only briefly.

### 47.6.1 Basic Process

As in any other reflow technique, the board must be supplied with sufficient solder for joint formation. Most commonly, solder paste is stenciled onto circuit board pads. Components are placed onto the solder paste in preparation for reflow. The board is conveyed into the reflow chamber, where it is exposed to the vapor-phase of a boiling liquid. This liquid is inert with respect to the solder and board. It is a dense synthetic of high boiling point (slightly higher than that of solder liquidus but not high enough to damage the circuit board or components). Historically, chlorofluorocarbons were used, but now only hydrofluorocarbons (HFCs) are acceptable due to environmental concerns. Material costs are high, at several hundred dollars per pound.

When conditions are optimized, the hot vapors begin to condense on the cooler PWB, heating it. As the process progresses, sufficient energy for sustained solder reflow results. Solder wets to lead and pad and, as the board is removed from the hot vapor, the molten solder solidifies, bonding component leads to circuit board pads.

### 47.6.2 Machine Subsystems

The vapor reflow soldering machine is composed of three main subsystems: conveyor, reservoir vessel, and heaters. The vessel has cooling coils surrounding it, placed well above the level of the liquid in the reservoir. These condense the vapors, returning the majority to the reservoir, as shown in Fig. 47.31.

### 47.6.3 Advantages and Disadvantages of Vapor-Phase Reflow Soldering

The process is exceptionally uniform in heating and is also very precise in temperature. This method of reflow negates problems associated with varying topologies and areas of high thermal mass that confound other soldering processes. Since the soldering occurs in an inert atmosphere, fluxes of lower activation level can be used. In the absence of air, solder-joint quality is generally excellent.

Although vapor phase reflow has the appearance of being a fast process, solder paste reflow recommendations must still be followed. If the paste is heated too rapidly, paste volatiles may boil, resulting in explosive solder ball formation. As in other soldering methods,

**FIGURE 47.31** In-line single-vapor heating system schematic. (Reprinted with permission from *Electronic Packaging and Production*, November 1982, p. 63, Fig. 1).

the maximum heating ramp rate must be commensurate with component manufacturer recommendations. A slow preheat is required to keep components from cracking. Plastic package popcorning is pronounced with this method of reflow.

Besides legislated environmental issues, there are health risks associated with vapor-phase reflow soldering. With the continued recycled use of HFCs, toxic materials such as hydrofluoric acid and perfluoroisobutylene are formed. These must be neutralized and their by-products must be disposed of properly.

When massive, densely populated boards are introduced to the vapor reflow oven, vapor collapse can occur—a condensation rate that outpaces that of vaporization. The result is that the internal atmosphere of the oven thins dramatically to the point that it cannot sustain adequate reflow. Vapor-phase machines that rely on immersion heaters are prone to this phenomenon. More recent machines include massive heating element housings that provide sufficient thermal inertia to preclude this problem.

Increased incidence of tombstoning, solder ball formation, and component displacement has been noted in this method of reflow. The condensing vapor transfers heat directly to the best thermal conductors, component leads, and pads. Excessive solder wicking can occur, transporting solder from between the lead and pad up the lead, where it is not needed. This can cause solder bridges proximal to the component body. Excess solder on the component lead decreases the lead's flexural compliance, making it less reliable. Furthermore, if the solder is wicked up the lead, the lead-pad interface will be solder-starved, resulting in an inferior solder joint. Additional information can be gleaned from older reference books and other authoritative publications, including previous editions of this book.<sup>11,12</sup>

## 47.7 LASER REFLOW SOLDERING

The laser has proven to be a versatile tool in many industries. For circuit board assembly, it can be used for marking, single-point soldering, or rework. Lasers can accommodate bonding of the finest or coarsest peripherally leaded surface-mount packages, and its performance and applicability are independent of device population density on the board, the thickness of the printed circuit board, or the presence or absence of package heat sinks. It can be used with most any component lead or PWB pad surface finish and any solder, including Pb-free alloys.

When laser soldering is implemented properly, high soldering yields and exceptional bond characteristics are possible<sup>13</sup>. Its use is usually relegated to low-volume soldering applications.

For successful laser soldering, it is necessary to use tooling to hold the component—or, more specifically, the component leads—down to circuit board pads.

Laser-based reflow is used as a rework tool, and laser systems are packaged expressly for this purpose and sold commercially. Boards are preheated to about 100°C within the system by means of a bottomsides resistance heater. A diffuse laser beam is then scanned around the package by a rapidly moving galvanometer. The impinging energy heats surface-mount leads or an entire BGA to the point of solder reflow for package removal. This system has the advantage of such localized heating that only the package targeted for rework reaches reflow temperature. Everything around it stays close to the system preheat temperature with almost no thermal spill-over from the laser. This is a distinct advantage over the hot-air repair method, where the hot gas stream used for package heating and reflow can inadvertently melt solder joints on adjacent components or components on the opposite side of the board.

Laser soldering requires no hot zones to profile or maintain, does not induce substrate warpage, and requires no heated bonding head that can degrade or vary with usage. Components can be spaced exceptionally close to one another—closer than currently permitted for other techniques, especially when one considers rework.

### 47.7.1 Lasers

The word *laser* derives from the acronym for *light amplification via stimulated emission of radiation*.

**47.7.1.1 Laser Subsystems.** All lasers are comprised of three main subassemblies: power supply, cavity/oscillator, and beam delivery optics (see Fig. 47.32 and Table 47.2). Although there are many configurations and additional accessories that may enhance a laser's output, only the basics are covered here.

**FIGURE 47.32** Comparison of the two most popular lasers used for soldering: (a) Nd:YAG; (b) CO<sub>2</sub>.

**47.7.1.1.1 Cavity/Oscillator.** *Lasing*, which is the laser photon generation and amplification process, occurs in the cavity, also known as the oscillator. The cavity contains the lasing medium, a material that is both the photon originator and amplifier of the laser beam. Photons, electrons, or other high-energy sources are used to raise certain atoms or ions in the lasing medium to a temporarily stable electronic transition, a meta-stable state. When the medium is returned to its stable, ground state, energy is released in the form of heat and fluoresced photons. These photons are, for the most part, reflected at the ends of the cavity and focused back through the lasing medium by the cavity optics, generating more photons with each additional pass.

**TABLE 47.2** Laser Systems and Subsystems

System	Subsystems	Name
A		Excitation power supply
B		Cavity
	B1	Nd:YAG crystal (lasing medium)
	B2	Flash lamp (excitation source for Nd:YAG)
	B3	Retroreflector
	B4	Partial reflector (laser beam exit optic)
	B5	Electrodes (excitation source for CO <sub>2</sub> laser)
	B6	Quartz tube
C		Delivery optics
	C1	Mirror
	C2	Final objective
D		Lasing gas CO <sub>2</sub> , N <sub>2</sub> , He

There are always two types of reflectors that bound a laser's cavity. The rear or retroreflector focuses and returns nearly 100 percent of the emission wavelength photons back through the cavity, further stimulating the lasing medium to emit photons. The front reflector is a leaky mirror lens, one that is reflective but somewhat transmissive also. It reflects most of the emission beam back into the oscillator for further stimulation of the lasing medium while allowing a small fraction of the laser beam to pass through it. The component of the beam that is transmitted by the front partial reflector is the working laser beam. It is monochromatic by virtue of the lasing medium, which limits photon emission to a set of discrete wavelengths, or laser lines, which are characteristic of the medium material, and by virtue of the optical coatings on the front reflector, which allow only one laser line through it.

**49.7.1.1.2 Delivery Optics.** Delivery optics, placed in the path of the laser beam, direct it to the work piece. In the case of laser soldering, the work piece is the circuit board or, more specifically, the leads, pads, or lead-pad combinations. The beam can be easily steered by means of wavelength-appropriate mirrors and can be focused to the required spot size via a final objective lens to accomplish soldering. The delivery optics can be held fixed and the circuit board moved beneath or, conversely, the optics can be moved to direct the beam as needed. Either can be done with great precision sufficient for any PCB soldering task. Moving the beam and moving the board both have their own advantages. Moving the optics in any direction is very simple and will not interfere with any PCB or surface-mount device fixturing requirements. Also, moving the circuit board may cause misalignment of component leads and circuit board pads. Fixed optics are more stable and require fewer adjustments, although, if engineered properly, moving optic beam delivery systems can be exceptionally stable and accurate.

Fiber-optics are in vogue for laser beam delivery, but it should be noted that, when dealing with high-energy-density laser beams as required for soldering, fibers are subject to damage if not precisely maintained. Fiber delivery has the advantage of allowing for easier steering of a beam in a complex machine that may preclude the use of orthogonal mirror and lens beam steering.

**47.7.1.2 Beam Characteristics.** There are many key differences between a laser beam and other light sources. (The term *light* is generally reserved for those wavelengths that are part of the visible spectrum and detectable by the human eye, but for the purposes of this discussion, *light* and *photonic emission* will be used interchangeably.) Laser beams have several distinctive characteristics. They are generally set to emit monochromatic radiation, which is also coherent radiation. Coherence here relates to the synchronized propagation of photons; that is, all waves of the emission radiation are in phase with one another.

**47.7.1.3 Laser Criteria for Soldering.** The choice of a laser for soldering is predicated on emission wavelength, required power, required beam diameter, machine reliability, and price. The optical properties of the target material are of primary importance in the laser selection process. In the case of surface-mount soldering, the absorption, reflection, and transmission characteristics of the PWB laminate as well as the reflectivity and absorptivity of the metallics (leads, pads, and solder) involved in the soldering process must be considered. The majority of circuit boards produced are composed of fiber-reinforced epoxy resin, although there are others. Each laminate has its own unique optical properties and characteristic laser damage threshold (LDT). LDT can be defined as the energy required to alter or damage the target material. In the case of an organic-based laminate PWB, it would be the laser energy necessary to char the board or cause the bonding pads to lift from the surface. Most any lead-pad surface finish on most any circuit board material can be soldered. For the purpose of this section's discussion, the focus will be on industry-standard glass-epoxy laminate and most any solder, be it lead-bearing or lead-free.

**47.7.1.4 Laser Choices.** There are few practical choices for laser selection, since only a few possess the characteristic energy, production-tested reliability, and economics necessary for PWB assembly. The most common are the neodymium doped yttrium aluminum garnet (Nd:YAG) laser, an example of a solid-state laser, and the carbon dioxide (CO<sub>2</sub>) laser, which has a gaseous lasing medium. These two types of laser are among the most common of the industrial lasers. Each has been on manufacturing floors in various industries since the early 1980s

They are versatile in terms of applications and capable of the output required to weld, braze, solder, cut, and mark. Although other lasers could be used for soldering, the Nd:YAG and CO<sub>2</sub> types are the most commonly available. They have proven track records and are also the most commonly reported in terms of application to soldering.

**47.7.1.5 Carbon Dioxide (CO<sub>2</sub>) Lasers.** In the case of the CO<sub>2</sub> laser, there are mirrors at both ends of the tube that contains the lasing gas—a mixture of carbon dioxide, nitrogen (N<sub>2</sub>), and helium (He). Each of the components of the mixture helps in the lasing process. The CO<sub>2</sub> is the lasing medium. Electricity is discharged directly into the CO<sub>2</sub>, resulting in its ionization and establishing a meta-stable state that decays, resulting in fluorescence (photon generation) and heat. These photons are reflected back through the laser cavity to stimulate the production of additional photons further. As this process continues, the beam intensifies and emissions from the cavity compose the working laser beam. The introduction of N<sub>2</sub> helps in the transfer of energy to excite the CO<sub>2</sub> molecules into their meta-stable state. The helium, with its high thermal conductivity, helps to transfer some of this thermal energy to the laser's cooled cavity walls. Were the cavity gases to become too hot, the CO<sub>2</sub> would dissociate and would be less effective as a lasing medium.

CO<sub>2</sub> lasers are known for their reliability and stability in manufacturing. Their emission is well into the IR spectrum at 10.6 μm (10,600 nm). It has limited use in PWB soldering since that wavelength is well absorbed by most organic materials (such as epoxy laminates) and is well reflected by most metallurgies. This is disadvantageous, since to get sufficient energy into a lead-pad combination, the CO<sub>2</sub> beam has to be kept to a small size to prevent it from spilling onto the PWB laminate. If the PWB were irradiated either directly or by errant reflection off a specular surface, it would char and the resultant carbon-rich residues might be electrically conductive enough to cause an electrical short circuit. There are three other points that detract from the use of the CO<sub>2</sub> laser as the preferred tool for circuit board soldering, each of which is discussed in the following subsections. Despite these drawbacks, the use of CO<sub>2</sub> lasers for soldering has been widely reported in the literature.

**47.7.1.5.1 Materials Compatibility.** The long wavelength of the CO<sub>2</sub> laser is readily absorbed by organic materials (e.g., glass-epoxy laminate, polyimide, and molded encapsulants).

**47.7.1.5.2 Fiber-Optic Delivery.** The CO<sub>2</sub> laser's output is not compatible with fiber-optic delivery. The wavelength is well absorbed by the most common fiber-optic material, fused silica.

**47.7.1.6 Nd:YAG Lasers.** The neodymium doped yttrium-aluminum-garnet (Nd:YAG) laser, commonly referred to as the YAG laser, has a solid-state medium. It relies on lamp excitation of a cut and polished yttrium-aluminum-garnet crystal that has been doped with neodymium to stimulate this solid-state lasing medium. The photons released by the solid-state lasing medium are used to stimulate more lasing medium-derived photons. Otherwise, the same lasing principles apply to the operation of that laser as to the gaseous CO<sub>2</sub> laser. Nonlinear optical materials can be used with the YAG laser to double the output frequency, halving the operating wavelength. This can be advantageous when working with highly reflective materials such as gold and copper, which are more optically absorptive at lower wavelengths. This, however, detracts from laser performance by decreasing available operating power, adding complexity to the system as well as increasing maintenance requirements.

**47.7.1.7 Spot Size.** First, the minimum practical spot size is relatively large. The theoretical diffraction-limited spot size of a focused beam is directly proportional to the beam wavelength and lens diameter, as described in Eq. 47.1.

$$S = f\lambda/D \quad (47.1)$$

where  $S$  = diffraction limited spot size  
 $f$  = focal length of the lens  
 $\lambda$  = wavelength of the laser  
 $D$  = lens diameter

Thus, for a lens of 25 mm diameter and 100 mm focal length, in conjunction with CO<sub>2</sub> or YAG lasers, the spot sizes shown in Table 47.3 are theoretically possible.

**TABLE 47.3** Theoretical Spot Size versus Laser Type

Laser type	Emission frequency ( $\mu\text{m}$ )	Theoretical spot size ( $\mu\text{m}$ )
CO <sub>2</sub>	10.6	42
Nd:YAG	1.06	4.2
Nd:YAG (Frequency doubled)	0.532	2.1

Imperfections in the lens or beam shape and other factors prevent practical achievement of these minimal spot sizes. Generally, the attainable focused beam diameter on the factory floor is about two to three times larger than the ideally calculated spot size. Note that for an Nd:YAG laser, the spot size is at least 10 times smaller than that of the CO<sub>2</sub> laser, providing a fine, high-energy-density spot for soldering.

**47.7.1.8 Lasing Operating Modes.** Both YAG and CO<sub>2</sub> lasers can be operated in a variety of modes, each of which can be used to advantage in soldering:

- **Continuous wave (CW) operation** CW is a constant emission analogous to the continuous output of a light bulb that is powered by a direct current source.
- **Pulsed laser output** Furthering the light bulb analogy, this mode is akin to a bulb operated by an alternating current or pulsating power supply, although more like a strobe with intense bursts. The pulsing can be attained through a variety of methods, including switched power supply, capacitive discharge, or mechanical shutter, or by means of an optically manipulated shutter, as by acoustooptic, electrooptic, or magneto-optic methods.

### 47.7.2 Laser-Soldering Fundamentals

There are relatively few variables associated with the laser in its application to soldering. This is one of the advantages for laser processing. Beam wavelength, irradiation time, and beam power are important to the process, as are the properties of the materials being joined. Reflectivity, thermal conductivity, and laser damage threshold must be understood before soldering is attempted. The wavelength will be fixed by the laser of choice, and the shorter the wavelength, the smaller the theoretical spot size, as discussed. Generally, the reflectivity of a metal is lower at shorter wavelengths, thus a metal is more easily heated by an Nd:YAG laser than with a CO<sub>2</sub> laser. The converse is true for many polymeric materials, which are more absorptive at longer wavelengths and therefore more prone to damage with increasing wavelength. Many polymeric materials are also absorptive at the UV end of the spectrum. A carbon dioxide laser beam is more likely to impart damage to a circuit board than the beam of an Nd:YAG laser, but either laser can inflict damage if the energy density is high enough. In fact, either laser can easily cut through a component lead or drill through a circuit board if parameters are not adjusted properly.

The reflectivity of metals varies widely with composition and surface condition. Every metal can be heated with a laser as long as the energy density of the beam and dwell time are sufficient for heating. This is also the case with laser-irradiated component leads, board pads, and solder during the laser bonding process. Measurements of the reflectivity of Sn-Pb solder show that a eutectic alloy can be as high as 74 percent at 10.6  $\mu\text{m}$  or as low as 21 percent at 1.06  $\mu\text{m}$ . Therefore, in the case of the CO<sub>2</sub> laser at 10.6  $\mu\text{m}$  on a Sn or Sn-Pb-plated lead and solder-coated pad, much energy will have to be directed at the metals to start the absorption process, since so little laser energy is absorbed by the solder and converted to heat; the rest of the energy is lost to reflection. The reflected or multiply reflected beam may impinge on adjacent components and damage package bodies or even the circuit board itself, causing charring. Therefore, Nd:YAG is preferable for circuit board soldering.

### 47.7.3 Through-Lead and Through-Pad Bonding

Generally, the laser beam is directed at the component lead to accomplish soldering, but when the lead material is highly reflective, as would be the case with a gold-plated finish, heating is slow and irradiation times impractically long. An alternative has been demonstrated whereby the beam is directed at solder-coated circuit board bonding pad.

**FIGURE 47.33** Laser soldering: (a) through-lead laser soldering; (b) through-pad laser soldering (B).

If there is leeway in design, the bonding pad can be extended to aid in this method, dubbed *through-pad bonding* (see Fig. 47.33b). In contrast to the usual beam impingement on the component lead, or *through-lead bonding* (see Fig. 47.33a), the beam is directed at the more absorptive solder or on the circuit board land, increasing process efficiency and locally melting the solder in the vicinity of beam impingement. Since the molten solder is in intimate contact with the lead and pad, the heat from the bonding process is efficiently transferred. The process can result in rapid soldering

along the entire length of the component lead and circuit board pad with rich solder fillets evident if the process is conducted properly.

### 47.7.4 Single-Point Laser Soldering

This method requires a laser beam that is smaller in diameter than the length or width of the component lead or bonding pad. The beam is stepped to each lead-pad combination and delivered with sufficient energy to result in solder reflow. The beam can be CW, pulsed, or

multiply pulsed to accomplish soldering as long as there is enough radiation delivered to cause the solder to undergo the phase change required for soldering and wetting. Due to the small beam diameter, as required by this technique for fine-pitch components, the energy density can be exceptionally high. In fact, it can be so high that if the lead is not in good contact with the bonding pad, then the laser's beam can damage the lead, perhaps cutting through it rather than soldering it. Overly intense irradiation can also cause a bonding pad to delaminate from the PWB.

In any laser soldering technique where very small spot size is required, the beam diameter must be precisely controlled. A small variation in beam diameter, either through change in laser parameters or in working distance (focus), can dramatically affect the delivered energy density. In the cases of a 10 W Nd:YAG laser beam focused to a spot of 0.1 mm (0.004 in.) and a spot of 0.2 mm (0.008 in.), this seemingly small change in spot size will result in a large change in power density (see Eq. 47.2).

$$P = p/d \quad (47.2)$$

where  $P$  = power density  
 $p$  = average power  
 $d$  = focused beam diameter.

For this example, the power density would vary from 1,273 W/mm<sup>2</sup> for the 0.1 mm diameter beam to 318 W/mm<sup>2</sup> for the 0.2 mm beam diameter, a fourfold reduction emphasizing the criticality of strict maintenance and process control when working with a small spot size.

In most cases, a Gaussian distribution of the beam's energy distribution across the focused diameter is assumed. It is customary to measure the beam at the  $1/e^2$  point (13.5 percent of the peak height), so, in fact, the beam is impinging on a slightly larger area. However, the most intense portion of the laser's beam is confined to the region bounded by the  $1/e^2$  points in two dimensions, as shown in Fig. 47.34.

**FIGURE 47.34** Laser energy density is measured from points on the distribution curve where the beam's intensity is  $1/e^2$  (13.5 percent) of peak intensity or between points A1 and A2 in this plot.

Single-point laser bonding has been applied to soldering tape automated bonding (TAB) lead frames to silicon die, TAB leads to PWB, or multichip modules as well as for soldering gull-wing leaded components to circuit boards. This technique is not suited for bonding area-array devices such as BGAs or CBGAs to PWBs.<sup>14</sup>

### 47.7.5 CW Scanning

In sharp contrast to single-point laser soldering, this technique relies on a larger, defocused moving beam to accomplish the heating. The beam may be many times the size of the narrowest lead or pad dimensions. In this technique, the laser beam generally spills over onto the substrate material, irradiating the lead, pad, or lead-pad combinations as well as interpad board surfaces. Because a larger beam diameter is used, a long focal-length lens and generous delivered laser spot size can be employed. This results in a wide process window in terms of final beam diameter and working distance of lens to the circuit board surface. The laser spot is moved at a rate such that the beam exposure to the board is below the laser damage threshold limit. It heats the lead-pad combination, the solder flux, and the board sufficiently to cause the solder to change state.

A variation of this technique utilizes orthogonally mounted galvanometers to move an Nd:YAG laser beam around the periphery of a surface-mount device sitting atop solder lands on a circuit board. The beam is driven at high velocity repetitively around the surface-mount device until all leads are heated to the point of solder liquidus. As the beam is turned off, the solder solidifies and solder joints result. This same galvanometer-driven technique has gained commercial acceptance as a BGA rework tool. A slightly defocused laser beam is aimed at the body of the BGA. The beam is rapidly moved around the package body at a rate below the laser damage threshold of the packaging material. With each pass, the component heats up a little more, eventually melting the BGA solder joints. The package is removed with an automated vacuum pickup tool while the solder is still molten. A new BGA can be attached using this same technique. This method can be applied to any type of rework, although component leads and pads would be targeted rather than the body, as was the case for the BGA.

### 47.7.6 Multiple-Beam Laser Soldering

One of the attractions of working with a laser is the fact that its beam can be split for multiple use within one station or even shared between two or more stations. The split can be accomplished by the use of bifurcated fibers or beam splitting mirrors. The beam of a single laser cavity can be duplexed to solder two sides of a surface-mount component simultaneously. It is entirely possible to share a common beam between two or more laser soldering stations either simultaneously or in a time-shared manner.

## 47.8 TOOLING AND THE NEED FOR COPLANARITY AND INTIMATE CONTACT

---

In all modes of laser bonding, the component leads must be in contact with solder lands on the PCB to accomplish joint formation. It is therefore necessary, in most cases, to use a specialized hold-down tool to ensure that leads contact pads. This detracts from the ideal of noncontact laser bonding. Several techniques have been developed and reported. One such method uses a transparent hold-down medium such as glass, quartz, or transparent high-temperature plastics. There are several significant problems associated with this approach, which can result in an inconsistent soldering process. First, these materials are rigid, making it impossible to hold a lead down to a low-lying pad abutted by normal height pads or, conversely, a high pad abutting lower pads (see Fig. 47.35).

During the soldering cycle, the glass can accumulate spattered flux and flux by-products that may change the delivered laser beam intensity, adding variability to the process.

Comb or pin arrays have been applied that match the lead configuration of a package. This type of fixture is expensive and easily damaged, especially if the soldering flux glues the comb teeth to the bonded component lead. Probably the most common method for rigid-leaded

**FIGURE 47.35** For laser soldering to be effective, it is necessary to have lead-to-pad, pad-to-pad, and lead-to-pad coplanarity: (a) noncoplanar component leads on constant-volume (coplanar) solder pads; (b) a coplanar lead array on noncoplanar PWB solder lands.

surface-mount packages is the body-push method (see Fig. 47.36), in which a force is applied to the component body, springing the leads just slightly. As the solder melts below the lead, the lead drops down to board level, where it is frozen in the cooling solder. It is necessary to control the amount of push such that the solder joint is not stressed by a lead frozen in compression. This is particularly the case for coarse-pitched component leads, where much force may be required to overcome a coplanarity problem. When board pads and component leads are reasonably coplanar, then this method is adequate for high-yield, high-reliability soldering as long as the noncoplanarity is in a negative direction, as indicated in Fig. 47.36a.

**FIGURE 47.36** The body-push method would be effective in (a), where a lead is below the level of adjoining leads. In the case of (b), too much force would be needed to push the component body down to make the high component lead coplanar with adjacent leads. This could result in too much stress in the solidified solder joints.

A compliant hold-down method has been reported that is inexpensive to fabricate and easy to implement. This consists of a silicone rubber foot and an aperture that allows the beam unobstructed access to the lead-pad combination. This method has been proven effective for TAB as well as for rigid leaded surface-mount device bonding. It obviates the problems associated with transparent hold-down methods in terms of flux build-up. The compliant foot holds leads to pads and can accommodate lead-to-pad noncoplanarity differences.

### 47.8.1 Flux for Laser Bonding

Requirements are much the same as for other reflow methods. Flux must be active enough to remove oxides from the component lead, bonding pad, and the solder. Its optical characteristics in terms of reflection, absorption, and transmission must not interfere with the solder process. If too absorptive, the flux could char, becoming more absorptive, and then overheat and wreak damage to the underlying circuit board. Also, if denatured, it will lose its chemical effectiveness as a fluxing agent. In laser soldering, particularly in the scanned methods, the flux adds a path of heat transfer to the board and preheats the next joint to be soldered. In the absence of a liquid flux, the PWB is more likely to char if the laser impingement is not stringently controlled. During soldering, the laser beam's output is quick and intense. The high energy of the process results in exceptionally high processing temperatures for very short durations. The high processing temperature aids in flux activation, making even the mildest of no-clean fluxes an effective soldering agent.

### 47.8.2 Fluxless Laser Soldering

There have been many reports of fluxless laser soldering. As used for inner-lead bonding to silicon die, these utilize a high-peak-energy, short-duration pulse. Under these conditions, when the mass of the lead and the bonding pad is small enough, the process is more akin to welding with the component lead melting and alloying with an underlying metal such as tin. To accomplish conventional reflow soldering by means of a laser, or any other technique, it is necessary to employ a liquid solder flux or gaseous analogue pretreatment to bond effectively. Plasma cleaning and inert storage may be one such method. Ultrasonic assisted laser soldering can be effective, but is slow, requiring precise placement of an ultrasonically agitated head and running the laser beam either through the ultrasonic tool or precisely adjacent to it. The ultrasonic agitation breaks up the oxides surrounding the molten solder and the component lead, allowing joining of the liquid solder to the component lead metallurgy. The use of gaseous phase carboxylic acid fluxing with laser bonding has been demonstrated.<sup>15</sup> This precludes the need for conventional liquid fluxes and leaves no visible residues on the circuit board. No cleaning is required and the assembly reliability is not degraded from the use of a gaseous fluxing approach.

### 47.8.3 Laser Solder-Joint Characteristics

There are very few differences between solder joints prepared by laser as compared to those formed by other methods. Laser soldering results in intermetallic formation, but the layer is extremely thin if the laser soldering cycle heating is kept short—much thinner than that found in solder joints manufactured by more conventional methods. Since the heating is highly localized, cooling is rapid resulting in exceptionally fine solder grain growth. The fine grain growth leads to greater joint strength initially. The strength advantage, although significant in magnitude, tapers off as the solder joint ages and metal grain coarsening occurs. Coarsening rate depends on ambient temperature and time.

### 47.8.4 Solder Sources and Defects Associated with Laser Reflow

Solder requirements are the same as for any other process. There are no alloy composition requirements specific to laser soldering, as this soldering method is compatible with leaded or lead-free solder alloys. Even high-temperature alloys can be soldered by this technique. When single-point laser reflow is applied, the board quality and integrity are not compromised if parameters are chosen and adequately controlled.

Laser soldering is not prone to solder bridges and if component leads are held down to solder-coated PWB lands, then soldering defects are rare. Perhaps the most common characteristic

defect unique to laser soldering is charring or burning of the circuit board, which occurs if too high an energy density is used and the laser damage threshold of the PWB is exceeded. Charring or burning of the PWB can also occur if the circuit board is grossly contaminated with grease or other organic contaminants. This is not to say that boards for laser soldering have extraordinary requirements for cleanliness. Requirements should be considered the same for this technique as for any other reflow process.

#### 47.8.5 Laser Safety Issues

Lasers are categorized by their safety hazard potential. A full review of these will not be provided, but suffice it to say that Class 1 is an intrinsically safe laser, posing no intra-ocular danger, while Class 4 lasers pose the greatest hazard. All lasers considered for soldering use are of the Class 4 variety. Because of this, they are generally embedded in appropriate interlocked cabinets with laser-safe viewing ports or a video camera incorporated to preclude direct ocular exposure to the laser's intense beam. When the Class 4 system is embedded in an interlocked cabinet, it is considered a Class 1 system and poses no hazard to the immediate area; laser-safe eyewear need not be worn except when interlocks are overridden for system maintenance. As mentioned previously, lasers, especially Nd:YAG, are known for their high uptime and lack of required expendables.

### 47.9 ADDITIONAL INFORMATION SOURCES

---

There are numerous excellent supplemental texts available for additional detail and instruction in laser technology. Those by S. Charschan,<sup>16</sup> Hecht,<sup>17</sup> and Ready<sup>18</sup> are particularly useful. Additional information on CO<sub>2</sub> lasers in the realm of soldering can be found in references.<sup>19, 20, 21, 22, 23, 24</sup>

### 47.10 HOT-BAR SOLDERING

---

Specifically suited to surface-mount assembly of packages with lead frames, hot-bar soldering has been in use for several years. The technique relies on a resistance-heated element to push component leads into contact with solder and bonding pads, simultaneously reflowing the solder. Compression of the leads onto the circuit board lands is continued as the heat is ramped down. Upon cooling, the solder solidifies and the heating element is withdrawn from the newly formed solder joints. The heated element is commonly referred to as the *hot-bar*, although the term *thermode* is also in widespread use.

Hot-bar soldering is best suited for low-thermal-mass, single-sided surface-mount assemblies. Each component type requires its own hot-bar bonding head assembly. These can be expensive, with the price dependent on the complexity, materials of construction, precision required, and overall size of the bonding head.

#### 47.10.1 Solder Application

The use of solder paste is discouraged because blade heatup is fast and may result in explosive solder ball formation from rapidly volatilized paste constituents. Also, the paste is likely to squeeze out from between the component lead and circuit board pad, which can cause the solder to bridge to adjacent conductors. In fact, even with solid solder coatings on the circuit board, bridging can be problematic in hot-bar bonding. This is usually a function of the volume of solder on the pad, the quantity of flux, its degree of activity, and lead-pad pitch. As the

solder is melted and displaced by the hot-bar, it bulges laterally to the point that the solder masses of two or more adjacent pads may touch one another, forming a solder bridge. Once the bridge has formed, the forces associated with lead-pad wetting and capillarity may not be strong enough to overcome the surface tension conditions established during bridge formation. If that is the case, the bridging defect(s) will persist (Fig. 47.37).

**FIGURE 47.37** As the hot-bar is forced into contact with component leads and circuit board pads (a), the solder may bulge laterally as shown in (b), resulting in solder bridges (c). Careful control of solder volume, applied pressure, and temperature profile during hot-bar soldering is required to preclude this defect.

Solid solder coatings such as hot air-leveled pads, solder-plated boards, or stenciled solder paste reflowed prior to hot-bar bonding are preferred for this bonding method.

#### 47.10.2 Fluxes and Fluxing for Hot-Bar Soldering

Soldering flux is applied prior to component placement and soldering. Flux choice should be tailored to the hot-bar process. The flux can be either liquid or paste. The flux chosen should be tested to resist charring and the development of polymerized decomposition products, or lacquers, which adhere to both circuit board and hot-bar. Residue build-up on the bar can adversely inhibit hot-bar performance by diminishing thermal transfer. The residue can also become thick and uneven enough to prevent the hot-bar from squarely contacting component leads. Baked-on aqueous-clean flux residues can make flux cleaning difficult. With no-clean flux, overheated residues may detract from the visual appearance of the printed circuit assembly.

#### 47.10.3 The Hot-Bar Soldering Operation

Generally, the board is preheated on a hot stage beneath the hot-bar, off to the side or even in a box oven prior to soldering. Sometimes hot air is used for preheating. This step is generally done after flux application, so the thermal profile has to be adjusted to prevent flux dry-out. Once component leads are aligned with solder-coated PWB pads, the hot-bar is pressed against

the lead-pad combinations and heated to reflow. Precise control of the heating process is required to prevent flux spattering or solder bridging. A mechanical stop is employed to keep the bonding head from exerting too much force on the lead and pad combination. Excessive force can cause the component leads to slide off pre-reflowed (domed) solder-coated pads. It can also enhance solder bridge formation and solder-starved joints by physically displacing solder from between leads and pads.

One approach to preventing bridged or solder-starved joints is to retract the hot-bar by several hundredths of a millimeter once the solder starts to reflow. This results in a surface tension coupling of solder between lead and land, reduced propensity for solder bridge formation, and robust joint formation upon cooling. As in any other soldering process, it is important to maintain proper reflow time-temperature characteristics. In hot-bar soldering, it is of paramount importance that the blade seating plane is maintained normal to the surface plane of the PWB. On the other hand, it should be noted that the coplanarity of solder on the PWB pads does not have to be exact. The hot-bar will reflow this solder and it will self-planarize, as does any liquid, and remain planarized into the solid phase.

#### 47.10.4 Hot-Bar Construction

The hot-bar bonding head can be composed of one or several blades. They are designed to solder one side, two sides, or all four sides of a gull-wing leaded component simultaneously. Generally the hot-bar assembly is configured to accommodate the maximum span of a lead set, permitting simultaneous bonding of all leads on a package side. In the case of some very long connectors or other large packages, the thermal uniformity of a single blade may not be adequate for the process. This is sometimes remedied by using a smaller hot-bar and stepping it along the length of the lead set until all leads are bonded. Another approach uses multiple hot-bars side by side, each individually controlled, to achieve the span and required thermal uniformity. Bar configuration is designed for the lead form to be bonded. It should sit flatly on the foot of the lead, neither contacting the radiused area of the lead form nor significantly overhanging the lead toe, as shown in Fig. 47.38.

**FIGURE 47.38** A hot-bar in contact with leads: (a) transverse view; (b) lateral view. The hot-bar must be positioned so as not to interfere with the leg of the formed component lead. It should sit squarely on the foot of the lead.

The bar itself can be manufactured to nearly any dimension, but there are limitations on its size; the longer the blade, the worse its longitudinal thermal uniformity. Variations in blade temperature may cause it to distort due to differential thermal expansion and contraction. Thermal uniformity is critical for consistent lead-to-lead soldering and joint quality per component side. The allowable variation in bar temperature is limited by the component specification, the damage threshold of the board to be soldered, the solder, and product reliability requirements. As in any other soldering process, the variation in process temperature must be understood and controlled to ensure highest board assembly yields and best-quality solder joints. Most hot-bar systems are configured with a fine-gauge thermocouples welded to the bar, an integral part of a closed-loop, temperature-controlled hot-bar heater system. There may be more than one thermocouple per bar.

Numerous bar designs and materials of construction are available; tungsten, titanium, and molybdenum are commonly chosen for their electrical resistance, durability, thermal conductivity, immunity to flux damage, and solder nonwetting characteristics. Some ceramics are also used for blade construction. The bar must be designed for uniform heating across its length and it must be able to shed heat rapidly to allow the solder to resolidify within a reasonable time. The blade has to expand and contract uniformly throughout the soldering cycle. Some blades have been seen to develop a “frowning” or “smiling” profile in their z-axis during heating due to differential thermal expansion or built-in stress in the metal, as shown in Fig. 47.39. For the same reasons, transverse warping of the blade is also commonplace.

**FIGURE 47.39** If not constructed properly, the hot-bar can develop a “smiling” profile (a), a “frowning” profile (b), or may warp along its length (c). (a) and (b) are front views whereas (c) is a top view. The dashed line in (a) and (b) shows the desired seating plane.

These conditions detract from proper blade contact with lead and pad combinations and are indicative of poor hot-bar design or poor choice of materials. Blade warpage, if the curvature is sufficiently large, may result in solder opens. There have been many solutions proposed in the realm of structure, materials of construction, and electrical input to permit highest uniformity of blade heating and contact to the bonding pads. D. Waller et al.<sup>25</sup> have patented a rigid molybdenum truss blade that has been found to be stable dimensionally and thermally uniform over long spans (in excess of 76 mm).

Usually the hot-bar blade is attached to a self-leveling, spring-loaded bonding head that allows the blade to self-planarize in relation to the underlying component leads and circuit board surface. Nonetheless, variations in board contour, such as a localized high or low spot, can render the concept of self-planarization useless and solder opens can result. Rigid-member hot-bars are excellent for accommodating differences in lead coplanarity because the blade

forces lead to pad. Driving a heavily sprung lead onto its corresponding bonding pad can, however, lock stress into the resultant solder joint because the solder is working to resist the spring force of the lead. This can detract from the joint reliability and cause premature joint failure.

#### 47.10.5 Maintenance and Diagnostic Methods

As with any process equipment, it is important to maintain the hot-bar properly. Check it frequently for distortion. Ensure that it remains flat and perpendicular to the circuit board to be bonded. Scrub the hot-bar on a ceramic flat to remove any baked-on flux residue. This may need to be done every few bonding cycles, depending on the flux and the criticality of the assembly.

Several diagnostic tools can be applied to assess hot-bar conditions. The two most important characteristics that must be understood and monitored are thermal performance and blade planarity.

#### 47.10.6 Thermal Monitoring

One of the most common methods of assessing hot-bar performance is to use a thermocouple-instrumented board, as is the case with any other soldering method. Preparing such a board for thermode use has its own requirements. Fine-gauge thermocouples are attached to leads of the component or the bonding pad of the circuit board to be soldered. Positioning thermocouples at both ends of the lead set and also near its center helps quantify the longitudinal thermal uniformity of hot-bar performance during soldering. It is also useful to deploy thermocouples on surrounding components to ensure that the hot-bar soldering process does not jeopardize the integrity of adjacent, previously soldered joints.

When preparing the thermal profile board for hot-bar soldering, avoid placing the thermocouple bead between component lead and bonding pad. The added height of the bead would prevent the bar from contacting adjacent component leads and results in point-contact heating that is not indicative of the bar's normal operation. Instead, place the thermocouple bead at the pad extension area in front of the lead tip or at the lead heel as indicated in Fig. 47.40.

**FIGURE 47.40** Just as in any other soldering method, a thermal profile board is needed for hot-bar soldering. Care must be taken that the thermocouple bead does not interfere with seating of the lead to pad or with the hot-bar blade to the lead and pad combination (a, b). Instead, the thermocouple can be attached with a high-temperature solder alloy in front of or behind the component lead (c) so that a common lead, pad, and bar seating plane is maintained.

### 47.10.7 Blade Planarity

As stressed throughout this section, the coplanarity of the hot-bar blade or multiblade assembly with respect to the bonding surface is of extreme importance to preclude solder opens during hot-bar soldering. There are numerous measurement methods that can help diagnose this; unfortunately, though, they are meant for evaluation of the blade(s) at room temperature, not at bonding temperature. As previously mentioned, a blade may distort temporarily or permanently during heating, but planarity measurements on hot blades are impractical. Therefore, the majority of techniques encountered are performed at room temperature.

J. A. Wilkins<sup>26</sup> suggests the use of a colorant, such as from a marking pen, applied to the cold bonding surface of a freshly cleaned thermode. Once the ink is dry, the blades are then scrubbed over a clean, flat ceramic plate. Low spots on the bar are indicated by the presence of colorant remaining on the bar after several circular swipes on the ceramic flat. Single-bar and two- or four-sided blade assembly planarity can also be evaluated using an array of ground, leveled, rigidly mounted pressure transducers. Bar pressure differential, an indicator of blade planarity, can be adjusted so as to be uniform from end to end and from blade to blade on the two-up or four-up hot-bar assembly. Of course, some hot-bar assemblies are self-leveling, but even these should be checked for planarity and force per blade to ensure best uniformity during soldering. The use of pressure transducers has poor spatial resolution.

### 47.10.8 Process-Induced Defects

Solder bridging is the most prevalent problem associated with this method of soldering. Recall that the solder can be squeezed out of the solder joint and that conditions may favor solder bridge formation. Solder opens result from lack of coplanarity between the hot-bar and the plane of the circuit board surface. Lead misalignment during the bonding cycle is another defect that detracts from this method. As pressure is applied to component leads by the hot-bar prior to the onset of solder liquidus, leads are sometimes forced to slide down any domed pre-reflow the solder deposits. This displacement causes misregistration of component leads to bonding pads, and may build stress into soldered joints. If the forces are great enough, it may also cause the whole package to move and misalign the entire lead set.

Because the heating is rapid, the thermode temperature is necessarily well above the solder liquidus temperature. If the time-temperature cycle is not carefully controlled, overly thick intermetallic compound formation can be a problem. This is especially true in this process, where the solder may be largely displaced from between lead and pad, and bond lines are excessively thin. Within the joint, the volume of intermetallic compound (hard and brittle) may be large compared to the remaining solder (soft and compliant). If this is the case, solder joints will be less reliable and more susceptible to brittle fracture. All of these obstacles have prevented the widespread acceptance of hot-bar bonding in manufacturing except in some niche applications where soldering by other methods may be difficult. Hot-bar bonding is most useful for low-volume, fine-pitch surface-mount soldering and rework.

## 47.11 HOT-GAS SOLDERING

---

Hot-gas soldering relies upon a heated stream gas heated to effect reflow. This noncontact, directed-energy method is most suited to bonding surface-mount components. Although hot-gas soldering has been around for years and after numerous machine offerings, it is not a popular method for soldering despite its evolutionary improvements. Instead, it has made its mark in the area of component rework—removal of previously soldered devices from a circuit board and replacement of same.

One disadvantage of this soldering method is that the thermal energy is not well localized. Most machines typically emit a hot-gas jet too large to be isolated to reflow only the device of interest. The gas jet, once impinging upon the board and component leads, is deflected and its backwash can be problematic. It may cause unwanted reflow of previously formed joints, especially on closely spaced adjacent components. This problem is typically overcome by the use of baffles that are either applied to adjacent components or by a singular baffle that confines the gas jet to the component to be soldered.

Hot-gas soldering nozzles are available in a variety of forms. The simplest of nozzles is the single orifice, which can be translated around the entire periphery of a component (see Fig. 47.41a). Some machines offer a double translatable nozzle assembly that can solder two opposing sides of a component simultaneously (see Fig. 47.41b).

**FIGURE 47.41** Hot-gas soldering nozzles: (a) A programmable moving nozzle translates hot gas in x-y axes; (b) double nozzles, each programmable, allow simultaneous soldering of all four sides of a component.

Solder can be applied to the board as a paste, solid pre-form, or solder-coated pad. In all cases, the component must be held down during the soldering process to ensure contact of component leads with bonding pads. Proper gas pressure, temperature, nozzle translation speed, and flux are required to effect joint formation. Otherwise, the same reflow considerations are required for this technique as for any other. Heating ramp rate, solder paste preheating, peak temperature, liquidus duration, etc., must be observed for successful joint formation and joint reliability considerations.

A thermocouple-instrumented profile board populated with components is needed to determine the proper soldering profile. Adding thermocouples to adjacent solder joints is recommended to ensure that the soldering profile will not inadvertently re-reflow neighboring components.

## 47.12 ULTRASONIC SOLDERING

This method relies on a heated, ultrasonically vibrated soldering tip that simultaneously melts and agitates the solder (Fig. 47.42). The ultrasonic energy is transferred from the soldering tip through the molten solder droplet beneath it and ultimately to the component lead and circuit

**FIGURE 47.42** The ultrasonic soldering iron is composed of four main components: an ultrasonic transducer; a horn for concentrating and directing ultrasonic energy; a resistance heater; and the soldering tip, which emits both thermal and ultrasonic energy.

board pad. The high-energy agitation of the solder droplet helps to cleanse bond-inhibiting materials from the solder and solder-metal interfaces (component lead and bonding pad). If soldering temperature is appropriate, any exposed solderable metal surfaces are rendered wettable by this technique. Ultrasonic soldering precludes the need for chemical fluxing agents. Aluminum and other difficult-to-join metals can be soldered by this method. The viability of this technique has been well proven on a commercial scale in the manufacture of air-conditioner heat exchangers.<sup>27,28</sup>

Ultrasonic soldering has also been applied as a batch or continuous mass reflow process. In these instances, the molten solder is ultrasonically agitated while the assembly to be soldered is immersed in it. Similar arrangements have been made for ultrasonically vibrating the part while dipping it in a molten bath or wave of solder. These mass processes are more common for non-electronic assembly.

Care must be taken in ultrasonic soldering to tune the tip amplitude and/or frequency to the mass of the system being soldered. Overagitation results in excessive cavitation and splashing of the liquid solder. This generates solder balls, which could short finer-spaced leads or pads. Additionally, ultrasonic agitation increases the dissolution rate of any soluble metals into the solder at any given temperature, which may degrade solder-joint strength.

This technique can be useful for the repair of opens or the installation of new or change-order components onto completed circuit assemblies. Because no flux is required, a previously cleaned board will stay clean through repair or upgrading operations. This technique is applicable to all peripherally leaded surface-mount components that are not susceptible to ultrasonic energy damage. It can also accommodate through-hole device soldering. Equipment availability is limited, with only a few manufacturers worldwide. Several past and recent publications provide a comprehensive review of this technology's applicability and attributes.<sup>29,30,31,32</sup>

# CHAPTER 48

---

# SOLDERING REPAIR AND REWORK

---

**Gary M. Freedman**

*Hewlett-Packard Corporation, Business Critical Systems, Singapore*

---

## 48.1 INTRODUCTION

---

As printed circuit assemblies (PCAs) become more densely populated, the probability of rework increases. So does the complexity of rework steps. Rework deserves consideration both in terms of board design as well as in conducting the repair. Deep preheating cycles, careful thermal profiling, and thermal masking of adjacent components become critical. PCAs are often mix-mount (surface-mount technology [SMT] and plated through-hole [PTH]). Additionally, they may contain press-fit components or other subassemblies that may be sensitive to overheating. Aside from hand repair with a soldering iron, there are two techniques that are the mainstays of repair: solder fountain and hot-gas. The former is a variant of wave soldering and is tailored to removal or post-soldering addition of PTH (solder-tail) components. Hot-gas (also known as hot-air) soldering is used primarily for removal and replacement of SMT components.

Because repair of dense assemblies is difficult, this chapter covers some additional descriptions and tips for repair. The onset of Pb-free soldering has increased the difficulty of repair processes due to generally higher melting temperatures and slower wetting times that are characteristic of the most prevalent Pb-free solders. Otherwise, repair involving Pb-containing solders and Pb-free solders is the same.

---

## 48.2 HOT-GAS REPAIR

---

This technique consists of directing a heated stream of air or other process gas such as nitrogen at the component to be removed. Modern hot-gas repair stations are sophisticated, with computer control, predictive reflow profiling, vision systems to assist in component alignment to bonding pads on the printed wiring board (PWB), preheating stations, and accommodations for component removal. Hot-gas repair is most often used for SMT components but can be adapted for PTH component removal.

**FIGURE 48.1** Schematic of hot-gas repair of a ball grid array (BGA) (B) soldered to a circuit board (C). Hot-gas (air or nitrogen) is injected through a baffled nozzle. In this diagram, the heated gas is directed under and on top of the BGA. A heat-resistant suction cup (A) is used to remove the BGA once all joints have reached reflow temperature. Gas injected through a heated platen (D) is used to preheat the circuit board, lessening the thermal load and shortening the rework cycle.

## 48.2.1 Hot-Gas Repair Equipment

**48.2.1.1 Hot-Gas Nozzle.** The heated gas is generally delivered through a component-specific nozzle. The gas stream is directed at the top of the component, under the component, or a combination of the two, depending on the nozzle design (see Fig. 48.1).

**48.2.1.2 Preheater.** Preheaters are used to help overcome the thermal inertia of the board. Since the nozzle exposes only a small amount of the board to a high-temperature gas stream, heating through this mechanism is limited. The preheater uses heated gas or infrared heating but heats a much larger area of the board. The preheating is set to attain a temperature much lower than the reflow temperature of the solder, but high enough that when nozzle heating is applied, reflow can take place in a reasonable period of time without overheating the component to be replaced or other components adjacent to the repair site.

Most hot-gas repair machines have a built-in bottom-side preheater. An alternative to preheating would be to bake the board in a box oven. The problem with this approach is rapid cooling of the board from the time of removal from the oven and during setup of the board on the hot-gas repair station.

**48.2.1.3 Vacuum Pickup Device.** This is generally a silicone rubber suction cup or a solid metal tube nested within the nozzle and connected to a vacuum pump. Silicone is chosen for its heat resistance and compliance. The vacuum can be toggled on and off to pick up and release a component. The vacuum pickup device serves two purposes. First, it is used to remove a component from the circuit board once the component has been heated by the hot-gas to the point of reflow. Following dressing of the repair site, the suction cup is used to hold the replacement component rigidly during lead-to-pad alignment and placement steps.

**48.2.1.4 Adjustable Stage.** This permits alignment of the nozzle to the PWB in the x-, y-, and  $\theta$ -axes. It is important for component removal but even more critical for component replacement and alignment of component leads to PWB bonding pads.

**48.2.1.5 Vision System.** This is used to align component leads to PWB bonding pads manually. Usually a split-image video system is used to view both component leads and board bonding pads simultaneously. The images are superimposed and the operator manually adjusts them for the best lead-to-pad alignment.

**48.2.1.6 Computer Control.** This is the heart of most hot-gas machines. It monitors and controls the various operations of the system, such as preheating and thermal profile. The rework engineer programs the profile manually.

## 48.2.2 Hot-Gas Repair Process

**48.2.2.1 Thermal Profiling.** As with any reflow process, whether for first-pass build or for repair, it is necessary to construct a thermal profile board as previously described to assess the impact of heating and to ensure that the heating is adequate, in accordance with the thermal

limits described by the solder paste manufacturer, the component specifications for thermal exposure, best solder wetting, and minimized intermetallic formation. In the case of repair, a dummy board is used with thermocouples attached to the component to be removed and critical adjacent components to ensure that reflow conditions are correct.

**48.2.2.2 Component Removal Preheat.** As discussed previously, preheating may be necessary to overcome the thermal mass of the assembly and to ready the board for the reflow step. Preheat temperature is set well below the reflow temperature of the solder alloy in use to confine reflow to the device being removed or replaced and to discourage widespread reflow in the vicinity of the removal or repair.

**48.2.2.3 Reflow and Removal.** The same considerations apply for this as for any reflow step. The ramp, soak, peak temperature and time above liquidus are dictated by the solder alloy used and should be roughly the same profile parameters that were used for the initial assembly of the board. Once the component has reached complete reflow, the vacuum pickup tool is engaged and the component is lifted vertically. Care should be taken to minimize the time above liquidus to minimize intermetallic compound thickness.

**48.2.2.4 Site Dressing.** Following component removal and while the board is still hot, the solder lands on the PWB can be prepared for component replacement by means of a hand soldering iron and a braided copper solder wick or a solder vacuum machine that simultaneously heats the pad by hot gas and vacuums up any excess solder. During the component removal step, solder surface tension capriciously allows some of the solder from the joint to be removed with the package leads and some to be left on the bonding pads. In the case of area-array packages (BGA, ceramic ball grid array [CBGA], etc.), the ball may remain with the package or with the land. This can make solder land dressing a labor-intensive operation. Care at this step is critical for success in resoldering a fresh component and for reliability. The dressed bonding pads should be smooth so as not to interfere with fresh component placement.

**48.2.2.5 Part Bake-Out.** As with first pass soldering, it is important to observe rules concerning component bake-out to remove any absorbed moisture and preclude part cracking during the reflow heating cycle. Guidance for part baking can be found in IPC/JEDEC J-STD-033.<sup>1</sup>

**48.2.2.6 Solder Paste or Flux Deposition.** Although this is not part of the hot-gas station, it is part of the hot-gas work cell and needs to be discussed. For most SMT components, solder paste is added to either the board or the component to effect a reliable solder joint for component replacement. This is generally done by ministencil similar to what is used for SMT solder paste deposition, but on a smaller scale; the stencil is only slightly larger than the component footprint. The paste is pushed through the stencil apertures with a razor blade or a miniature stainless-steel squeegee. Programmable syringe-dispenser machines are sometimes used, but solder paste is known to separate when under pressure, i.e., solder alloy separates from the solder flux. Choosing the largest needle bore, slowest dispense rates, and lowest pressures will help to mitigate paste separation. Also, use of direct drive auger pump rather than an air-pressure-driven dispenser will help to reduce paste separation.

Sometimes in BGA repair, solder paste is not used. Instead, solder from the BGA ball is used to make the solder joint, and solder flux must be added for this bonding step. The flaw in this methodology is that lowered solder volume results as compared to the original solder joint and the BGA reliability may not be as robust as when first soldered. In fact, any repaired joint is less reliable than a first-pass solder joint due to thickening intermetallic layer formation that comes with each reflow cycle. Addition of solder paste results in a better process because the paste compensates for small differences in BGA ball sizes. It comes upon reflow, adding some compliance to make up for non-coplanarity solder balls. Opens are less likely to occur, although more process precision is required to dispense the paste and place the BGA

without causing solder bridges. Eliminating solder paste is not an option for area-array devices with noncollapsible interconnects, such as ceramic column grid arrays (CCGAs) or CBGAs. Solder has to be added for rebonding of this type of component since the interconnects (balls or columns) are of a high-temperature solder alloy and will not reflow. Most commonly, the necessary solder is added by the aforementioned ministencil method.

**48.2.2.7 Soldering Preheat.** After flux deposition, the board is preheated to a temperature about 50 to 70°C below solder liquidus. Generally, the hot-gas rework station has its own preheater and component and board preheating is part of the reflow profile.

**48.2.2.8 Component Pickup.** As the board is preheating, the component is picked up and readied for placement. After the component is placed on a pickup station, the nozzle with vacuum pickup is placed and lowered over the component and the vacuum is activated. The component is raised up and readied for the alignment step.

**48.2.2.9 Component-to-PWB Alignment, Placement, and Reflow.** Generally, a split vision optics system is used and the semitransparent image of the component to be placed is superimposed over the video image of the PWB bonding pads for that component. When the two are manually aligned, the component is lowered on to the solder paste- or flux-coated bonding pads and the thermal cycle begins.

Once reflowed and the solder reaches solidus, the rework process is complete. The board is then ready for inspection.

**48.2.2.10 Inspection.** Visual inspection should be conducted as practical to ensure integrity of any visible solder joints and also the area surrounding the rework. Ensure that solder mask is not charred or delaminated. Also check whether bonding pads have delaminated (not possible on inner rows of area-array packages).

For BGAs and other area-array devices, following a visual check, use transmission x-ray to inspect for solder bridges. Sometimes this method also reveals lack of solder. Lastly, if in-circuit testing or functional testing is done on the first-build product, then it should be applied to the reworked product also.

### 48.2.3 Hot-Gas Rework Guidelines

Generally the number of SMT solder rework cycles per component per board is kept to two or three. Beyond that, the board should be scrapped to avoid reliability problems. The key in all reflow steps is to limit the amount of time at or near solder liquidus in order to minimize intermetallic compound (IMC) formation. IMC thickness increases with each reflow cycle and is temperature-dependent also. IMC is brittle—the weakest link in terms of solder joint structure and resultant joint strength. During component rework and replacement, minimizing thermal excursion is all important. Too often, overly high temperatures are used during rework and dwell at liquidus are prolonged as compared to a normal mass reflow soldering cycle. When a component is removed and replaced, IMC from previous soldering operations or other thermal excursions remain on the pad since the IMC becomes an integral part of the pad.

For illustrative purposes, consider the case of a surface-mount component with a copper lead-frame and copper bonding pad and either a leaded (Pb'd) or lead-free (Pb-free) solder alloy on the bottom side of the PWB. During the first-pass assembly, the bottom side of the board is built first. During that soldering process, an intermetallic layer forms at the copper lead-to-solder interface and also at the solder-to-bond pad interface. During topside soldering, the components on the bottom side of the board undergo a second reflow. Assume that a part soldered during the bottomside assembly fails and requires removal. The removal and replacement processes necessitate additional reflow cycles to the affected component site, including component removal; site repair, and component replacement. With each soldering cycle, the intermetallic layer builds and reliability generally degrades with increasing

### Intermetallic (IMC) Thickness as a Function of Soldering Cycles

**FIGURE 48.2** Soldering steps required for first-pass soldering of a bottomside component on a PWB and success reflow steps encountered during first-pass soldering and repair. Note that the intermetallic compound formation thickness is not truly linear with each step. Thickness depends on materials of the soldering system, time above solder alloy liquidus, peak temperature, etc. The illustration is meant to show that with each reflow cycle, there is increased intermetallic layer thickness.

intermetallic layer thickness. Therefore, careful process control is needed to minimize time above solder liquidus. Figure 48.2 depicts soldering and repair steps and a hypothetical impact to intermetallic layer thickness common to any soldering and repair cycles.

The thermal profile used for component replacement should be predicated on the four things: (1) the solder paste manufacturer's recommendations for reflow, (2) component manufacturer's specification for peak temperature and heating ramp rate, (3) optimization of the reflow profile, and (4) results of thermal profile established from trials with the instrumented product profile board.

For no-clean boards, the same solder paste used for the initial assembly should be used for the repair. For aqueous-cleaned boards, often a no-clean solder chemistry is used to preclude the need for another wash cycle. If solder paste is not added, then a paste flux (identical to that comprising the solder paste) should be used. This will obviate solder chemistry interactions and reduce likelihood of long-term corrosion.

## 48.3 MANUAL SOLDER FOUNTAIN

PTH components are generally repaired by solder fountain, which is akin to a wave-soldering system with a vertically pumped jet of solder. It is significantly smaller than a wave-soldering machine and generally lacks a conveyor, a fluxer, and preheaters. Since the equipment is much smaller, often benchtop-mounted, it permits an operator to manually remove parts and replace them. The classic solder fountain is a manually controlled system. Nozzles are chosen to shape the molten solder jet to match closely the size of the area to be soldered. Nonetheless, a shield or pallet is often used to localize the soldering and to prevent contact of the molten solder with previously soldered components on the board.

The board requiring repair is shielded, except in the area of component replacement, and positioned over the solder fountain. The shaped solder fountain is directed at the repair site. Once the component solder joints go molten, the component can be pulled out with gloved hand or pliers, some flux can be added, and a new component can be inserted to complete the rework within one thermal excursion. Care must be taken to ensure that all solder joints have gone molten on the component being reworked. If not, PTH barrels can be ripped out of the board or barrel annuli can be damaged.

To aid the solder fountain process, dense assemblies can be batch-heated in a box oven to make the repair process more efficient and limit exposure of the board to the turbulence of the molten solder wave. Limiting the soldered assembly's time near or above solder liquidus is key for solder joint and product reliability. As mentioned previously, time above solder liquidus along with peak temperature will define the intermetallic thickness for a given metals system, and intermetallic thickness will in part define the solder joint reliability. The turbulence of the

solder fountain is known to enhance dissolution of certain metals into the molten solder of the fountain. Copper PTH barrels can be thinned and PTH annuli (bonding pad atop the PTH) can be thinned or completely dissolved, impairing the degrading solder joint either to make a connection or to ensure long-term reliability. The high turbulence, high temperature, and long dwell times all hasten dissolution in this fashion. For this reason, precise process control, including strict exposure time limits and minimum solder pot temperature, must be imposed for this largely manual operation. This process is best suited for repair and should be avoided, if at all possible, for first-pass soldering of printed circuit assemblies.

#### **48.4 AUTOMATED SOLDER FOUNTAIN**

---

This version of the solder fountain incorporates a programmable head and is used mostly for first-pass soldering, but can be an effective soldering repair tool once the PTH component is removed, the site is prepped, and a new component is placed. A programmable nozzle emitting a precise jet of molten solder is directed at the leads of the component to be soldered. The nozzles allow point soldering of very fine PTH pitches.

#### **48.5 LASER**

---

Laser is a recent innovation in rework and repair. The fundamentals of laser for initial soldering or for repair have already been discussed in Chap. 47. In the commercial incarnation of this technique, a laser beam is quickly scanned around component leads or, package surface, in the case of area-array devices such as BGAs and chip-scale packages (CSPs). It is most effective for plastic packaged components rather than the thermally massive CBGAs, CCGAs, and so on. In this technique, the component body is heated. Otherwise, there is little difference between this and alternative rework or repair techniques.

Since the energy of the laser beam is more tightly confined to the area it irradiates, the heating is more localized. This can be advantageous when trying to remove or replace a component on a densely populated, double-sided PCA. Otherwise, the same caveats must be kept in mind regarding IMC formation and pulling components before they are fully reflowed. Care must be taken to assess carefully the assembly for laser damage threshold so as not to char components or PCAs during either removal or component resoldering.

#### **48.6 CONSIDERATIONS FOR REPAIR**

---

##### **48.6.1 Mixing Aqueous With No-Clean Chemistries**

Care must be taken when using fluxes for the rework and repair processes. If an aqueous-clean solder chemistry is used for building the PCA, then either no-clean or aqueous flux formulations can be used. If an aqueous chemistry is used for the repair, then the board must be subjected to another aqueous cleaning cycle. Be sure to check that all components at that stage are compatible with the aqueous cleaning process.

No-clean solder flux formulations can be used for rework and repair even if the PCA was manufactured with an aqueous clean chemistry, although the reverse is not recommended. Sometimes when a no-clean board is subjected to an aqueous cleaning, the no-clean flux residue takes on a white, gummy characteristic that is conducive to dendritic corrosion, which can result in soft or hard electrical shorting. Saponified aqueous cleaning can be used, but must be tested for effectiveness in removing the polymerized flux residue from the no-clean process and for compatibility with the selected no-clean flux to avoid generation of corrosive byproducts. This is particularly important under connectors, area-array devices, and other components with low headroom between the underside of the body and the PWB surface.

### 48.6.2 Pooled Flux

Another consideration with no-clean solder chemistries is that of pooled, unactivated flux residue. No-clean solder flux is generally harmless after it has gone through the thermal cycle associated with solder reflow. It is activated and denatured by the heat. If the flux is applied generously and the flux pool does not see the high temperatures associated with solder joint formation, acids remaining in the unheated flux residue can cause reliability problems. These acids are normally denatured, evaporated, or sublimed through the high-temperature excursions of the soldering process. If the flux acids remain, corrosion can occur in the long term. There are commercial flux solvents that can be used to dilute and wash away excess flux; otherwise, the assembly can be baked briefly to about 120°C to denature the flux. Check with the flux manufacturer for specific recommendations regarding flux residue management. The problem can be avoided by eliminating the use of liquid flux and using small amounts of paste flux instead. In the case of core wire, use the smallest diameter practical to limit flux residue.

### 48.6.3 Component Bake-Out

Components that have been sitting out may be subject to water absorption. When components are heated during rework, where the heating cycle is more localized and perhaps more extreme than in the slow heating experienced during mass oven reflow soldering, moisture-induced popcorning may be a more serious problem. Follow IPC or component manufacturer recommendations for presoldering moisture bake-out. Refer to Sec. 50.2.2.5 for further discussion on this topic.

### 48.6.4 Gold Finger Protection

There is ample opportunity to ruin gold edge connector fingers on a circuit board during the repair operation. Care should be taken to keep both solder and flux away from gold fingers during repair. Mechanical shields or acrylic-adhesive polyimide tape can be used to protect fingers from smeared solder paste, loose solder debris, or flux. If solder comes into contact with gold, the gold will rapidly dissolve into the solder mass and the solder will spread on the finger. The solder cannot be removed from the gold finger without scraping and replating, a costly process. Solder is not a reliable connector contact material, especially with today's high-density, low normal-force electrical connectors.

Keep solder away from gold fingers. Keep gold finger temperature as low as possible. Ensure that gold fingers are never handled, even with gloved hands. Avoid lint and fibers. After rework, clean gold fingers with a suitable solvent. Use a soft brush, lint-free cloth, or other nonabrasive material for this cleaning. Clean gold fingers on each side of the board separately.

Avoid folding the lint-free cloth over both edges and wiping repeatedly; the cloth will wear against the glass-epoxy expunge and shred, leaving lint on the board. A better alternative is to use a soft, ESD-safe brush with solvent to clean the gold fingers and follow with a filtered-air blow-off to dry. Avoid any materials that will scratch the gold surface finish on the fingers. The underlying nickel, if exposed to the atmosphere will oxidize and, is known to be problematic for separable contact reliability.

---

## 49.1 INTRODUCTION

---

Electronic connectors are attached to printed circuit boards in four ways (see Fig. 49.1):

- Oven reflow surface-mount technology (SMT) soldering
- Wave soldering (for solder-tail components)
- Pressure interconnect, a solderless method relying on mechanical forces to hold interconnect elements together to make contact
- Press-fit, another mechanical, solderless method (which is the subject of this chapter)

Press-fit, also referred to as *press-pin*, *compliant-pin*, and a number of other trade names, has been in use for many years and is a proven and reliable interconnect method. Once used exclusively for passive backplanes, more recently press-fit connectors have gained in popularity and are commonly incorporated on complex motherboards and daughter-cards. Just as circuit boards have become more complex (with thicker, higher layer counts, densely routed circuit traces, and high component counts), so too have press-fit connectors. They are available with high pin density (pin pitch down to 1 mm) and pin counts in the thousands per connector and even strip-line shielding for enhanced high-speed signal performance. Press-fit connectors can be applied to either or both sides of a PCA and are repairable, although first-pass assembly yields are always near 100 percent. Press-fit is easier and more reliable than soldering and does not subject the printed circuit assembly (PCA) to additional thermal or chemical processes—an advantage for reliability, and especially advantageous for today's dense circuitry. Since it requires very little energy (no soldering), minimizes materials (no solder), and calls for no chemicals for its application, it is environmentally beneficial. The press-fit process is simple in theory and generally so in practice, relying on oversized connector leads forced into in plated through-holes in the PWB. The plated through-holes in the PWB are sized specifically for the press-fit connector to be applied. As the connector pin is forced into the board, there is slight deformation to the press-fit pin and to the PTH barrel. The result is a mechanically stable, electrical contact.

**FIGURE 49.1** Four methods of connector attach to printed wiring boards (PWBs): (a) SMT applied by reflow soldering; (b) plated through-hole (PTH) solder-tails that are wave-soldered; (c) pressure-interconnect, which relies on mechanical forces for electrical contact; and (d) press-fit, which relies on mechanical deformation of the connector lead and PTH barrel to make intimate electrical contact.

## 49.2 THE RISE OF PRESS-FIT TECHNOLOGY

There is a resurgence in press-fit connector popularity driven by increasing board complexity, the component density of today's PCAs, and the appearance of backplanes populated with active components. Press-fit connectors are typically used on very thick boards that would be difficult, or impossible, to wave-solder. Elimination of wave soldering increases manufacturing yield and allows a denser component layout on the bottom side of the board, contrary to what is dictated by wave soldering. Another advantage of using press-fit connectors is that it is a means of lead (Pb) abatement since no solder is needed for press-fit installation. Given the climate of increasing importance of environmental responsibility and the potential for lead abatement legislation passing in several countries, use of press-fit components will likely increase. Since Restriction of Hazardous Substances (RoHS) legislation allows Pb for certain products such as two-processor servers and telecommunications equipment until 2010, there is no need to solder the same connectors that are press-fitted and, thus, press-fitting significantly limits the need for Pb.

Connector bodies may or may not be compatible with the thermal rigors of reflow or wave, so press-fit connectors are typically applied after all mass soldering of the PCA is completed. Further, press-pin connectors are not generally soldered into place since rework would be rendered impractical. Rework of press-fit connectors will be discussed later in this chapter.

## 49.3 COMPLIANT PIN CONFIGURATIONS

There are many different press-fit pin configurations—far too many for this chapter to review each one. Instead, three commonly used styles will be described as an introduction to press-fit technology. The first has a lead of square or rectangular cross-section that is sized to deform

**FIGURE 49.2** A square or rectangular pin forced into round hole. This is the most primitive of press-fit techniques.

the board's plated through-hole slightly upon insertion. This is the proverbial “square pin in a round hole.” The lead is tapered at its end to facilitate initial PTH insertion (see Fig. 49.2).

Second is the square-pin variant sometimes referred to as the “H” section, which consists of a sculpted rectangle, an “H” in cross-section, whose corners are meant to deform (see Fig. 49.3).

The third and most prevalent configuration is the collapsible pin known as “eye-of-the-needle” (EON) (see Fig. 49.4).

Upon insertion and pressing into the PTH, the EON pin folds upon itself axially in a controlled manner, as depicted in Fig. 49.5.

The plated through-hole barrel is slightly deformed from the mechanical interference of the press-fit pin against it. The resultant forces from the collapsed press-fit lead against the PTH barrel wall result in stable, long-term mechanical and electrical contact.

**FIGURE 49.3** “H”-section press-fit pin. The sculpted cross-section of the pin allows the pin to deform slightly. This deformation along with some deformation of the PTH barrel upon insertion allows for reliable mechanical and electrical contact.

**FIGURE 49.4** “Eye-of-the-needle” configuration press-fit pin, shown before compression.

**FIGURE 49.5** As the EON pin is driven into the PTH barrel, its compliant section collapses inward upon itself. The resultant forces between the pin and the PTH barrel wall result in a stable, intimate mechanical and electrical contact.

## 49.4 PRESS-FIT CONSIDERATIONS

### 49.4.1 Proper Loading

The load necessary to apply a press-fit connector depends on a variety of factors, including pin design, pin material, pin size, pin surface finish (plating), PTH surface finish, plating thickness, pin and hole size, and the number of pins per connector. The connector manufacturer should provide the required loading per pin for each connector for proper insertion and connector seating.

### 49.4.2 Correct Design and Size

Press-fit connector leads are designed to work within a tight range of PTH barrel diameters. The compliant pin normal force exerted against the PWB plated through-hole barrel wall must be maximized to anchor the connector into the PWB reliably, both for mechanical stability and electrical contact. The connector manufacturers will recommend proper PTH diameter and tolerances for their products. The resultant press-fit coupling is analogous to the solder joint. If the pin and barrel are sized properly and materials are appropriately finished, the anticipated joint life will be better than that of soldered assemblies. Also if the pin and barrel are sized correctly, the pin-to-barrel normal force will be high enough to form a gas-tight seal for long-term electrical and environmental contact reliability. The pin must be strong enough longitudinally to prevent buckling during the pressing operation. Pin normal forces must be optimized so as not to

damage the PTH barrel—high enough for good contact, but light enough that the pin insertion will not damage the barrel or the PWB.

#### 49.4.3 Reproducible Connector Press

Since pressing force generally ranges from some 10s of grams to kilograms per lead, the mechanical advantage of a reproducible press machine is required for press-fit connector application.

### 49.5 PRESS-FIT PIN MATERIALS

---

#### 49.5.1 Base Material

For purposes of affordability, mechanical integrity, electrical properties, and materials conservation, all electrical contacts, regardless of assembly methodology, are made from inexpensive base metals and plated with a minimum thickness of a more precious or more practical material. Many press-fit connectors have been made of beryllium-copper alloy, but due to beryllium dust toxicity, a factor in press-fit lead preparation, the switch to safer phosphor-bronze or other copper alloys has occurred throughout the industry.

#### 49.5.2 Surface Finishes: Pin and Barrel

Since most materials oxidize readily upon exposure to the atmosphere, gold or other noble metals are often used to prevent or retard oxidation of SMT or PTH component leads or PWB solder lands and plated through-hole barrels. However, most circuit boards and component leads are covered with less noble materials such as tin (Sn) or tin-lead (Sn-Pb) and instead rely upon a fluxing agent to remove naturally occurring oxides prior to and during the soldering process. In a solder joint, the component lead and pad interface materials are wetted by and sealed in solder. The solder gives the interconnection mechanical rigidity and seals the contact surfaces from the environment. This is not the case with press-fit technology.

The press-fit process is compatible with all surface finishes on the pin and the PTH barrel. The frictional properties of some materials are more favorable to the press-fit process than others. Sn-Pb is known to have favorable properties for the press-fit process. Pb is known for good tribologic properties and acts as a lubricant for the press-fit process. Copper is less favorable but is not a problem if the PWB hole is sized properly for the press-fit pin.

#### 49.5.3 Materials in Light of RoHS

With the onset of the European Union's (EU) RoHS legislation, there is additional consideration for the press-fit process. The original directive banned Pb for most PWB materials and assembly. This resulted in two problems. First, press-fit connector contacts converted to Sn instead of Sn-Pb would risk Sn-whisker formation. Unlike Sn-coated SMT component leads, there is no reflow associated with press-fit technology. Without the reflow step, Sn-whisker formation is much more likely to occur. Second, increased frictional forces from Pb-removal on currently designed products made pressing difficult and in some cases resulted in damage to the PWB. EU's RoHS technical advisory committee was petitioned and an exemption to the RoHS legislation was enacted permitting the use of Pb in surface finishes for "compliant pin connector systems."<sup>1</sup>

#### 49.5.4 The Gas-Tight Seal

In the case of the press-fit connector pin, there is neither a physical wetting of material nor metallic encapsulation to protect the interconnection. Additionally, no chemical fluxing agents are used.

Instead, the press-fit pin is anchored solely by the mechanical interference between connector lead and the PTH barrel of the PWB. Oxides on the surface of the press-fit pin and mating PTH barrel are broken loose by the high frictional forces associated with the press-fit assembly operation, so nobility of materials, oxide build-ups, and material shelf-life are less critical considerations than in soldering. If conditions are proper in terms of sizing and materials, the press-fit process results in a gas-tight contact between the connector pin and the PTH barrel wall.

The notion of a gas-tight seal as the product of a proper press-fit is crucial to connection reliability. If an electrical contact is to be reliable, the interface between the two mating surfaces must remain chemically and mechanically stable. The gas-tight, smeared, metal-to-metal contact attained during the press-fit operation mitigates oxidation of either contact (PTH barrel or press-fit pin) and prevents fretting corrosion, which is a common failure mechanism for mechanically mated contacts, especially those subjected to vibration. Press-fit interconnection is considered at least as reliable as a soldered connection and there is no solder joint to degrade or crack with time.

## 49.6 SURFACE FINISHES AND EFFECTS

---

Surface finish of the PWB's PTH has a significant effect on the force required to seat a press-fit connector. Changes in surface finish and PTH finish quality can have a profound effect on pressing force and reliability.

### 49.6.1 Tribology

Every material has frictional (tribologic) properties. Some are naturally lubricating, such as Sn-Pb alloys, and others are notably nonslippery, such as tin or copper. Copper is one of the least slippery of the surface finishes and typically requires more pressing force than Sn-Pb or gold finishes for a comparably sized hole. Tin's crystalline structure is also rather resistant to sliding. In some cases, extra attention to PTH finished hole size (FHS) is required. The PWB vendor should be alerted to the fact that holes are being placed in the board for press-fit, so FHS and surface finish conditions are appropriate for the press-fit component. In some cases, for some materials such as copper, the holes could be specified for the upper end of its FHS as expressed by the connector vendor to aid in insertion. FHS should be just that: the hole size after surface finish is applied.

If tribologic forces are too great, then the PTH barrel can be pushed out of the board or otherwise damaged. Trial boards and pressing parameters should always be assessed before full manufacturing commences. Only very small changes or imperfections can interfere with the typically high yields of press-fit connections.

As previously mentioned, recently the European Union exempted press-fit connectors from its RoHS legislation, allowing the use of Sn-Pb coatings on compliant tails. The Pb adds a small amount of lubricity, allowing for easier pressing into notably difficult surface finishes such as organic solderability preservative (OSP)-copper.

### 49.6.2 PTH Barrel Finish

Barrel finish can have a profound impact on the press-fit operation. If a PTH barrel is too thin or poorly sized for the compliant pin, the pin may pierce the barrel wall or break internal connections to it. OSP-copper finish—since it is a watery, thin topical coating—adds no appreciable thickness to the PTH lands or barrel, so its control in high-aspect-ratio holes is not an issue in terms of press-fitting. Electroless/immersion surface finishes are generally thin and self-limiting in thickness, and as with OSP-copper, there is no appreciable change in PTH hole diameter adding little impact to the press-fit process.

At the other end of the spectrum are hot air solder leveling (HASL) and electroplated finishes, which may add significant material to PTH barrel walls and annular rings. Too thick a HASL coating can lead to PTH barrel diameter reduction. During pressing, the press-fit pins may be overcompressed, causing them to yield and collapse beneath the connector rather

than go into their respective through-holes. Sometimes solder from the HASL surface finish can redistribute during SMT reflow cycles, causing a bulging meniscus within the PTH. This condition is depicted in Fig. 49.6a. Compare this illustration to that in Fig. 49.6b, which shows a normally finished PTH with even wall coating, a relatively uniform barrel diameter, and an evenly coated primary-side annular ring. With the advent of RoHS, HASL finishes are less common, but press-fit is commonly used in high-end servers and telecommunications equipment where the use of Sn-Pb solder is currently exempt from RoHS Pb-free requirements.

Excessive plating on PTH barrel walls and annular pads (see Fig. 49.6c, d) can cause premature collapse of the compliant section of the press-fit pin. This condition may result in excessive pressing force to get the pin into the hole as well as insufficient normal contact force from the collapsed press-fit pin section to the barrel once fully seated in the hole. This condition poses an electrical contact reliability risk, as shown in Fig. 49.6e, where the pin is not actually in contact with the PTH barrel walls.

Figure 49.7a shows a precollapsed press-fit pin that is making only intermittent contact due to the PWB condition as depicted in Fig. 49.7b.

High-aspect-ratio holes (PWB thickness: PTH diameter) may have irregular plating where the thickness closest to the board's outer layers is within acceptable thickness limits, whereas plating thickness in the middle of the PTH may have unusually thin deposits. These thin deposits are caused by plating bath stagnation and exhaustion—a zone of poor electrolyte circulation within the high-aspect-ratio barrel. This condition may also lead to poor contact of the press-fit pin against the PTH barrel wall and contact reliability issues. The opposite can be detrimental also, where the PWB vendor strives to attain the proper plating thickness within the PTH barrel, but plates too much material at the barrel openings and on annular rings.

### 49.6.3 Slivers

The Pb of Sn-Pb solder-coated barrels is known to reduce the force required for press-fit connector insertion and seating. Although Sn-Pb coating is one of the best surface finishes for pressing, if it is thick, then the press-fit connector pin may skive a thin sliver of solder and push it out the secondary side of the PWB (see Fig. 49.8). Very often these slivers

**FIGURE 49.6** Barrel profile as a result of surface finish coating: (a) A PTH barrel with excess surface finish from HASL, which has formed a meniscus upon solder reflow. Other plating defects can result in such a meniscus, although the problem is uncommon. (b) A normal PTH barrel with evenly coated walls and annular rings. (c) Excessive plating on PTH barrel walls and annular pads. (d) Excess plating on annular ring causing pin interference and premature EON pin collapse. (e) An overly compressed pin resulting from excess plating on PTH annular ring. This condition poses a reliability risk.

**FIGURE 49.7** (a) Excess nickel plate on a PTH annular ring has caused two problems. First, it has shaved material from the press-fit pin (arrows labeled “x”). Additionally, it caused compression of the compliant section of the pin. When fully seated in the PTH, the pin was too loose for reliable contact. The “y” labels demark a gap between the press-fit pin and the PTH wall. Compare this to (b), where pin shaving is evident but the pin is in intimate contact with the PTH barrel. (Scanning electron microscope (SEM) micrographs courtesy of A. Alexander, Jabil Circuits, Penang, Malaysia.)

**FIGURE 49.8** A solder sliver (dashed outline) pushed out of a HASL-coated PTH.

remain attached to the pin or the PWB, or they become jammed between the pin and barrel. The sliver may break free of its source and cause an electrical short locally or elsewhere in the system.

## 49.7 EQUIPMENT

Several types of mechanical presses are used for applying press-fit connectors to PWBs. The lever-activated arbor press is the most primitive but suffices for simple, low-lead-count, coarse-pitch connectors. One step up is the pneumatically driven press. Although it is easier to operate than the lever-activated arbor press, it does little for process control or assembly repeatability. Higher on the evolutionary scale is the pneumatic/hydraulic combination (the so-called “air-over-oil” press), which offers a somewhat more controllable process. High-precision pressing cycles are mandated by the latest press-pin connectors with their delicate, molded body features, fragile electrical shielding, and fine pin pitch, so it is advisable to use a machine that is computer-controlled. Aside from force and speed precision for process reproducibility, press cycle data can be stored along with process recipes for ram force, speed of compression, and component location if equipped with programmable axes. Data logging is critical for statistical process control and is useful for press cycle root-cause defect analysis or machine troubleshooting.

The state-of-the-art connector press is electromechanically actuated, relying on a motor-driven coarse-pitch lead screw with tachometer speed control, z-axis positional encoders, and load cell feedback for an accurate pressing cycle (see Fig. 49.9).

**FIGURE 49.9** An electromechanical connector press.

Some commercially available machines are automated even to the point that they are able to shuttle boards into the press, pick and place connectors, select a connector-appropriate pressing tool and supporting tool anvil, rotate the tools to the proper orientation, and press multiple connectors sequentially on a single board or multiple nested boards. There are several ways to control the press-fit process. Methods and merits of each are discussed in the remainder of this chapter, but first a more detailed review of the mechanics of the press-fit process is in order.

## 49.8 ASSEMBLY PROCESS

Press tool and support plate are fabricated to match connector requirements and PCA layout. The PCA is placed on the press-fit tooling fixture support plate. The operator manually places the connector into the appropriate plated through-holes in the PWB. The ram and tool are aligned to the connector to be pressed. When press-fit connector leads are forced into PWB plated through-holes during a pressing cycle, there is a characteristic fingerprint of force versus vertical distance traveled for each connector and PWB type. The various events and slopes that comprise the fingerprint are shown in Fig. 49.10.

As pressing progresses, connector leads are forced into the plated through-holes and the compliant section of its pins deform elastically, then plastically. Continued resistance is encountered due to the friction of the collapsed pins sliding along the PTH barrel walls. Another inflection in the plot occurs where the connector fully seats against the PWB. Further force affects little or no change in distance and the press cycle ceases. Were the cycle to continue, damage to the PWB would result.

**FIGURE 49.10** Force versus distance plot of a press-fit cycle. Inflection points and regions are as follows: (a) initial force is applied to the press-fit connector; (b) the compliant section of the pin collapses; (c) the pin collapse is complete; (d) the pin slides along PTH barrel wall, creating friction; (e) the connector is fully seated; (f) continued pressing makes little change in press distance. The pressing cycle is complete.

## 49.9 PRESS ROUTINES

For best results, a method that allows real-time measurement and control of the pressing process is preferred and is available on today's commercial presses. There are four commonly used pressing routines, but only three take advantage of force-sensing, distance-sensing, or real-time feedback control of the connector press. Connector complexity and equipment availability dictate press-fit assembly methodology.

### 49.9.1 Uncontrolled Pressing

This was the most prevalent technique for a long time, but it rapidly lost ground to more sophisticated pressing methods, as described later in this section. It commonly relies on an arbor press and human muscle to force the press-fit connector into the PWB. There is neither force sensing nor speed control. It is the least reliable way to press connectors into PWBs and is not recommended for complex connectors or fragile PWBs. If too high a ram speed is used on a delicate connector, its pins may buckle. This method may not provide enough force for some high-lead count connectors.

Although this type of pressing is discouraged, it may be adequate for low lead-count, coarse-pitch connectors in noncritical assemblies. As with any press routine, a suitable support fixture must be used beneath the board to keep the assembly from breaking or flexing. It should incorporate support to counter the forces of the ram, and relieved areas to accept protrusion of press-pins below the bottom side of the board and clearances for bottomside components as shown in Fig. 49.11.

**FIGURE 49.11** The supporting fixture is critical for good press-fit application. It must have clearances for press-pin protrusion and any bottom-side components.

### 49.9.2 Height-Limited Pressing

As previously described, connector presses have matured into sophisticated machinery; improved greatly over the arbor press. Some are capable of precisely determining ram height above a datum such as the top surface of the PWB. If board-to-board thickness is consistent, then the connector can be forced into the board to a predetermined standoff

height as required by the connector specification. Just as connector pin dimensions vary from connector to connector, so do plated through-holes in the PWB. Pressing to a predetermined height (that is, *press to height*) ensures that the connector will be seated the same way each time, regardless of the pin or hole condition and the resultant force required to seat the connector (see Fig. 49.12). Variations in PWB thickness, variability in the molded cross-section of the connector body, or molding flash can result in imprecision and negate some of the benefits of this approach.

**FIGURE 49.12** Height-limited pressing forces the connector to a predetermined standoff distance, “Z,” from the surface of the PWB.

### 49.9.3 Force-Limited Pressing

Force-limited pressing (or *press to force*) relies on the intelligence of an instrumented connector press to sense that a predetermined force limit has been reached, at which time the pressing cycle is terminated. The force limit can be roughly set to coincide with the average force required per compliant pin (available from the press-fit connector manufacturer’s specification) multiplied by the number of pins per connector. Application of upper and lower tolerances of specified force per pin coupled with knowledge from empirical trials will help refine the acceptable press force envelope for a given set of materials. This technique is highly sensitive to the material conditions of the compliant pins and the plated through-hole diameters.

### 49.9.4 Gradient-Limited Pressing

The slope or gradient of the final portion of the force-versus-distance plot (refer to Fig. 49.10, and the inflection labeled “e”) can be used to trigger the end of the press cycle and retract the ram. This routine ensures that regardless of pin size, hole size, board or connector variations, the connector will not be overpressed. This is most reliable when a very steep slope is chosen and refined empirically. Gradients in the range of  $\geq 75$  percent are generally favored. This routine is also known as *press to gradient*.

### 49.9.5 Rework for Press-Fit Connectors

The press-fit operation is inherently high yielding, but problems with the process or a bad press-fit connector may necessitate the removal and replacement of a connector. As a result of the press cycle, the compliant pins of a press-fit connector are plastically deformed. Therefore, once used, the same connector cannot be removed and reinserted in a circuit board. However, most press-fit connectors are designed to be reworked—that is, repaired or replaced. In some cases, individual leads or contacts can be replaced. In other cases, banks of leads or contacts can be substituted. Some press-fit connectors require complete removal of the damaged connector for replacement with a new one. Many different press-fit connectors are on the market, and each has its own manufacturer-recommended repair strategy.

Press-fit assemblies are generally designed to accommodate at least two connector replacement cycles. The two cycles are predicated on (1) the normal force exerted by the press-pin’s compliant section on the PWB’s plated through-hole barrel wall, and (2) the quality and condition of the PWB’s plated through-hole barrel surface after subsequent press-fit connector removals and replacements.

Were the normal force of the compliant section on the PTH barrel of a press-pin excessive, it might cut through the barrel and even damage surrounding innerlayer interconnects or traces. Instead, the normal force is optimized to permit gas-tight seal without excessive deformation or deep skiving of the plated through-hole barrel. Once a connector or connector pin is replaced, the new connector/pin must result in a gas-tight pin-to-barrel seal for reliable contact. Each time that a new press-pin is inserted into a plated through-hole, there is opportunity for the barrel to deform; the more insertions into the barrel, the deeper the deformation. It is for that reason that the industry standard design goal for compliant pin connectors is generally targeted at only two replacement cycles. Beyond two replacements, there is the possibility that the barrel will be thinned and damaged, impairing press-pin contact reliability or compromising the trace-to-barrel interconnection.

Press-pin rework tools vary greatly. In some cases, they are designed to remove and replace a single pin. In other cases, the tool may be designed to help dislodge an entire connector from a circuit board. Some tools are designed to remove the molded connector body only. Then individual pins are pulled by pliers one by one in preparation for replacement. Sometimes multiple press-pin ground or power leads are stamped into discrete wafers, and then the wafers are inserted into the plastic molded connector body to form a single press-fit connector. In this case, individual wafers can sometimes be removed and replaced rather than having to replace single leads or the entire connector. Repair tools and repair strategies are generally available from the connector manufacturer.

To avoid damage to the board, components, or solder joints, the PWB must be supported so that it is not flexed during press-fit component removal or replacement. It is a good practice to verify circuit integrity by electrical test before and after repair to ensure that it is not degraded as a consequence of the repair cycle. If a connector is replaced because of pin stubbing on the surface of the circuit board upon the original installation, ensure that the surface and underlying traces of the circuit board have not been damaged by the errant lead (see Fig. 49.13).

**FIGURE 49.13** (a) Misaligned pin stubbing on the surface of the PWB. (b) The stubbed pin has folded under the connector. Stubbing may damage the PWB surface or subsurface traces.

## 49.10 PWB DESIGN AND BOARD PROCUREMENT TIPS

### 49.10.1 Clearance for Press-Fit Tools for Assembly and Rework

To avoid process problems and damage to adjacent components, there should be sufficient clearance in the PCA design to permit room for the pressing tool, board supports, and use of any associated rework tools.

### 49.10.2 Long Pins Preferred

When possible, use press-pin contacts slightly longer than the board thickness so that connector pins will protrude on the bottomside of the board after the pressing cycle. Pin protrusion permits easy inspection of the finished assembly. A missing pin is evidence of pin stubbing or buckling.

### 49.10.3 PTH Size and Finish

Follow the press-fit connector manufacturer's recommendation for PTH finished hole size, tolerances, and acceptable or tested surface finishes. Use cross-section sample boards with high-aspect-ratio (depth:diameter) holes to qualify the PWB vendor and determine typical PTH barrel profile. Ensure that wall thickness of plated through-holes are uniform throughout their depth and meet connector specifications. Make certain that the surface finish on the PTH annular ring does not interfere with insertion of the compliant press-fit pin.

## 49.11 PRESS-FIT PROCESS TIPS

Several things can be done to ensure adequacy of the press-fit operation in manufacturing.

### 49.11.1 Use a Proper Press

Use of an electromechanical press is recommended for best precision and process feedback. Its precision and feedback mechanisms will minimize the impact on the PWB, or connector.

### 49.11.2 Check Pins for Straightness

Prior to insertion into the board, check press-fit connector pins for straightness and integrity. An inexpensive go/no-go gauge (see Fig. 49.14) can be machined to check that connector pins are not bent. It should be constructed so that it neither compresses the compliant section of the press-fit pin nor damages its surface coating. This is especially helpful for fine-pitch press-fit connectors (1 mm centers) and is better than relying on visual inspection for pin field integrity.

**FIGURE 49.14** Gauge for checking connector pin position prior to pressing. This is best used for high lead count, fine-pitch pin press-fit connectors.

### 49.11.3 Keep the Press-Fit PTH Clear of Foreign Material

Protect press-fit PTH holes from extraneous solder, flux, surface-mount adhesive, spot mask, or other contaminants from surface-mount, wave-solder, or hand-solder processes. Use of a wave pallet or high-temperature masking tape (e.g., polyimide tape) to shield press-fit locations during other processing is advisable. If tape is used, inspect first articles to ensure that high-temperature masking tape residue does not foul press-fit holes. Polyimide tape with acrylic-based adhesive is best for this application, as residues will be absent or minimal.

### 49.11.4 Use the Proper Press Tooling

Use hardened-steel pressing tools as sold or recommended by connector manufacturer to avoid damage to the connector or the PCA.

### 49.11.5 Provide Proper Board Support

Adequately support the PCA during the pressing operation so that connectors can be fully homed and that the board is not overflexed. Excessive board flexure may cause solder-joint cracking, broken PWB circuit traces, and board delamination. This is especially important for the characteristically inflexible ball- or column-based solder joints of area-array devices such as BGAs and CCGAs.

The best support will be localized directly under the connector to be pressed. Ensure that the support includes clearance for backside pin protrusion; otherwise, pins will stub and bend on the supporting anvil. Support tooling design should carry appropriate relief features for bottomside components.

## 49.12 INSPECTION AND TESTING

---

### 49.12.1 Connector Inspection

Check the connector after pressing for even bottomside pin protrusion, topside connector body seating height, damage to the connector body, inaccurate mating pin positions (within the connector as opposed to within the board), damage, or movement of electrical shields if the connector is so equipped.

### 49.12.2 PCA Inspection

Check the PCA for surface damage in the area of the pressing operation. A mispositioned or damaged press tool or board support can damage components or overly compress the laminate causing outer- or innerlayer trace damage. Look for errant tooling marks on the PWB surface after the press-fitting operation. Overcompression of the board can lead to compressed or severed traces within the board. A compressed trace may impact current capacity and result in localized circuit overheating or otherwise impact signal integrity.

### 49.12.3 Solder Sliver Inspection

Check the bottomside of the board for solder sliver formation. This is especially relevant in the case of HASL boards. Brush these out if required and inspect. Loose slivers may cause electrical shorting on the board or other boards within the system enclosure. Work with the

PWB vendor to ensure that drilled and plated holes are sized appropriately for the press-fit process and that excess solder from the HASL process does not adversely alter the finished hole size or shape.

#### 49.12.4 Electrical Testing

In the case of high-friction surface finishes, such as OSP-copper, forces applied during the press-fit process may be so great as to cause damage to the PTH barrel or adjacent inner- or outerlayer circuit traces. Check the board visually and by electrical test as part of a first article inspection.

#### 49.12.5 Check Tooling Frequently

Check for excessive tool wear or damage. A damaged tool can ruin a connector or PWB and replicate the damage over many boards.

### 49.13 SOLDERING AND PRESS-FIT PINS

---

Apply press-fit connectors after all SMT and wave-soldering operations. Do not try to solder press-pin connectors in place. Press-fit connector bodies may not be reflow-compatible. Soldering a press-fit connector will also make rework difficult or impossible.

# CHAPTER 50

---

# LAND GRID ARRAY INTERCONNECT

---

**Gary M. Freedman**

*Hewlett-Packard Corporation, Business Critical Systems, Singapore*

---

## 50.1 INTRODUCTION

---

The land grid array (LGA) device is a solder-less package that relies upon pressure contact to interconnect it to the board mechanically and electrically. Interconnection is accomplished through a socket or interposer that is sandwiched between the LGA integrated circuit (IC) package and the printed wiring board (PWB). The socket has compliant, conductive contacts that match the LGA and PWB contact land patterns on each. A system of insulators, stiffeners, and fasteners keeps the LGA in intimate mechanical and electrical contact with the PWB. Care in assembly and cleanliness is of utmost importance for successful pad-to-land contact and subsequent assembly reliability. The reader should be aware that there are leadless soldered packages also called land grid arrays, but this chapter will deal with the pressure-interconnect variety of leadless package.

Most often, an LGA-type interconnect is used for mounting a central processor unit (CPU) chip or other active device to a PWB. It is also used for some connectors. An advantage of this type of interconnect is that it makes it possible to exchange a chip without the need to unsolder and re-solder, facilitating rapid rework, engineering changes or field upgrades without soldering and without degradation in reliability. The LGA concept has been applied to connectors also. Although the technique has been in use for several years, it is still a niche technology but will likely increase in importance as input/output (I/O) counts continue to increase and package size limitations for soldering are met.

---

## 50.2 LGA AND THE ENVIRONMENT

---

Since the LGA connection to the PWB is solderless, it is environmentally friendly, requiring no heating for solder, soldering, or rework. It is easy to move into compliance with the European Union's (EU) Restriction of Hazardous Substances (RoHS) requirements since solder considerations (at least external to the package) are absent.

### 50.3 ELEMENTS OF THE LGA SYSTEM

There are five key elements and several subelements that make the LGA system practical and reliable. These are pictured in Fig. 50.1, but be aware that there are many variations. Key elements will be described in a generic sense in this chapter.

FIGURE 50.1 Elements of an LGA stack.

#### 50.3.1 PWB and LGA Issues

**50.3.1.1 Contact Lands.** The PWB is much like any other board. It has lands to accommodate electrical interconnect of the LGA socket to the board. The lands correspond in size and shape to socket requirements. Most often, the LGA lands on the PWB are electrolytic nickel covered by electrolytic gold. Hardened gold is often used for added contact durability and reliability. Other surface finishes can also be used, but should be tested for reliable and long-lasting contact.

**50.3.1.2 Drilled Holes.** LGA sockets have the requirement for two sets of drilled holes in the PWB. One set is used to accommodate fastening of the bolster plate through the PWB. The second set is used to orient and retain the socket on the PWB. The closely toleranced orientation holes correspond to molded locating pins on the LGA socket and they are meant to locate the socket contacts properly on the LGA lands of the PWB. The socket manufacturer will provide guidelines and drill pattern recommendations. It is good practice to make the locating pins different sizes and to drill the PWB accordingly to polarize the socket so it cannot be misoriented on the board.

**50.3.1.3 PWB Layout Considerations.** There are some layout considerations such as avoidance of components in the vicinity of the LGA socket, bolster plate, and pressure plate. PWB flatness should be considered so that best contact can be made to the board once the LGA interconnect system is fully assembled.

#### 50.3.2 Bolster Plate

LGA technology relies on a pressure interconnect system, and the bolster plate is the rigid backside element that serves to anchor the LGA system to the PWB. It is inserted through pre-drilled holes in the circuit board and provides the means for fastening the clamping mechanism

**FIGURE 50.2** Stainless steel bolster plate (l) and insulator (r). (Courtesy of Hewlett-Packard.)

that holds the LGA stack together. It is typically fashioned from a stiff metal such as stainless steel or thick aluminum (see Fig. 50.2).

The bolster plate may be orthogonal or sculpted to accommodate components in the vicinity of the bolster plate or to permit access to test points for in-circuit testing (ICT) or diagnostics. The design of the bolster plate must be such that it is rigid upon fastening and must flatten out any local bow or warpage in the vicinity of the LGA contact field on the PWB to ensure that all electrical contacts are made and mechanical stability is imparted to the LGA stack.

Usually an insulator is applied over the surface of the bolster plate and positioned against the underside of the PWB to prevent electrical shorting of the metal bolster to any electrical features on the secondary side of the PWB (through-hole vias, test pads, and so on). It is best not to include any components on the secondary side of the board beneath the bolster plate. If components must be included, the bolster plate will have to be relieved for clearance so that these components will not be crushed during LGA assembly.

### 50.3.3 Active Component (LGA IC)

The LGA is an IC package usually made from a rigid substrate such as ceramic. It looks like a ceramic ball grid array (CBGA) without solder interconnects (balls) on its underside (see Fig. 50.3). In all other respects, it is like any other ceramic package. It typically has gold pads on its underside that serve as the contact points for the LGA socket. The contacts are usually electrolytic nickel overplated with electrolytic gold. Sometimes a hardening agent such as cobalt is co-plated with the gold to enhance contact durability for improved long-term reliability.

**FIGURE 50.3** LGA package topside (a) and underside (b). The package is similar to a CBGA without any solder interconnects. (Courtesy of Hewlett-Packard.)

50.3.4 Socket

Many types of LGA sockets (also referred to as *interposers*) are available. There are interposers with traditional dimpled leaf-spring contacts, Fuzz Button contacts, and even metal-filled polymer contacts. The contacts are held on a molded insulating substrate. The contacts and socket frame are customized to fit the LGA package and corresponding PWB footprint (see Fig. 50.4).

**FIGURE 50.4** LGA sockets: (a) a socket with metal-filled polymer contacts; (b) a socket with Fuzz Button contacts; (c) closeup of a single wire-wound Fuzz Button.

Each contact is interconnected through the molded substrate in some fashion, and the socket can be considered double-sided for interconnecting both the LGA IC and the PWB (see Fig. 50.5).

**FIGURE 50.5** Interposer sockets electrically connecting the PWB with an LGA IC: (l) spring contact; (r) Fuzz Button contact.

Additional subelements such as fasteners and springs may be required to enable or enhance fastening, shock and vibration resistance, and thermal management.

Although Fuzz Button technology is among the most reliable of LGA interconnect schemes, some defects are common to this socket style. Pulled wires (see Fig. 50.6) as well as leaning and missing contacts have been seen, although the interconnect reliability is quite high if the socket is in good condition prior to assembly and if the LGA stack is assembled correctly.

If too much pressure is applied to metal-filled polymer contacts, they can deform and flow over time, lessening contact pressure, and result in open or intermittent contact failures.

**FIGURE 50.6** Fuzz Button LGA socket with a stray strand of wire, which can cause electrical shorting.

### 50.3.5 Pressure Plate

The pressure plate is fastened atop the LGA package and couples to the bolster plate. It forces the LGA package in contact with the socket and the socket to the lands on the PWB for completion of the electrical circuit. Besides being responsible for interconnecting the socket to package and board, coupled with the bolster plate, it imparts the necessary mechanical rigidity to the LGA stack for shock and vibration resistance and reliable operation. Of course, shock and vibration resistance will be dependent on bolster plate and pressure plate designs, including any springs, fasteners, and such. Force on the stack has to be such that it damages neither the LGA IC nor the PWB. Guidance is needed from the LGA package manufacturer and from the LGA socket manufacturer as to how much force can be applied to the stack without damaging the board, socket, or IC package.

### 50.3.6 Thermal Management

Frequently, thermal management solutions are built into the LGA stack. The heatsink, if constructed properly, can be used as the pressure plate. A thermal interface material such as graphite sheet or other thin thermal transfer material can be used between the heatsink and the IC package to enhance heat dissipation.

## 50.4 ASSEMBLY

---

In addition to good design, proper assembly strategy and precise assembly are crucial to LGA interconnect reliability. The following steps should help the engineer to achieve good results, but as stated previously, if the design is flawed, interconnect reliability will be as well.

### 50.4.1 Order of Assembly

LGA-mounted component assembly should be done after all other soldering, press-fit, and mechanical assembly steps are completed. Most LGA sockets are not rated for high-temperature excursions. The stress of other assembly may be enough to interfere with good LGA interconnection.

Gold pads on the PWB must remain as clean as possible—free of solder, flux deposits, chemicals, and contaminations. Once assembled, all chemicals must be kept away from the LGA socket. The heat of rework can also cause interposer damage or LGA device failure, so rework is best completed, where feasible, before LGA assembly.

#### 50.4.2 Prior to PWB Processing

A high-temperature masking tape can be used to cover LGA lands on the PWB. This will protect it from flux residue, spattered solder, and so on. The tape should be capable of sustaining multiple reflow cycles. A polyimide tape with acrylic adhesive is recommended to minimize tape adhesive residue. Silicone-based adhesives have been found to leave residues that can interfere with electrical interconnect. Since silicone is largely insoluble in most common solvents, attempts to clean any residue will be futile.

#### 50.4.3 PWB and LGA Land Cleaning

It is good practice to clean LGA pads on the IC and the PWB prior to application of the socket. Even if a masking tape is used, there is the opportunity for materials to condense under the tape. A wipe with isopropyl alcohol, methanol, or Vertrel-based cleaners is useful for normal flux condensates and other process residues. Do not flood the area with solvent. Instead, use a solvent-saturated lint-free wipe or sponge. Be aware that even lint-free materials can snag on PWB pads, edges, and drilled holes and may leave fibers or debris. Tests should be made to find the most appropriate and abrasion-resistant cleaning material. Ensure that the cleaned lands are perfectly dry before assembly. A Vertrel-based cleaners is ideal for this due to its low, sub-room-temperature boiling point. It can cause some local moisture condensation during the boiling process, which may leave a slight, localized, innocuous discoloration on land surfaces.

#### 50.4.4 LGA Socket Cleaning

Although it is important for the socket to be clean, never wipe it to clean as it may damage the fragile contacts. Even the use of compressed air to remove dust may dislodge or damage a contact. It is best to work with the socket supplier to ensure that interposers arrive clean and ready for use.

#### 50.4.5 Inspection

Inspect LGA pads on the PWB and on the LGA prior to assembly. Inspect both sides of the interposer to ensure that contacts are present and in good condition.

#### 50.4.6 Socket Application

It is important to seat the socket onto the PWB such that it is maintained parallel to the PWB. Applying it at an angle can cause damage to the delicate contacts of the socket and compromise contact reliability. The same can be said about sliding the socket on the board; it is likely to result in socket contact damage.

The socket must be oriented properly on the board so that the contact pattern of the socket matches the land pattern on the PWB. There are molded guide pins on the socket that help with this, with one peg larger than the other to match a similar drill pattern in the PWB. The socket usually has a missing corner contact to match the LGA IC package and corresponding LGA land pattern on the PCA. It is important not to drop the LGA IC package on the socket, as doing so could damage delicate socket contacts.

### 50.4.7 Fastening

So many mechanical designs are available that listing any particular method for LGA assembly is impractical. Some rely on spring clips whereas others use traditional screw fasteners, as shown previously. If held by four screws, as often is the case, then a tire lug torque pattern should be employed to ensure even tightening (see Fig. 50.7).

Slow and even tightening is important to avoid damage to either the LGA IC device or the LGA socket and to ensure proper compression for reliable electrical contact.

The number of revolutions per fastener depends on the pitch of the screw and socket requirements. Ideally, a four-headed torque driver assembly should be used with each head rotating at the same speed and a calibrated slip-clutch on each driver to prevent overtightening of the stack.

A tooling plate with strategically located board supports should be created to hold the PCA during LGA stack assembly in order to minimize board flexure and to prevent damage to soldered parts on the PCA.

**FIGURE 50.7** Manual torque pattern for even fastening of the LGA. Each fastener should receive the same number of turns or partial turns to ensure even seating of the LGA stack.

### 50.4.8 LGA Socket Rework and Reuse

Ease of IC replacement for upgrade or repair is one of the most important benefits of using pressure interconnect technology. Most LGA sockets are designed for multiple reuses. Check with socket manufacturer for the number of reuse cycles; some are specified for as many as 20. Reliability and reuse depend on a number of factors, including mechanical robustness of the socket, thermal exposure, proper assembly, and contamination from process chemicals such as flux, flux cleaners, alcohol, and so on. Note that there are usually no reuse limits on other parts of the system (LGA IC, printed circuit assembly, bolster plate, heatsink, or pressure plate), but these should be inspected to ensure that contact platings are in good condition and that mechanical fasteners are not showing signs of mechanical wear out.

When removing the LGA IC package component or the socket itself, ensure that the socket contacts have not stuck to either the IC or to the PWB lands. If there is contact sticking, the contacts can be bent, broken, or pulled out of the socket. Any of these will compromise interconnect integrity. Sticking is most prevalent with filled-polymer or Fuzz Button-style contacts, although there can be enough adhesion of plated spring contacts to LGA IC or PWB-plated lands to result in damage to the fragile socket contacts. It is also important to remove the LGA IC package straight out of the socket to avoid damage to the LGA socket if it is to be reused.

## 50.5 PRINTED CIRCUIT ASSEMBLY (PCA) REWORK

If soldered joints on the PCA need to be reworked in the vicinity of the LGA stack, use a thermal profile board, perform a mock repair, and measure the thermal effect on the socket. Ensure that the LGA IC and socket temperatures are maintained within their respective manufacturer's thermal guidelines. Also make certain that process chemicals, flux, cleaners, and such do not run under the LGA socket.

## **50.6 DESIGN GUIDELINES**

---

### **50.6.1 Traces Beneath LGA Elements**

It is advisable to keep active traces off the surface of the PWB where they could get crushed by the bolster plate or the socket. Since the bolster plate is flat and large, the forces are spread out. The molded socket frame exerts a more concentrated force on the PWB surface due to its narrow outline and could compress any surface traces running beneath it.

### **50.6.2 Clearance for Tall Components**

The pressure plate or heatsink usually overhangs the LGA IC package. For this reason, tall components should be kept outside of the pressure plate/heatsink footprint to prevent mechanical interference with the LGA stack.

### **50.6.3 Components Under Bolster**

As previously mentioned, it is unwise to put components under the bolster plate. If components are required in this area, then the bolster plate should be relieved to allow clearance of these components. This may require the use of an extra-thick bolster plate to preserve its stiffness after relief machining.

## **51.1 INTRODUCTION**

---

### **51.1.1 Reasons for Appropriate Acceptance Criteria**

Other than the financial tie between the user and supplier, nothing affects the relationship between these two more than product acceptability and quality. These issues define the relationship. As the printed circuit board (PCB) is the foundation for almost all electronic products, the user cannot tolerate defective boards. At the same time, cost is always a critical issue and imposing expensive and unnecessary acceptance criteria can be a major disadvantage. Failure to provide acceptable and quality product is the largest factor that affects the deterioration of the relationship between user and supplier. All of the components in an electronic product rely on the PCB to get information and power from place to place. An interruption of this process because of a defective PCB results in a failed product. In other words, a poor-quality product at a low price is worthless.

**51.1.1.1 Customer Satisfaction.** Brand name is one of the most valuable things that the original equipment manufacturer (OEM) possesses. A product's success or failure is quite dependent on the perceived quality that the brand name suggests. OEMs rely on getting products quickly from the design programs to market, and a slowdown due to quality issues can significantly impact a product's introduction and thereby affect their brand. The negative publicity from field failures can also have a significant affect on a brand. Agreed upon acceptance and quality criteria reduce the likelihood of nonconforming PCBs.

**51.1.1.2 Reduction of Cost.** If the PCB buyer clearly states the required acceptability and quality criteria to the manufacturer, the manufacturer can more clearly understand the buyer's costs. Cost reductions are a permanent fixture in the manufacturing environment. For companies to survive in this competitive market, they must address costs. Unacceptable, low-quality product that cannot be sold is a direct and significant cost.

**51.1.1.3 Liability and Litigation.** Showing that the PCB was purchased to mutually agreed upon “standards” goes a long way to minimizing litigation and financial liability.

### 51.1.2 Printed Circuit Board Functions

A PCB is required to do three things for the buyer when it is received:

- The PCB physical form should match the intended design. The dimensions and placement position of the interconnection points along with the quality of the coating on these interconnection points must be acceptable and of high quality to facilitate the attachment of components.
- The PCB should provide proper interconnection between components. This allows the assembly to function properly as intended.
- The PCB should provide insulation between interconnection points that should not be connected.

These three items should be “acceptable and of high quality” at the time of purchase and continue to remain “acceptable and of high quality” throughout the expected life of the product. There are a lot of details between the few preceding lines defining those three things. The rest of this chapter will define the details of “acceptability” and “quality” for the PCB in order to fill in the spaces created by the three previously listed requirements.

### 51.1.3 Industry versus Customer Standards

Properly implemented acceptability and quality criteria give both user and supplier a clear picture of what is expected. Without clear instructions on how the acceptability and quality of the PCB should be implemented at the supplier, the user is unlikely to get a product that meets his or her needs. A clear definition of what the user wants can help make the relationship between the two much more successful, especially as complexity of the PCB makes acceptability and quality criteria more critical and challenging. In general, PCB manufacturers have gotten larger and produce many more PCBs. This makes the user’s individual PCBs a much smaller part of the big picture and their uniqueness may be lost. Therefore, it is essential to define what is required for acceptability and quality clearly and early in the relationship between the user and supplier.

### 51.1.4 Objectives of Acceptability and Quality Criteria

The PCB needs to be supplied at a quality level that is capable of withstanding the assembly process, as it will undergo several operations to mount and rework components and connectors. This assembly and rework process has gotten more complicated and damaging to the PCB, especially with the introduction of lead-free products. The acceptability criteria should attempt to anticipate the conditions of the soldering process to ensure the PCB will survive the assembly and rework process and still function as intended.

## 51.2 SPECIFIC QUALITY AND ACCEPTABILITY CRITERIA BY PCB TYPE

---

Many unique inspection properties for PCBs are dependent on their type of manufacture. There are two major classifications of printed circuits: rigid PCBs and flexible PCBs.

## 51.2.1 Rigid PCBs

Rigid PCBs make up the bulk of what is built around the world. Rigid PCBs are used in a variety of applications and products. The materials and testing procedures for each type of PCB can be dramatically different. These manufacturing details are thoroughly covered elsewhere in this book and are only touched on here. The processing for multilayer PCBs is a multiple of that required for single- and double-sided PCBs, plus surface preparation, lay up and lamination processes are needed. The additional processes required for each additional layer introduce opportunity for anomalies to creep into the PCB.

**51.2.1.1 Single-Sided PCBs.** These contain no plated-through holes (PTH), eliminating the need to inspect the attributes associated with PTHs. These PCBs are much simpler to manufacture and PCB shops specializing in these types of PCBs have fewer processes to manage. Many single-sided PCBs are manufactured using a punching process to make part mounting holes and create the outline of the PCB. Single-sided PCBs are typically the least expensive type of PCBs and are usually used in simple and inexpensive applications.

**51.2.1.2 Double-Sided PCBs.** These differ from single-sided PCBs in that the circuitry is on both sides of the PCB and there are PTHs connecting the top to the bottom. Moving from single-sided to double-sided PCBs requires the manufacturer to keep consistency of the image from top to bottom, and also requires drilling and through-hole-plating processes. These additional processes also require increased inspection, as the attributes they represent can significantly affect acceptability and quality of the PCB.

**51.2.1.3 Multilayer PCBs.** These are much more complex than double-sided PCBs as they require that circuitry be embedded within the PCB. The PTHs must also make connection to internal layers as well as top and bottom layers. Multilayer PCBs also introduce the lamination process, which is where the manufacturer actually creates the composite PCB from layers of circuitry in a lamination press under high pressure and heat.

**51.2.1.4 Backplane PCBs.** These multilayer PCBs have connector arrays installed that hold other PCBs. These arrays must be rigid enough to ensure that insertion of PCBs does not affect their performance and reliability. They usually have many layers and tend to be large and thick. Here, again, the manufacturing processes differ from those of traditional multilayer PCBs, and additional requirements for the connector area and PTH areas are necessary.

**51.2.1.5 High-Frequency PCBs.** These can be any of the preceding types of PCBs and have unique properties that allow high-speed electrical signals to travel within or on the PCB without significant degradation. The materials used and geometry of the circuit are critical to produce the correct impedance for these signals to maintain integrity. Additional testing is typically performed to verify the more precise nature of the requirements for these types of PCBs, such as controlled impedance.

## 51.2.2 Flexible PCBs

Flexible PCBs must be capable of bending and flexing, either for installation or continuously throughout the product's life, and come in single-sided, double-sided, multilayer, and high-speed versions just like the rigid PCBs previously described.

## 51.2.3 Rigid/Flexible PCBs

Rigid/flexible combination PCBs combine the benefits of the rigid PCB with integrated flexible parts. This type of PCB requires evaluation of both the rigid and flexible sections for acceptability.

## 51.3 METHODS FOR VERIFICATION OF ACCEPTABILITY

---

### 51.3.1 Production PCB

Most acceptability criteria are evaluated on the production PCB by visual or dimensional means. Visual inspection is typically done under low magnification by human operators. Although the human eye is very capable of catching inconsistencies in the circuit patterns and surface materials, it is not always consistent and can allow nonconforming attributes to slip through. Because of this, many companies have turned to using automated optical inspection (AOI) machines to check pattern integrity, consistency, and dimensions. AOI provides a much more consistent evaluation of circuit geometry than the human eye, but is a slower and more costly option. Many visual inspection attributes have dimensional attributes attached to them. It is important to note that magnification for inspection of dimensional attributes should be sufficient to make an accurate measurement to determine acceptability.

### 51.3.2 Test Coupons and Patterns

For testing purposes, there are several reasons to utilize test coupons and patterns that are representative of the PCBs rather than the PCBs themselves. The downside of using coupons is that they take up space on the manufacturing panel and therefore increase the overall cost of the PCBs. Also, the test coupons are not actually part of the PCB and are typically placed at the edges of the production panel, where production attributes may be different from the production panel. This can cause the coupons and patterns to reflect different attributes than the PCBs they are attempting to represent. It is very important to take steps to ensure that the test coupons and patterns are actually manufactured in a manner that is representative of all the attributes of the PCBs associated with them. It is important to ensure that any holes in the coupon are drilled with the same tools and parameters as those on the corresponding PCB. Coupons and patterns are typically used in situations where using a PCB for testing would either not provide the information required or the PCB would have to be destroyed in order to get the information. Coupons and patterns can be used for microsectional analysis, electrical measurements, environmental simulation, and reliability evaluation. See Fig. 51.1<sup>1</sup> for an example of test coupons taken from IPC-2221. (Unless noted otherwise, figures in this chapter are courtesy of the Association of Connecting Electronics Industries [IPC], and are taken from the publication IPC-600, "Acceptability of Printed Circuits." These figures can be found in that document under the headings noted in this chapter for specific topics. Figures credited to the author of this chapter are taken from presentations made by him. Other figures are from the sources noted in the captions. For further details on design and placement of coupons, see IPC-2221.)

### 51.3.3 Microsection

Microsectioning the holes from a PCB provides a cross-sectional view of the construction of the PCB. Microsectioning a PCB with a design that removes nonfunctional pads makes it virtually impossible to inspect all the interconnecting layers in the hole, so microsections are typically done on associated and optimized coupons containing PTHs that contain pads on all the layers. Microsectioning PCBs requires great skill, as the PCB contains both hard and soft materials and the area of interest is very small. Improper microsection technique can either create or hide anomalies. For example, interconnection separation can be created or hidden by improper techniques.

**FIGURE 51.1** Quality conformance test coupons taken from IPC-2221.  
 (Courtesy of IPC.)

## 51.4 INSPECTION LOT FORMATION

An inspection lot consists of all the PCBs fabricated from the same materials, using the same processing procedures and constructions and produced under the same conditions. Differing PCBs can be combined to form an inspection lot, but then they must all be submitted together for inspection. It is the PCB manufacturer's responsibility to maintain traceability for all the PCBs in an inspection lot along with any corresponding test coupons that were separated from the production panels. The success of inspections greatly depends on how the inspection lot is formed. The goal of forming the inspection lot for a particular attribute is to allow, if applicable, a smaller sampling of the inspection lot to be representative of the entire lot. In forming inspection lots and sampling groups, the methodology for producing the attribute and the consistency of that methodology or process must be taken into consideration. Some PCB processes are done in batch form and others are done on a panel-by-panel basis. Understanding process techniques is critical in forming inspection lots and sampling groups that are representative of the product.

### 51.4.1 Sampling Inspection

For some attributes, 100 percent inspection is not necessary or prudent. In these cases, a sampling of the PCBs from the inspection lot is allowed to represent the entire inspection lot. Most performance documents specify which attributes can use sampling inspection and to what extent sampling may be performed. There are many sampling plans available; the most widely known, and historically used, is MIL-STD-105, which describes an Acceptable Quality Level (AQL) for samples of an inspection lot. However, it allows a small amount of defective material to be considered "acceptable" and has typically been replaced by sample plans where defective parts that are found during inspection cause the lot to be termed "nonconforming." This style of plan is defined as Defective Parts (C) Equals Zero ( $C=0$ ). If the inspection lot is

considered “nonconforming” during a sampling procedure, the supplier may elect to screen 100 percent for the nonconformance, removing only the nonconforming PCBs from the inspection lot.

#### 51.4.2 Inspection Tool Calibration

It is important that the all inspections be carried out with equipment that is calibrated and traceable to internationally recognized standards. Two of the documents that govern inspection equipment and facilities are ISO-17025 and IPC-QL-651.

### 51.5 INSPECTIONS CATEGORIES

---

#### 51.5.1 Materials Inspection

This inspection usually consists of certifications from the material supplier, supported by data from the supplier’s own inspections. The materials used must be inspected by the PCB manufacturer to ensure compliance with customer requirements.

#### 51.5.2 Qualification Inspection

The PCB supplier must provide proof to the user of its qualifications to build the product specified. The user must then review this proof in order to minimize the risk associated with buying from the PCB manufacturer. This process usually includes the PCB manufacturer supplying a self-declaration of capabilities such as those found in the IPC-1710, and then supplying some kind of physical sample or testing data to support the assertions made in the self-declaration. It is up to the PCB user to determine the level and detail of qualification required.

#### 51.5.3 Quality Conformance Inspection

These product verification inspections use specified acceptability criteria and are performed prior to shipment of the PCBs to the customers. These inspections can be defined either by industry or customer standards, or a combination of both.

#### 51.5.4 Reliability Testing

This testing consists of looking for imperfections in the PCB that may show up some time during the product’s field life. They include accelerated life testing for both the interconnection and insulation attributes of the PCB. Please see Chaps. 57, 58, and 59 for a detailed discussion of reliability testing.

### 51.6 ACCEPTABILITY AND QUALITY AFTER SIMULATED SOLDER CYCLE(S)

---

The user expects the PCB to survive the assembly and rework process. Temperature excursions that approach or exceed the base material’s glass transition temperature ( $T_g$ ) can significantly affect some attributes of the PCB. For these attributes, it is important that the PCB be examined after solder cycling that simulates the type and quantity of soldering operations (rework included) that the PCB is expected to undergo during the assembly process. It is

**FIGURE 51.2** Damage done to PCBs during typical leaded and lead-free solder cycles. (Courtesy of Microtek Laboratories.)

important to note that each rework process usually includes two soldering cycles: one to desolder the affected part, and one to reattach a new part.

### 51.6.1 The Effects of Lead-Free Assembly on PCB Acceptability and Quality

The soldering process has a significant and detrimental effect on the PCB's reliability and quality. The lead-free assembly process increases both the soldering temperature and the time the PCB is exposed to that temperature. This will accelerate degradation of the base material and can have significant impact on the PCB. Figure 51.2 shows damage related to time and temperature above T<sub>g</sub>. It is essential to establish that the PCB was capable of being assembled and was acceptable when it was delivered to the assembly organization, as poor assembly

techniques can severely compromise the integrity of the PCB. It is almost impossible to look at a PCB after assembly and definitively state that the fault lies entirely with the PCB manufacturer or with the assembly organization.

### 51.6.2 PCB Issues Created by Lead-Free Assembly

- **Copper reduction** Lead-free solder, when molten, rapidly dissolves copper into it. One must be very careful when using lead-free solder on copper surfaces without a protective barrier of some type (e.g., nickel); otherwise, the copper conductors may be reduced to a point where they are not adequate for the design.
- **Base material degradation** Base materials begin to degrade and decompose during soldering and can reduce the insulating properties of the resin system in the base material.
- **Conductive anodic filament (CAF)** As the base material system degrades, the resistance to CAF formation decreases.
- **Delamination** In extreme cases, the resin system can lose cohesive or adhesive properties, causing catastrophic failure.
- **Increased expansion causing premature PTH failures** Base materials expand when exposed to soldering temperature. This expansion becomes pronounced above the  $T_g$  of the resin system in the base material. The increased temperature of lead-free soldering can cause premature failure of the PTHs due to this increased expansion. See Fig. 51.3 for PTH expansion characteristics with temperature.
- **Solderability** Lead-free solder does not wet as well to solderable surfaces as leaded solder does, so pad size, solder quantity, and flux type and quantity must be taken into account.

FIGURE 51.3 Z-axis expansion characteristics of 150°C  $T_g$  PCBs versus temperature. (Courtesy of Microtek Laboratories.)

## 51.7 NONCONFORMING PCBs AND MATERIAL REVIEW BOARD (MRB) FUNCTION

Standards and customer documentation establish minimum quality and acceptability requirements for the inspections performed. If the PCB does not meet these requirements, it becomes nonconforming. This does not necessarily mean the PCB is scrapped, although this is often what happens to nonconforming PCBs. What it does mean is that with a generic standard, samples that do not meet the stated requirements must be “disposed” outside

the standard. To determine whether a nonconforming PCB is or is not “scrap,” a material review board (MRB) must be established to evaluate the nonconformance(s). The MRB is usually made up of one or more representatives from the departments of quality, production, and design. The purpose of the materials review board is to effect positive corrective action within a short time to eliminate the cause of recurring discrepancies and prevent recurrence of similar discrepancies. The MRB’s responsibilities include:

- Reviewing questionable PCBs or materials to determine conformance with acceptability, quality, and design requirements
- Reviewing nonconforming PCBs for effects on design functionality
- Authorizing repair or rework of nonconforming PCBs when appropriate
- Establishing responsibility and/or identifying causes for nonconformance
- Authorizing the scrap of excessive quantities of materials

When all else fails and the PCBs do not meet the intended end product use, they need to be scrapped.

## **51.8 THE COST OF THE ASSEMBLED PCB**

---

The cost of the assembled PCB continues to increase because of density, complexity, and rising material and component costs. The value added to the PCB can be 10 to 20 times the cost of PCB. If it is found that a nonconforming PCB is the cause of failure, the total cost of the assembly process is likely to be passed on to the PCB manufacturer.

## **51.9 HOW TO DEVELOP ACCEPTABILITY AND QUALITY CRITERIA**

---

### **51.9.1 Using Industry Standards**

There are both advantages and disadvantages to using industry standards for acceptability and quality requirements.

#### **51.9.1.1 Advantages**

- International standards represent a consensus of what is possible and common for acceptance.
- They increase the likelihood of PCB users getting what they expected.
- The PCB manufacturer is unlikely to become as expert in complying with a “customer” specification as it would an industry standard.
- The more experience the quality personnel at the PCB manufacturer obtain in acceptability criteria, the better they will be at spotting nonconformance.
- Industry standards are a great place to start developing company-specific requirements for acceptability and quality.

#### **51.9.1.2 Disadvantages**

- International standards are developed by a cross section of the industry. The resultant standards often represent the “least common denominator” requirements in order to satisfy the broad range of participation.
- Although these standards may meet most of a PCB buyer’s needs, they often leave deficiencies that necessitate additional requirements being imposed upon the PCB supplier.

- By nature, international standardization efforts always lag the state-of-the-art in the industry.
- Standards can over- or underspecify requirements for an industry segment's needs.

## 51.9.2 Industry Specifications

The following are lists of the most commonly used specifications for PCBs. IPC standards are the most widely used in the industry and therefore are referenced in this chapter as examples.

### 51.9.2.1 *Defence Supply Center Columbus (DSCC)*

- MIL-PRF-55110, "Printed Wiring Board, Rigid, General Specification for"
- MIL-PRF-31032, "Printed Circuit Board/Printed Wiring Board, General Specification for"
- MIL-P-50884, "Printed Wiring Board, Flexible or Rigid-Flex, General Specification for"

### 51.9.2.2 *International Electrotechnical Commission (IEC)*

- IEC-61188, "Design of Printed Boards and Printed Board Assemblies"
- IEC-62326, "Printed Board Performance for Capability Approvals"
- IEC-61189, "Test Methods for Printed Boards and Printed Board Materials and Printed Board Assemblies"

### 51.9.2.3 *Institute for Interconnecting and Packaging Electronic Circuits (IPC)*

- ANSI/J-STD-003, "Solderability Tests for Printed Boards"
- IPC-1710, "OEM Standard for Printed Board Manufacturer's Qualification Profile (MQP)"

### 51.9.3 Using Customer Standards

Customer standards should reflect the unique nature and needs of the company's products. Unfortunately, company history often can affect these criteria and overemphasize criteria for failures that were previously experienced. It is recommended that customer standards be used to augment, not replace, industry standards. Consider the following when creating a customer standard:

- Understanding where and how the product will be used can influence the use of extended or reduced criteria in specific requirement areas.
- Understanding the stresses to which the assembly process exposes the PCB is fundamental in defining the acceptability criteria. Process elements such as leaded or lead-free, reflow or wave solder, double-sided reflow, hand-soldering, and rework all significantly impact the requirements of the PCB.

## 51.10 CLASS OF SERVICE

---

Functionality through operational life should be the ultimate criteria for acceptance. To account for the fact that a PCB will see different end-use environments and conditions, acceptance criteria are typically broken into three classes of service. Each company must establish the level of acceptance as it is dependent on the functional criteria to which the PCB will be subjected. The IPC has established recommended guidelines for acceptance, based on end use, categorized as Classes 1, 2, and 3. The following subsections describe the classes.

### 51.10.1 Class 1: General Electronic Products

Class 1 includes consumer products and some computer and computer peripherals suitable for applications where cosmetic imperfections are not important and the major requirement is the functioning of the completed PCB.

### 51.10.2 Class 2: Dedicated Service Electronic Products

This class consists of communication equipment, sophisticated business machines, and instruments for which high performance and extended life are required, and for which uninterrupted service is desired but is not critical. Certain cosmetic imperfections are allowed.

### 51.10.3 Class 3: High-Reliability Electronic Products

Equipment and products for which continued performance or performance on demand is critical belong in Class 3. Equipment downtime cannot be tolerated, and the equipment must function when required (e.g., life support systems, flight control systems). PCBs in this class are suitable for applications in which high levels of assistance are required and service is essential.

## 51.11 INSPECTION CRITERIA

---

When inspecting PCBs, the requirements can be separated into externally observable attributes (those where acceptability can be determined from the outside of the PCB) and internally observable attributes (those that require microsectioning to determine acceptability). The actual requirements vary by specification, but the requirements stated in this chapter generally follow IPC document guidelines.

### 51.11.1 Externally Observable Attributes

Visual examination for applicable attributes is typically conducted at 3 diopters ( $\sim 1.75 \times$  magnification). If it is not possible to determine whether the condition is acceptable at this magnification, progressively higher magnifications should be used to confirm acceptability. Dimensional requirements such as conductor spacing or width may require different magnifications and devices with measurement scales or reticules as part of the inspection tool to allow accurate measurement(s) of the specified dimensions. The PCB users may also specify other magnifications and inspection tools. Note that the use of higher magnifications for visual-type attributes can produce false results due to illumination and attribute contour effects. Visual inspection criteria are difficult to define grammatically. An effective way to define visual inspection criteria is to use line illustrations and/or photographs. The IPC utilized this method in the publication IPC-A-600, "Acceptability of Printed Boards," to "visually standardize the many individual interpretations to specifications on printed boards." Of the different types of inspections specified, surface visual inspection is the least expensive. Visual inspection is performed on 100 percent of the PCBs or on a sampling based on an established sampling plan. Inspection for visual imperfections, following a sampling plan, is done on the premise that the PCBs were 100 percent visually screened during the fabrication process. Externally observable imperfections can be divided into 10 groups:

- Surface imperfections in the insulating material such as burrs, nicks, scratches, gouges, cut fibers, weave exposure, and voids
- Subsurface imperfections such as foreign inclusions, measling/crazing, delamination, pink ring, and base material voids
- Conductive pattern imperfections such as loss of adhesion, reduction of conductor width or thickness due to nicks, pinholes, scratches, surface plating, or coating imperfections
- Hole characteristics such as diameter, misregistration, foreign material inclusions, and plating or coating imperfections
- Marking imperfections affecting such characteristics as location, size, readability, and accuracy
- Solder resist surface coating, coverlayer, and coverfilm imperfections such as misregistration, blisters, bubbles, separations, adhesive squeeze out, delamination, adhesion, physical damage, and thickness
- Flawed dimensional characteristics affecting such characteristics as PCB size and thickness, hole size, pattern accuracy and registration, conductor width and spacing, and annular ring (dimensional inspection is usually performed using a sampling plan)
- An unclean PCB surface due to such materials as ionic and organic contaminants
- Poor Solderability of the PCB including wetting, de-wetting, and non-wetting
- Electrical discontinuity, circuit shorts, and if required, impedance

**51.11.1.1 Surface Imperfections in the Insulating Material.** Surface imperfections include burrs, nicks, scratches, gouges, cut fibers, weave exposure, and voids. The imperfections, when minor, are normally considered to be cosmetic issues, and usually have little or no effect on functionality. However, they can be detrimental to function in the edge board contact area and if they reduce the insulating properties of the material below acceptability limits.

**51.11.1.2 Subsurface Imperfections.** Subsurface imperfections are those that are visible from the surface of the PCB but are below the surface of the PCB. (see Fig. 51.4)

**51.11.1.2.1 Inclusion.** An *inclusion* is a foreign particle, metallic or nonmetallic, in a conductive layer, plating, or base material. Inclusions in the conductive pattern, depending on degree and material, can affect plating adhesion or circuit resistance. Inclusions in the base material are put into the categories of translucent/nonmetallic and opaque/metallic. Translucent particles are acceptable. Opaque particles are acceptable as long as they do not reduce the minimum conductor spacing below the minimum requirement.

**FIGURE 51.4** Base material defects: (a) blistering, (b) fiber exposure, (c) measling, (d) crazing, (e) crazing, (f) measling. (Courtesy of Sandia Laboratories and IPC.)

#### 51.11.1.2.2 Measling/Crazing, Delamination, Blistering, and Weave Texture/Exposure.

The IPC formed a special committee in 1971 to consider base material imperfections and to define them better with illustrations and photographs. The conditions are defined and discussed here:

- Measling** This internal condition occurs in the woven-fiber-reinforced laminated base material in which the bundles are separated at the weave intersection. Measling manifests itself in the form of discrete white spots or “crosses” below the surface of the base material. A report compiled by the IPC, “Measles in Printed Wiring Boards,” was released in November 1973. The report stated that “measles may be objectionable cosmetically, but their effect on functional characteristics of finished products are [sic], at worst, minimal and in most cases insignificant.” The IPC Acceptability Subcommittee readdressed the subjects of measles and crazing in 1994 and verified the 1973 findings. IPC standards allow measles in PCBs with the exception of “high-voltage” applications. As hole spacing has continued to decrease, new attention has focused on measles. There is a concern that measling could contribute to the formation of CAF on designs with close hole spacing, and the requirements for measles will likely adjust to accommodate these designs.
- Crazing** An internal condition occurring in the woven fiber-based base material in which the glass fibers within the yarn are separated, crazing can occur at the weave intersections or along the length of the yarn. This condition manifests itself in the form of connected white spots or crosses below the surface of the base material, and is usually related to mechanical and/or thermally induced stress. Limited crazing is an acceptable condition as long as it does not reduce the space between conductive patterns below the minimum conductor spacing, the distance of crazing does not span more than 50 percent of the distance between adjacent conductive patterns, and no propagation results from thermal testing that replicates the manufacturing process. If crazing is present at the edge of the PCB, it should not reduce the minimum distance between PCB edge and conductive pattern.
- Delamination** This is a separation between plies within the base material, between a material and the conductive foil, or between any other planar separations within a PCB.

Blistering and delamination are considered to be major imperfections. Whenever a separation of any part of the PCB occurs, a reduction in insulation properties and adhesion occurs. The separation area could house entrapped moisture, processing solutions, or contaminants, and could contribute to electrochemical migration or produce other detrimental effects in certain environments. The delamination or blister area may also propagate to the point of complete PCB separation, normally manifesting during assembly operations. Last but not least is the effect on solderability in PTHs. Entrapped moisture, when subjected to soldering temperatures, has been known to create steam that blows holes through the plated side walls, exposing the resin and glass of the PTHs and creating large voids in the solder fillet.

- **Blistering** A localized swelling and separation between any of the layers of a laminated base material or between a base material and a conductive foil or protective coating, blistering is a form of delamination.
- **Weave texture** In this surface condition of base material, a weave pattern of glass cloth is apparent although the unbroken fibers of the woven cloth are completely covered with resin. Weave texture is an acceptable condition and should not be confused with weave exposure.
- **Weave exposure** In this surface condition of base material, the unbroken fibers of woven glass cloth are not completely covered by resin. Weave exposure is considered a major imperfection. The exposed glass fiber bundles allow wicking of moisture and entrapment of processing chemical residues into the base material.

*51.11.1.2.3 Haloing.* A mechanically induced fracturing or delamination on or below the surface of the base material, haloing is usually exhibited by a light area around holes, other machined areas, or both. Haloing should not penetrate more than 50 percent of the distance to the nearest conductor and should not reduce electrical spacing below the given requirement.

*51.11.1.3 Conductor Pattern Integrity.* Several methods can be used to determine conductor pattern integrity. Comparison equipment, overlays, and AOI machines are routinely used to compare the pattern to the digital image of the pattern. The most common conductor pattern inspection tool is the aided human eye using low ( $<3\times$ ) magnification. The loss of adhesion and imperfections that reduce the conductor volume or spacing make up this category of imperfections. Voids in conductors and lands can be detrimental to function, depending on the degree of imperfection. Voids or pinholes reduce the effective conductor width, reduce current-carrying capacity, and can affect other design electrical characteristics, such as inductance and impedance. Voids in lands are also detrimental to solderability. Pinholes or voids in the conductor or land can undermine the finish coating. The presence of conductive elements in areas in which they were not intended can reduce spacing to a point where the insulation between conductors can be jeopardized. The degree that these imperfections affect the PCB depends on the intended design of the circuit. The imperfections in this group are defined as follows. (see Fig. 51.5).

**FIGURE 51.5** Dents, pits, pinholes and voids. (Courtesy of Sandia Laboratories.)

- **Dent** This is a smooth depression in the conductive foil that does not significantly decrease foil thickness.

- **Pit or dish-down** This is a depression in the conductive layer that does not penetrate entirely to the base material but does reduce the cross-sectional area of the conductor. These imperfections are almost impossible to detect as they rarely give visual cues to the inspector.
- **Scratch** This is a slight surface mark or cut that may or may not go all the way through to the base material.
- **Void or Pinhole** This is the absence of conductive material in a localized area going all the way to the base material.

*51.11.1.3.1 Conductor Width.* The conductor width is the observable width of a conductor at any point chosen at random on the PCB, normally viewed from vertically above unless otherwise specified. The conductor width affects the electrical characteristics of the conductor. A decrease in conductor width decreases current-carrying capacity and increases electrical resistance. Although the conductor width definition is very basic, there are two different interpretations as to where on the conductor the measurement is performed. The minimum conductor width (MCW) is measured at the minimum observed width of the conductor, and the overall conductor width (OCW) is measured at the observable width. Plating outgrowth of the top of the conductor during pattern plating can prevent the minimum width from being seen unless cross-sectioning is performed. The OCW is nondestructive and easily measured. The difference between the MCW and the OCW (see Fig. 51.6), which is measured from vertically above, can have an effect on the current-carrying capacity, inductance, and impedance of the circuit. IPC-6012, "Qualification and Performance Specification for Rigid Printed Boards," addresses conductor width requirements and allows added width reductions for edge roughness, nicks, pinholes, and scratches of 30 percent (Class 1) and 20 percent (Classes 2 and 3) from the minimum specified on the procurement documentation. The document states that this reduction also applies to the MCW reflected on the procurement documentation, and this allowance should be carefully considered against design needs.

**FIGURE 51.6** Overall conductor width (OCW) measurement “W.” (Courtesy of IPC.)

*51.11.1.3.2 Conductor Spacing.* Conductor spacing is the distance between adjacent edges (not centerlines) of isolated conductive patterns or features. The spacing between conductors and/or lands is designed to allow sufficient insulation between circuits. A reduction in the spacing can cause electrical leakage or affect the capacitance of the circuit. The cross-sectional width of conductors is usually nonuniform. Therefore, the spacing measurement is taken at the closest point between the isolated conductors and/or external *annular ring* (the portion of conductive material completely surrounding a hole).

*51.11.1.3.3 External Annular Ring.* The portion of conductive material completely surrounding a hole is called the annular ring (see Fig. 51.7). The primary purpose of the annular ring is that of a flange surrounding the hole; it provides an area for the attachment of electronic component leads or wires and acts as an anchor for the circuit. The minimum annular ring dimension needs to be defined by the PCB user and will differ based upon the function of the

**FIGURE 51.7** Minimum external annular ring (includes plating). (Courtesy of IPC.)

holes and whether they are plated or not. Annular ring dimensions that are less than those specified can interfere with attachment of the component, and a pad breakout (zero annular ring) condition associated with the area where the circuit enters the pad can reduce the current-carrying capacity of the circuit. After verifying the dimensions of the PCB and then verifying that the minimum widths of the annular rings on all other lands are within the procurement documentation requirements, the pattern is found to be in registration with the drilled hole location. Front-to-back pattern registration can also be inspected in this manner.

**51.11.1.3.4 Plating Adhesion.** A common method of inspecting for plating adhesion is the tape adhesion test, which is described in detail in the IPC test method IPC-TM-650, 2.4.1. The basic test method is performed by adhering tape of known properties onto the plating, rapidly removing the tape, then inspecting the tape for removed plating on the tape adhesive.

**51.11.1.3.5 Peel Strength.** Peel strength is the force per unit width required to peel the conductor or foil from the base material. It is usually associated with the acceptance testing of copper-clad base material upon receipt, but it is sometimes used to test the adhesion of the conductors to the finished PCB. Peel strength tests of conductors are usually performed after the specimens have been dip or reflow soldered. Peel strength tests of conductors are a good method of ensuring that the conductor-to-base material adhesion is sufficient to withstand assembly and rework operations.

**51.11.1.4 Hole Characteristics.** PTHs provide circuit interconnection from the surface of the PCB to internal layers and to circuitry on the opposite side. For this reason, much attention is correctly focused on the acceptability and quality of these holes. Nonconformance in the PTHs is a serious concern.

**51.11.1.4.1 Roughness and Nodulation.** *Roughness* is an irregularity in the side wall of a hole; *nodulation* is a small knot or an irregular lump found in or on the plating. Although roughness and nodulation are not desirable, they are allowable in small amounts. Roughness and nodulation create one or more of the following nonconforming conditions:

- Reduced hole diameter
- Impaired lead insertion
- Impaired solder flow through the hole
- Voids in solder fillet

**FIGURE 51.8** Plating void. (Courtesy of IPC.)

**51.11.1.4.2 Voids in the Plating and Finished Coating.** A void is the absence of material where it is intended to be. Copper-plating voids are evaluated again during microsectional analysis, but this sampling is very small and this attribute should be thoroughly evaluated during visual inspection of the PCB. When visually evaluating voids in the PTH copper, no more than 5 percent of the holes on the PCB should exhibit evidence of voids. In holes that have voids (see Fig. 51.8), there should be no more than one void that is less than 5 percent of the hole length. Voids in the finish coating of the PCB (see Fig. 51.9) that do not extend to the copper plating are allowed in larger quantities than voids in the copper plating. There should again be surface finish voids in no more than 5 percent of the PCB holes, and these holes should have no more than three voids that are each less than 5 percent of the hole length.

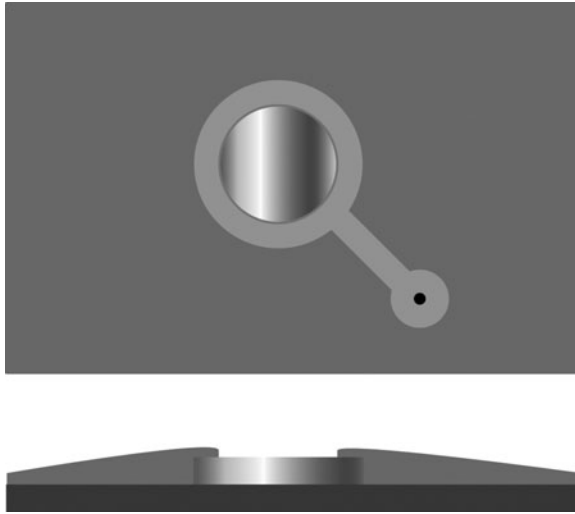

**FIGURE 51.9** Voids in finished coating. (Courtesy of IPC.)

**51.11.1.4.3 Hole Diameter.** Hole size is the inner clearance diameter of the finished plated-through or unplated hole. A PTH is a hole in which electrical connection is made between internal or external conductive patterns, or both, by the deposition of metal on the wall of the hole. An unplated hole, termed an *unsupported hole*, is a hole containing no conductive material. Hole size measurement is performed to verify that the hole meets the intended design requirements. This size requirement is usually associated with the fit of component leads, mounting hardware, etc., plus adequate clearance for attachment metal. PTHs providing layer-to-layer interconnections, where no components are soldered into the hole, are called “via” holes. Via holes do not have a fit requirement, so only the plating integrity is critical. Drill blank plugs and optical magnifiers are used to verify hole diameter. The latter method is utilized when soft coatings over the copper are used. The optical method prevents deformation or removal of the soft coatings within the hole. When drill blank plug gauges are used, the inspector should use a soft touch to prevent damage to the hole. The drill blank gauges should be cleaned prior to use to prevent solderability degradation. Plating nodules are sometimes present in the hole and restrict the penetration of the gauges. Forcing the gauges into the holes causes the nodules to be dislodged, resulting in voids in the PTH side wall.

**51.11.1.4.4 Lifted Lands.** During visual examination there should be no evidence of the lifting of lands from the base material surface. Lifted lands can trap contaminants during the assembly process and are considered undesirable for assembly.

**51.11.1.5 Marking (Legend/Silkscreen) Imperfections.** The marking of part number, revision letter, part mounting information and orientation, etc., on a PCB is evaluated for location, size, readability, and accuracy. Marking imperfections are usually considered minor, but markings that are missing, incorrect, or partially obscured could have an effect on functionality. Marking that encroaches into the soldering area can also be a significant issue and should not reduce the solderable areas below what is stated in the procurement documentation.

**51.11.1.6 Solder Resist Coating Imperfections.** A solder resist is a coating material used to mask off or to protect selected areas of a pattern from the attachment of solder. A solder resist can also be used as electrical insulation between isolated conductors or to define the soldering area for ball grid array (BGA) patterns. Attributes inspected are registration, blisters, bubbles, adhesion, wrinkles, tenting, soda strawing, and delamination. Misregistration at land areas reduces or prevents adequate solder fillet formation or can expose adjacent conductors. The minimum land area to obtain adequate solder filleting should be reflected by the minimum acceptance criteria. Wrinkles, flaking, peeling, and delamination provide sites for moisture absorption and contaminants to settle on or into the PCB and can reduce the insulation between adjacent conductors, increasing the potential for electrochemical migration (ECM). When solder resist is used to define BGA patterns, the shape and position on or around the land is important to proper soldering of the BGA (see Fig. 51.10)

**FIGURE 51.10** Soldermask defined BGA land. (Courtesy of IPC.)

**51.11.1.6.1 Tenting of Vias.** Tenting of via holes is the process of covering holes with solder resist where soldering is not required or desired. This is done to prevent the potential for shorting during the assembly process and to allow for vacuum-based test fixtures to draw the assembly down onto test pins for functional test. The requirement here is that all vias that are required to be tented are covered by resist.

**51.11.1.6.2 Soda Strawing of Solder Resist.** A soda straw is a long tubular void along the edges of conductive patterns where the solder resist is not bonded to the base material surface or edge of the conductor (see Fig. 51.11). If this void is allowed to reach the point where the solder resist meets the outside environment, fluxes, fluids, and other contaminants may end up trapped in the soda straw, leaving the potential for future ECM or corrosion.

**FIGURE 51.11** Soda straws between copper trace and soldermask. (courtesy of IPC.)

**51.11.1.7 Coverlayer Characteristics.** Flexible and rigid/flexible PCBs are covered with either a coating similar to solder resist or a coverfilm adhered to by acrylic adhesive. Covercoat acceptability requirements are the same as those for solder resist.

**51.11.1.7.1 Coverfilm Separations.** When a film is adhered to the flexible PCB surface, separations between the film and PCB surface can occur. There should be no more than three small separations that do not reduce the spacing between conductors by 25 percent or below the minimum stated in the procurement documentation. Separations along the edge of the PCB are not allowed, as they can trap contaminants.

**51.11.1.7.2 Adhesive Presence on Attachment Surfaces.** The presence of adhesive from the coverfilm should not reduce the solderable surfaces below the minimum reflected on the procurement documentation.

**FIGURE 51.12** Layer-to-layer registration, x-ray method. (Courtesy Sandia Laboratories.)

**51.11.1.8 Dimensional Characteristics.** Contour dimensional inspection verifies that the outside border dimensions, cutouts, and key slots meet the procurement documentation requirements. Contour dimension requirements can be considered fit requirements. Both undersized and oversized PCBs can affect functionality, depending on the degree of requirement violation. Incorrect placement or size of key slots prevents the proper mounting of the PCB. Measuring methods vary from the use of a ruler or calipers to sophisticated coordinate measurement machines (CMMs). The sophistication of the method is naturally dependent on the required dimensions and tolerances.

**51.11.1.8.1 External Dimensions.** The external dimensions of a PCB are usually measured by calipers and micrometers. They can also be measured with a CMM or comparison gauges and templates. Tolerances for these dimensions should be reflected on the PCB procurement documentation. It is important to ensure that the measurement tools being used have sufficient accuracy to perform the intended measurements.

**51.11.1.8.2 Registration, Layer to Layer, X-Ray Method.** The x-ray method provides a nondestructive way to inspect layer-to-layer registration of internal layers of multilayer PCBs. It utilizes an x-ray machine and either Polaroid film or camera sensors to image the internal layers. The multilayer PCB is x-rayed in a horizontal position. The x-ray images are then examined for evidence of hole breakout of the internal lands. The lack of an internal annular ring denotes severe misregistration of layers (see Fig. 51.12).

**51.11.1.8.3 Flatness (Bow and Twist).** *Bow* is the deviation from flatness of a PCB characterized by a roughly cylindrical or spherical curvature such that, if the PCB is rectangular, its four corners are in the same plane (see Fig. 51.13). *Twist* is the deformation parallel to a diagonal of a rectangular sheet such that one of the corners is not in the plane containing the other three corners (see Fig. 51.14). Excessive bow and/or twist on a PCB are detrimental to the assembly process when the PCB must fit into card guides or packaging configurations in which flatness is critical. It can also interfere with the proper mounting of the assembly into the intended case. The method for bow and twist measurement can be found in IPC-TM-650 method 2.4.22. The maximum

With constraining force applied to both corners of the same edge. 1 & 2 deflection from surface plane.

**FIGURE 51.13** Bow measurement of PCB. (Courtesy of IPC.)

**FIGURE 51.14** Twist measurement of PCB. (Courtesy of IPC.)

bow or twist allowed is 1.5 percent unless the PCB has surface-mounted devices (SMDs) attached where the requirement is reduced to a maximum allowable of 0.75 percent.

**51.11.1.8.4 Cleanliness (Solvent Extract Methods).** PCBs are fabricated using wet chemistry and mechanical techniques. Some of the chemical baths contain metallic salts and organic materials. These chemicals, if left on the surface, could affect the functionality of the PCBs by reducing electrical insulation resistance and promote corrosion or ECM on the conductor pattern. This condition is usually associated with low operating voltage (10 volts or less) and requires three components: moisture, metallic contaminants, and voltage. The ionic cleanliness test measures the conductivity of a de-ionized water and alcohol solution used to wash the PCB. Commercial equipment is available to perform ionic cleanliness testing. The organic cleanliness test uses an organic solvent wash (e.g., acetonitrile) to remove “loose” organics from the surface of the PCB. This wash solution is collected on a glass plate and the solvent is allowed to evaporate. Any organic contamination in the wash solution leaves a cloudy residue on the glass that can be subsequently analyzed for composition. These two tests are mutually exclusive in that the organic test cannot detect ionic contamination and vice-versa. Note that when a solder mask is required on PCBs, an additional cleanliness test is performed on the uncoated PCBs before coating.

**51.11.1.9 Solderability Inspection.** Solderability inspection measures the ability of the attachment points to be wetted by solder in the areas for the joining of components to the PCB. Three terms are used to describe acceptability of solderability:

- **Wetting** The formation of a relatively uniform, smooth, unbroken, and adherent film of solder to a basis material, wetting is the preferred and acceptable condition.
- **De-wetting** This condition results when molten solder has coated the attachment surface and recessed, leaving irregularly shaped mounds of solder separated by areas covered with a thin film of solder that fully covers the basis metal. De-wetting is not acceptable for attachment points but is allowed on ground or voltage planes for Class 1 and 2 products.
- **Non-wetting** This nonconforming condition is the partial adherence of molten solder to a surface that it has contacted, leaving some of the basis metal exposed.

**51.11.1.9.1 Solderability Testing and Coating Durability.** Many methods for inspecting PCBs for solderability both quantitatively and qualitatively have been established. However, the most meaningful method is that used in the actual assembly soldering operation (hand, wave, drag, reflow soldering, etc). ANSI/J-STD-003, “Solderability Tests for Printed Boards,” addresses the recommended test methods and subsequent storage conditions that have no adverse effect

**FIGURE 51.15** “Wetted” solder joint. (Courtesy of IPC.)

on the solderability of those portions of the PCB intended to be soldered. Test coupons or PCBs are subjected to accelerated aging for a length of time defined by a coating durability requirement reflected on the procurement documentation, followed by solderability testing. Solderability is acceptable when the surfaces to be soldered have fully wetted. See Fig. 51.15 for acceptable criteria for PTHs, and Fig. 51.16 for examples of non-wetting.

**FIGURE 51.16** Non-“wetted” solder joint. (Courtesy of IPC.)

**51.11.1.9.2 Coating Durability Requirements.** The coating durability requirements are classified into three categories:

- **Category 1** Minimum coating durability is required. The PCB is intended to be soldered within 30 days from time of manufacture and likely to experience minimum thermal exposure.
- **Category 2** Average coating durability is required. This classification is intended for PCBs likely to experience storage of up to 6 months from the time of manufacture and moderate thermal or solder exposure.
- **Category 3** Maximum coating durability is required. This classification is intended for PCBs that are likely to experience long storage (over 6 months from time of manufacture) and that may experience severe thermal or solder processing steps, etc. It should be recognized that there may be significant difficulty involved, a cost premium, or delivery delay associated with PCBs specified to meet this durability level.

**51.11.1.9.3 Surface Finishes.** Tin-lead solder alloys (e.g., 63/37) are the most popular alloy used for surface finishes on PCBs. Other surface finishes are rapidly finding their way onto the PCBs. IPC-6012 lists more than 20 different surface finishes that are now in use for PCBs. Lead-free alloys are also appearing on PCBs. It is important to understand that the composition and type of the surface finish influence solderability. The procurement documentation must state specifications for surface finish. Methods available for analyzing the alloy composition on the plated PCB include wet analysis, atomic absorption, and x-ray fluorescence (XRF). XRF is popular because of the ease of obtaining the alloy composition and thickness nondestructively.

**51.11.1.10 Electrical Inspection.** These inspections are performed to verify circuit integrity after processing and substantiate that the electrical continuity, signal integrity, and isolation characteristics of the PCB meet the design specifications. Electrical inspection methods are typically performed on the production PCBs, but evaluation of signal integrity is routinely performed on specially designed test coupons. Two popular nondestructive electrical tests are insulation resistance and circuit continuity tests. These are usually performed on 100 percent of complex PCBs, especially multilayer ones. Automated electrical test equipment with either stationary or moving test probes allows the probes to make contact with the all parts of the circuit pattern in order to verify the continuity and isolation characteristics of the PCB.

**51.11.1.10.1 Circuit Continuity.** Continuity tests are performed on PCBs to verify that the printed circuit pattern is interconnected as designed. Testing can be performed with an inexpensive multimeter for simple PCBs or with more elaborate automated equipment such as a computer-enhanced bed-of-nails or flying probe tester. These types of automated testers can either be preprogrammed with the circuit interconnection information derived from the computer design files or can use a known good “golden” PCB as a test template to learn the interconnection information. The preferred method is to perform the continuity test on all PCBs submitted for acceptance. This method is especially recommended for multilayer circuitry, where the internal patterns and interconnections cannot be inspected visually after fabrication.

**51.11.1.10.2 Insulation Resistance (Circuit Shorts).** The purpose of this test is to measure the resistance offered by the insulation system of a PCB to an applied voltage. Low insulation resistances can prevent proper operation of circuits by permitting the flow of leakage current. This test can also reveal the presence of contaminants from processing residues. The test is performed by applying voltage to isolated nets and measuring the current flow between these nets. Test voltages of 40 to 500 VDC and minimum insulation resistances of 100 to 500 meg-ohm are popular. As with continuity testing, insulation resistance testing typically employs automated test equipment using stationary or moving probes.

**51.11.1.10.3 Impedance.** Impedance (see Fig. 51.17) is the amount of resistance a circuit offers alternating current (AC) signals. High frequency AC circuits require that the impedance of PCB circuits be matched to that of the components in order to transfer the most signal between the components on the assembly. Proper impedance matching also reduces radio wave emissions (EMF) from the assembly. Impedance is measured using Time Domain Reflectometry (TDR) and is typically measured using a specially designed test circuit on a coupon. Requirements for impedance as well as test circuit design must be supplied to the PCB manufacturer. Variations in impedance of up to 10 percent around the nominal value are expected and are not unusual do to standard process variations in circuit geometry and insulation make up. Tighter control of impedance is possible, but special attention must be made to processes and materials to achieve reductions in variation.

## 51.11.2 Internally Observable Imperfections

These are imperfections where evaluation from the outside of the PCB is not possible. They require the preparation of a microsection in order to view and evaluate conformance. Preparing a microsection of the PCB requires a great deal of skill. The method of sample removal, the microsection materials used, and the grinding/polishing techniques all significantly affect

**FIGURE 51.17** Impedance diagram of a PCB. (Courtesy of Microtek Laboratories.)

the ability to produce a microsection that will reveal and not hide imperfections. The basic methodology for the preparation of microsections can be found in IPC Test Method 2.1.1, but numerous papers and articles have been written on the art of the microsectional preparation process. The use of test coupons to perform microsections is optimal due to the fact that internal layer connections do not always appear for every layer in holes on the PCB, whereas they always appear in a properly designed microsection test coupon. See Fig. 51.18 for a microsection of a multilayer PTH.

**FIGURE 51.18** Vertical PTH microsection of a multilayer PCB. (Courtesy of Microtek Laboratories.)

**51.11.2.1 Microsectioning.** Samples for microsectioning are removed from the PCB or test coupon. The removed specimen should contain at least three of the smallest holes in a line that will allow microsectioning. Because shearing of microsection samples from a PCB or coupon can result in creating failure mechanisms that are not truly present in the production PCB, the practice is not recommended. Routing or sawing microsection samples is the preferred method for sample removal. The samples should be mounted in a resin-based medium that does not produce too much heat during curing and does not shrink away from the surface of the holes being evaluated. Holes should be fully filled, as partially or nonfilled holes result in poor mount conditions, difficult sanding/polishing processes, and possibly erroneous thickness results. Examination under a microscope for internally observable attributes should be performed at 100× magnification. If it is not possible to determine whether the condition is acceptable, progressively higher magnifications should be used until accurate determination of acceptance is determined. Polishing vertical PTH cross sections to the center of the hole  $\pm 10$  percent is critical. If the hole is polished less than or more than the center of the hole, the measured plating thickness will be artificially high. Horizontal plane, PTH cross sections are recommended as references for internal-layer interconnection quality and are prepared by grinding from the top down through the hole to the inspection area. See Fig. 51.19 for an example of a horizontal microsection.

**FIGURE 51.19** Example of interconnection separation in a horizontal microsection. (Courtesy of Microtek Laboratories.)

Although horizontal PTH cross sections are usually more accurate for plating thickness, interconnection separation, and annular ring measurements, they do not allow adequate inspection of other attributes such as voids, plating uniformity, adhesion, etchback, and nodules. Surface plating thickness measurements are taken from vertical cross sections of conductor areas. Microsection mounts are usually etched with an appropriate etchant to show grain boundaries between the copper-clad foil and copper plating and to remove copper smearing introduced during the polishing process.

**51.11.2.1.1 Thermal Stress Solder Float Test.** Soldering temperatures expose PCBs to thermal and mechanical stress and may deform the PCB shape and cause premature degradation of the base material. Thermal stress inspection is performed to predict the acceptability of the PCBs after the assembly and rework process. PTH degradation, separation of platings or conductors, and base material delamination are induced or amplified by the thermal stress test. The PCB specimen is oven-conditioned to reduce moisture, placed in a desiccator on a ceramic plate to cool, fluxed, floated in a solder bath, and placed on an insulator to cool. Visual inspection for imperfections is followed by microsectioning of the PTHs and inspection under a microscope for integrity. Test coupons are typically used for thermal stress inspection.

**51.11.2.2 Microsection Evaluation.** The evaluation of internally observable attributes in the microsection consists of the following set of inspections:

- Subsurface attributes in the PCB material such as delamination, blistering, cracks, ground plane clearance, and layer-to-layer spacing
- Internal conductor attributes including over- and under-etch, conductor cracks and voids, and foil thickness
- PTH attributes including size, annular ring, plating thickness, plating voids and nodules, plating cracks, resin smear, etchback, wicking, innerlayer (post) separation, and solder thickness

### 51.11.2.3 Subsurface Imperfections in the PCB Material

**51.11.2.3.1 Base Material Voids after Thermal Stress.** Heat from soldering operations will transfer quickly through the copper holes and pads in a PCB to the base material in close proximity to the copper. This rapid heat movement can easily cause imperfections to occur in the base material and this area near the holes is exempted from evaluation for base material imperfections. This area is defined as the “thermal zone” and described in detail by IPC-A-600. Outside this thermal zone, base material voids should not exceed 0.08 mm for rigid PCBs and 0.5 mm for flexible PCBs or flexible portions of rigid-flexible PCBs. Base material voids found in the same plane of flexible or rigid-flexible PCBs should not have a combined dimension greater than 0.5 mm (see Fig. 51.20).

**FIGURE 51.20** The thermal “A” zone. (Courtesy of IPC.)

**51.11.2.3.2 Clearance of Holes to Power/Ground Planes.** Electrical isolation between power/ground planes and nonconnected holes is necessary to ensure that shorting does not occur. This is especially true with holes that are nonplated and used for mounting of the PCB to a frame, as without proper clearance, the mounting hardware can cause shorting to the frame or between power and ground. The minimum distance of this clearance should reflect the minimum electrical spacing requirement on the procurement documentation (see Fig. 51.21).

**51.11.2.3.3 Delamination and Blistering.** Delamination or blistering observed in the microsection is a nonconforming condition and the inspection lot should be rescreened in accordance with the externally observable visual requirements for delamination and blistering set forth earlier in this chapter.

**FIGURE 51.21** Clearance between PTH and power/ground plane. (Courtesy of IPC.)

**51.11.2.3.4 Resin Smear.** Resin smear is transferred from the base material onto the surface or edge of the internal conductive pattern during the drilling process. Excessive heat generated during drilling softens the resin in holes and smears it over the exposed internal copper areas. This condition creates a resin insulator between the internal land and subsequent plating in the holes, and the result is open or poorly connected circuits. The imperfection is removed from the holes by chemical or plasma cleaning prior to metallization. Inspection for resin smear is performed by viewing vertical and horizontal microsections of PTHs and any evidence of it is nonconforming. (See Fig. 51.22 for an example of resin smear prior to etchback.)

**FIGURE 51.22** Resin Smear in PTH, vertical microsection. (Courtesy of IPC.)

**51.11.2.3.5 Etchback.** Etchback is a process for the controlled, positive removal of non-metallic materials from side walls of holes to a specified depth. It is used to remove resin smear and then to remove the reinforcement material laterally to expose additional internal conductor surfaces. The degree of etchback is critical to function. Too much etchback creates excessively rough hole side walls and causes weak PTH structures. Etchback requirements range between 0.005–0.08 mm. The degree of etchback is measured by evaluating vertical PTH cross sections of multilayer PCBs and is determined “effective” if at least one of the top or bottom surfaces of the internal conductor is attached to the plated copper on both visible sides of every conductor layer. (See Fig. 51.23 for an example of acceptable etchback for all classes.)

**51.11.2.3.6 Negative Etchback.** This is a condition where the internal copper conductors rather than the insulating material in the hole have been laterally removed. This condition is not allowed when positive etchback is required. In all other cases, negative etchback should be minimal or nonexistent.

**51.11.2.3.7 Layer-to-Layer Spacing.** The minimum spacing between two consecutive layers in the PCB is determined by drawing an imaginary plane between the two most eccentric points of each of the two layers in the field of view and measuring the distance between these two planes. (See Fig. 51.24 for an example of minimum dielectric thickness between layers)

**51.11.2.4 Internal Conductor Imperfections in the Microsection.** In theory, circuits should be rectangular. Circuits are usually designed with this rectangular shape in mind. In practice, circuits are trapezoidal. Depending on how the circuit is formed, this shape could be close to

**FIGURE 51.23** Effective etchback in PTH, vertical microsection. (Courtesy of IPC.)

**FIGURE 51.24** Layer-to-layer spacing, minimum dielectric thickness, vertical microsection. (Courtesy of IPC.)

a rectangle or differ significantly from it. The further from a rectangle that the shape is, the less volume the circuit has to conduct current compared to a corresponding rectangular circuit. Terms like *outgrowth*, *undercut*, *overhang*, and *etch factor* are used to define the attributes of these shapes (see Fig. 51.25 and 51.6).

**51.11.2.4.1 Conductor Width.** This attribute is measured at the widest point of the circuit in the microsection. The procurement documentation should state the minimum allowable width. (See Fig. 51.6)

**51.11.2.4.2 Conductor Thickness.** Conductor thickness depends on the thickness of the base foil used and the additional plating added to the surface during any plating processes. Allowances for expected reduction of both foil and plating thicknesses due to manufacturing processes must be considered. A detailed table of these minimum acceptable conductor thicknesses with allowances for manufacturing processing can be found in IPC-A-600.

FIGURE 51.25 Circuit geometry. (Courtesy of IPC.)

**51.11.2.5 PTH Imperfections.** Nothing affects the function of the PCB more than imperfections in the PTH. These imperfections are usually not observable from the surface, and microsectional sampling of holes is limited to almost statistical insignificance. Despite this, evaluations of the microsection represent one of the most important evaluations that can be done on a PCB.

**51.11.2.5.1 Annular Ring.** Minimum internal annular ring is evaluated on the internal copper land that exhibits the shortest distance between its outer edge and where it ends in or at the plating in the hole. It should be noted that a microsection identifies layer shift in only one direction and that microsections in both x and y directions should be evaluated to determine accurately the actual shift that may be present. Horizontal sections from the top of the PCB down to the layer in question give a 360° view of the pad and can be used to exactly identify minimum annular ring and layer shift. The procurement documentation should specify the requirement for minimum annular ring (see Fig. 51.26), and in cases where the allowable annular ring is zero or “breakout,” the breakout cannot be allowed in the area where the circuit enters the pad, as this will reduce the circuit’s current-carrying capacity.

**51.11.2.5.2 Lifted Lands.** Lifted lands on the PCB surface prior to thermal stress are not allowed and if found, the entire inspection lot should be reevaluated to the externally observable visual requirements for lifted lands described earlier in this chapter. Lifted lands after thermal stress are allowed.

**51.11.2.5.3 Cracks.** Cracks in the foils and platings in the microsection are broken into the following six categories (see Fig. 51.27):

FIGURE 51.26 Internal annular ring measurement, horizontal and vertical microsection (does not include plating). (Courtesy of IPC.)

- “A” type cracks occur in the external foil. They do not extend into the plating and are acceptable for all classes of PCBs.
- “B” type cracks occur in the external foil. They go completely through the foil and extend into, but not completely through, the plating and are acceptable only for Class 1 PCBs.
- “C” type cracks occur in the internal foil and are nonconforming for all classes of PCBs.
- “D” type cracks completely penetrate the external foil and plating and are nonconforming for all classes of PCBs.
- “E” type cracks occur in the barrel plating of the hole. They are non-conforming for all classes of PCBs.
- “F” type cracks occur in the corner of the plating of the hole and are nonconforming for all classes of PCBs.

FIGURE 51.27 Types of cracks in the PTH, vertical microsection. (Courtesy of IPC.)

51.11.2.5.4 *Plating Nodules.* Plating nodules should not reduce the PTH diameter below the minimum requirement specified in the procurement documentation.

51.11.2.5.5 *Plating Thickness.* Plating thickness should be measured at three places in the plated hole and averaged. The absolute minimum plating thickness observed should also be recorded. The minimum plating thickness requirements for the three-area average along with the absolute minimum thickness observed are defined in IPC-6012 (see Fig. 51.28).

FIGURE 51.28 Measurement of plating thickness in PTH, vertical microsection. (Courtesy of Sandia Laboratories.)

51.11.2.5.6 *Plating Voids.* When found in the microsection, plating voids should be limited to one per microsection. No void should span more than 5 percent of the PCB thickness or be present at the interface of internal copper foil to the plating.

51.11.2.5.7 *Solder Resist Thickness.* When the procurement documentation specifies this thickness, it should be measured at the thinnest area observed between the copper and the surface of the solder resist. This is usually at the corner of the copper trace.

51.11.2.5.8 *Wicking.* During the drilling and hole cleaning process, glass fibers from the base material can be removed inward from the hole surface. During the copper-plating process, the copper will follow this glass removal topography, creating pockets of plating that extend laterally from the hole into the base material. This wicking can significantly reduce the electrical conductor spacing between holes or between holes and internal circuits. The maximum allowances for wicking can be found in IPC-A-600. (see Fig. 51.29).

51.11.2.5.9 *Interconnection Separation.* This is defined as the separation between the internal copper foil and the copper plating in the hole. It is also sometimes referred to as *post separation*. Any evidence of this imperfection in the microsection makes the associated PCBs nonconforming. This imperfection is a severe issue that will likely reduce the service life of the PCB (see Fig. 51.30).

FIGURE 51.29 Wicking, vertical microsection (Courtesy of IPC.)

**FIGURE 51.30** Interconnection separation, vertical micro-section. (Courtesy of Microtek Laboratories.)

*51.11.2.5.10 Material Fill of Blind and Buried Vias.* When blind or buried vias are present in a PCB, it is important that they be microsectioned and evaluated in addition to any through holes evaluated. Buried vias are typically filled with resin, and this resin should fill a minimum of 60 percent of each buried via.

## 51.12 RELIABILITY INSPECTION USING ACCELERATED ENVIRONMENTAL EXPOSURE

---

Reliability inspection consists of performing specific tests to ensure that the PCB will function under the influence of the climatic and/or mechanical forces to which it will be subjected during use. Environmental tests are performed on preproduction PCBs or specifically designed test coupons to verify design adequacy and manufacturing process control. Specific tests are sometimes specified as part of the PCB acceptance procedure to expose a prospective failure situation. Specific environmental testing, as part of the acceptance procedure, is prevalent in high-reliability programs. Note that it is recommended that a simulation of the cycles required for component assembly and rework be performed as a preconditioning prior to environmental exposure. Test results then relate to the actual condition of the PCB after assembly. Specific test methods for performing these tests can be found in IPC-TM-650.

### 51.12.1 Thermal Shock

The thermal shock test is particularly efficient in identifying (1) PCB designs with areas of high mechanical stress and (2) the resistance of the PCB to exposure of high- and low-temperature extremes. This test is periodically required in IPC-6012 for product acceptance and is also used for PCB supplier qualification inspection. A thermal shock is induced on a PCB by exposure to severe and rapid differences in temperature. The test is usually performed by transferring the PCB from one temperature extreme (e.g., 125°C) to the other (e.g., -55°C) rapidly, usually in less than 2 min. A resistance difference in excess of 10 percent between the 1st and 100th cycles is considered nonconforming, but requirements in the thousands of cycles are sometimes specified for high-reliability PCBs. The thermal shock test can produce cracking of plating in the holes and base material de-lamination (refer to IPC-TM-650, method 2.6.7.2, for the procedure). Note that continuous electrical monitoring during thermal shock cycling will detect intermittent electrical circuits that may not be detected with periodic measurement techniques. Intermittent circuits usually occur at the high-temperature extreme.

Basic Surface Insulation Resistance (SIR) Test Pattern

**FIGURE 51.31** Basic SIR test pattern. (Courtesy of Microtek Laboratories.)

#### 51.12.2 Surface Insulation Resistance (SIR)

SIR testing evaluates the electrical resistance between two surface electrical conductors separated by dielectric material. This test detects the bulk conductivity and electrical leakage through surface electrolytic contaminants when the samples are exposed to a high-humidity environment. The test conditions are a relative humidity of 85 to 92 percent at a temperature range of 35 to 45°C without the use of an electrical forcing potential. (See Fig. 51.31 for example of a SIR test pattern.)

#### 51.12.3 Moisture and Insulation Resistance (MIR)

This is an accelerated method of testing the PCB for the deteriorative effects of condensing high humidity and heat conditions typical of tropical environments. The test conditions are a relative humidity of 90 to 98 percent at a cycling temperature range of 25 to 65°C with a forcing voltage potential of 10 to 100 VDC applied to the test circuit(s). After the required test cycles are completed, the PCB is subjected to insulation resistance testing. Test specimens should exhibit no blistering, measling, warp, or delamination after the moisture resistance test.

#### 51.12.4 Dielectric Withstanding Voltage

This test is used to verify that the component part can operate safely at its rated voltage and withstand momentary overpotentials due to switching, surges, and similar phenomena. It also serves to determine whether insulating materials and spacings on the PCB are adequate. The test is performed on either an actual PCB or a test coupon. Voltage is applied between mutually insulated conductors on the specimen or between insulated conductors and power/ground planes. The voltage is increased at a uniform rate until the specified value is reached. The voltage is held for 30 sec. at the specified value and then reduced at a uniform rate. Visual examination of the specimen is performed during the test for evidence of flashover or breakdown between contacts. The test can be either destructive or nondestructive, depending on the degree of overpotential used.

### 51.12.5 ECM and CAF Testing

ECM and CAF tests are intended to detect the growth of conductive metal filaments on a PCB under the influence of a direct current (DC) voltage bias. This filament growth may occur at either an external or internal interface. Growth of the metal filaments is by electrolytic deposition from a solution containing metal ions that are dissolved from the anode in the test circuit and then transported by the electric field toward the cathode. ECM comes in two forms. First are surface dendrites, which form on the internal or external surfaces between the two test electrodes. The second form of ECM is CAF, in which filaments form along the surface of the glass-fiber reinforcement between a hole and another hole or conductor along the surface of the fiber. ECM and CAF testing is done at a relative humidity of 85 to 92 percent at a steady-state temperature range between 35 to 85°C using forcing potentials ranging from 10 to 100 volts DC during the test.

---

## CHAPTER 52

---

# ACCEPTABILITY OF PRINTED CIRCUIT BOARD ASSEMBLIES

---

**Mel Parrish**

*STI Electronics, Inc. Madison, Alabama*

---

### 52.1 UNDERSTANDING CUSTOMER REQUIREMENTS

---

When determining the acceptance criteria to use in building or manufacturing a printed circuit board assembly (PCBA), one first and foremost must look at the contract between the supplier and the purchaser of the product. Always determine the needs and/or wants of the customer through contractual communications or, less formally, by talking to the customer if a contract is not detailed enough or does not even exist.

In some situations, contracts are not the norm, such as for consumer electronics built for retail sale or captive production efforts where the customer and producer are one and the same. In these cases, the company must determine the level of quality desired based on company culture and goodwill, reputation for quality products, and the desired life cycle of the product. Consequences for an unintended or unexpected failure may be a significant driver in this consideration. An electronic medical device used for life support has much greater consequence attached to continued successful operation than a disposable electronic device such as a toy that is intended to be discarded after a short term of use. Additionally, the intended operational environment may have an even greater impact on what should be expected for the acceptability of production. Consider that a product used for military operations such as space travel, arctic conditions, or tropical environments is subjected to much harsher conditions than an office product that sits on a desk in a temperature-controlled environment where the temperature will not vary more than 10°F during its expected life cycle. The range of these expectations is significant and is a paramount consideration for what can be defined as acceptable or nonconforming.

Most standards that define acceptability have roots traceable to the various Department of Defense (DoD) military standards established in the 1960s and 1970s. The advent of complex electronics systems required a standardized approach to acceptability based on lessons learned through testing and product failure analysis that was accomplished by laboratory or research activities. The resulting definitions for acceptance became very restrictive, and although the requirements were initially intended only for harsh environment exposure or products that have a significant consequence for failure, they were used successfully to increase performance of all soldered electronic assemblies. Most commercial production did

not share the need for critical continued performance and the accompanying significant impact on production cost. Despite an effort to approach acceptance from a cost-prevention or value-added viewpoint, the military standards are no longer maintained and the DoD research sources for maintaining technology currency were eliminated. The demise of military standards allowed the industry to develop consensus standards for soldering processes and also acceptability. Undoubtedly the most significant of these is IPC-A-610, which creates varying levels of acceptability for broad application ranging from medical and military products to disposable electronics. Not all products need to survive after an explosion or operate for 30 years without interruption.

Each company should decide whether to build its product to an industry standard such as IPC-A-610, "Acceptability of Electronic Assemblies," or develop its own workmanship manual that would closely match IPC-A-610 levels for quality. The advantage of adopting a common standard is the universal understanding of expectations it supports between the customer and producer and thus circumvents the need for lengthy negotiations over individual interests. Where individual custom standards are used, the production processes must be adjusted for each customer or product as it is addressed for production. On the other hand, common standards can be transitioned from one project to the next without significant change. The use of a common standard can take into account the perspective of collective experiences of the consensus participants who are involved in the development. Creating an individual standard can also be a rather daunting and expensive task that can provide limited return without the broad application to bear the cost. In any case, the workmanship manual decision must support the company's objectives to achieve customer expectations for quality with regard to its product.

Detailed specifications may be called out in a drawing or contract, or there may not be any documentation that identifies requirements. In the latter case, the recommendation is to revert to accepted industry standards or an internal quality requirement such as a workmanship manual.

### 52.1.1 Lead-Free Soldering

Any acceptance criteria decision should define lead-free materials and processes acceptability. Until the advent of the European Union's adoption of the Directive on Restriction of Hazardous Substances (RoHS), which went into effect in July 2006, all electronic design and also production control was based on the precedent that soldering processes would be accomplished with tin-lead (SnPb) soldering materials. Tin-lead solder has specific properties that were instrumental in the multitude of component attachment methods that evolved for production of electronics. Had the solder of choice over the years been other than tin-lead, many of these common configurations might have evolved differently. The current reality is that component designs intended for tin-lead attachments are being soldered with various lead-free alloys, driven by the requirement to remove lead from electronic products. Acceptability for these designs has not changed that much, as reflected in current IPC acceptability standards. The attachments still need to have solder that flows over the connection interface surfaces, forms a fillet, and wets to the constituents that form the attachment. What has changed significantly is the surface appearance of the resulting solder connection. Most lead-free solders exhibit surface roughness that would cause concern for those accustomed to the normal appearance of tin-lead. In fact, if solder finishes created by tin-lead had the same surface appearance, they would have rightly been considered contaminated or overheated. The current IPC-A-610 standard provides a side-by-side contrast of similar solder connections accomplished with both tin-lead and lead-free solder alloys for appearance perspectives.

Outside of the considerations of acceptability appearance, there are additional concerns for materials compatibility issues and adverse properties such as hot tear, tin whisker, tin pest, accelerated and increased process temperature exposure, and others. These considerations should be developed elsewhere in this reference.

This section presents common possibilities for acceptance criteria.

## 52.1.2 Military, Space, and Commercial Specifications

Reference to these types of specifications is common in the applicable markets. No great amount of detail will be discussed; however, they are all worthy of some discussion since they can provide a great deal of insight into the rationale of “product acceptability” and its origin.

**52.1.2.1 Military Specifications.** Military specifications have been widely accepted for use in many markets outside of their intended military products. The one with the most relevance to workmanship or acceptability criteria at the assembly level was MIL-STD-2000, a unified standard created from several individual services and production standards. It was created to combine the various requirements into a single standard to make it easier for military contractors to implement a single performance requirement. Many lower-level supporting specifications for components, designs, materials, and printed circuit boards (PCBs) were part of the family of documents to support performance and acceptance requirements as a package. Each specification was designed to be compatible with the eventual success of the end product. In an effort to increase understanding by all of the parties involved, and to ease compliance issues, the services provided training and certification at various locations throughout the country, and even at some international locations. The typical training audience often included customer representatives as well as producers. The title of MIL-STD-2000 was “Standard Requirements for Soldered Electrical and Electronic Assemblies.” However, all of the military soldering requirements standards, including MIL-STD-2000, have been rescinded for future production through DoD acquisition reform initiatives. Nevertheless, some products still use the requirements because they have been adopted internationally and because they provide relative benefit for the product’s specific industry segment.

MIL-STD-2000 was an extensive document that defined the nonconformance conditions that required disposition as rework, repair, or use as is. This of course required some action by the manufacturer to evaluate a given defect anomaly and make a decision regarding its impact on the form, fit, or function of the intended use. It also allowed some level of customer involvement concerning these decisions if the contract prescribed it. MIL-STD-2000 also limited the assembly materials for a manufacturer in terms of the solder alloys, flux activity levels, cleanliness, conformal coating, solder mask, and their acceptance conditions, either through a flow down to a supporting specification or internal requirements. Any deviation from standardized process and materials as specified in these documents required qualification and/or customer consent before use. However, the document allowed flexible contractual application dependent upon the product demands for performance. “General Requirements” for standard production were much less stringent than “Detail Requirements,” which were used for demanding performance or consequence products such as those intended for missile or space applications. Contracts were required to specify “Detail Requirements” before they were imposed; otherwise, only the “General Requirements” were required as a default. The intent of flexible requirements was to allow the use of a single standard for everything from complex weapon systems to office equipment. Unfortunately, they were not commonly applied that way, and the overly stringent requirements originally intended for critical systems were attached to applications such as office or communication products that did not benefit from the more stringent and costly production effort.

Solder connection characteristics for both plated through-hole and surface-mount devices were defined by solder finish, fractures, voids, solder coverage and quantity, and wetting and filleting. The PCB requirements after assembly were detailed in terms of conductor finish and condition, conductor separation from the board, cleanliness of the assembly, weave exposure, delamination, measles, haloing, and bow and twist. In addition, part markings were expected to remain legible even after assembly processing.

If specifically imposed by individual contract, the services provided, through established training resources, traceable training and certification of the people making decisions. This training provided a cadre of qualified instructors who in turn could train people for their company or organization. Its interesting that prior to elimination of these schools, the majority of

students attending the certification-training program were from commercial production companies with no contractual performance for DoD. In addition to establishing product acceptance criteria, the specification also detailed methods for process control and defect reduction to be used in assembly. One hundred percent inspection was required unless specific conditions were met, so that sample-based inspection might be used with confidence.

As a result of elimination of the various military standards, most DoD and termed high-reliability production is defined through contractual implementation of the commercial IPC equivalent standards, such as J-STD-001, and IPC-A-610.

**52.1.2.2 Space Production Requirements.** Standards associated with space applications have significantly different purposes than process control documents commonly used for large-volume production electronics. For the purpose of space applications, there is seldom a large enough production volume to benefit from process development, and each individual product must be acceptable based on the environments experienced with space applications. These could be quite similar to the initial developments for DoD acceptance discussed earlier since they also involved space considerations. Current space application standards have evolved from NHB 5300 through to NASA-STD-8739.3, “Soldered Electrical Connections.” Additionally, the space user community has created a space addendum to the commercial standard J-STD-001 for the opportunity to employ consensus standards used by many of their contractors for various other programs. The addendum modifies requirements to a degree consistent with space interests and in effect makes the performance and acceptance requirements similar to that of the NASA-generated standard.

**52.1.2.3 J-STD-001 and IPC-A-610 Industry Standards.** These consensus industry association standards are widely recognized as the most common standards for requirements and workmanship for PCB assemblies, both nationally and internationally. They allow flexible definition of requirements based on three distinct classes of product, and the acceptability and performance requirements change based upon the contract provisions for the individual product as these classes are applied.

**52.1.2.3.1 J-STD-001, “Requirements for Soldered Electrical and Electronic Assemblies.”** Since “acquisition reform” and elimination of the very commonly adopted military standards, IPC standards have filled the resulting void and have also brought with them additional valuable practices and perspectives from commercial producers. J-STD-001, “Requirements for Soldered Electrical and Electronic Assemblies,” was first released in April 1992 as a modification of the previous IPC-S-815, which had limited application, likely due to the competition from contractually imposed military and other industry-unique standards that were available to the users and managers at the time. IPC-S-815 had very similar criteria to that of the military baseline or “General Requirements” discussed earlier.

The resulting J-STD-001 defines three levels of electronic assemblies based on the intended end-item use. The three classifications were established to reflect differences in consequences of failure, harshness of the operating environment, and expected term of operation. The three classes are summarized as follows:

- **CLASS 1: General Electronic Products** This class includes products suitable for applications where the major requirement is function of the completed assembly.
- **CLASS 2: Dedicated Service Electronic Products** Class 2 includes products where continued performance and extended life is required, and for which uninterrupted service is desired but not critical. Typically the end-use environment would not cause failures.
- **CLASS 3: High-Performance Electronic Products** These include products where continued high performance or performance-on-demand is critical, equipment downtime cannot be tolerated, end-use environment may be uncommonly harsh, and the equipment must function when required. Examples include life support or other critical systems.

J-STD-001 addresses many of the same subjects as MIL-STD-2000, and in most cases for Class 1 and 2 production, the requirements are again similar to the “General Requirements” of the previous standards. The Class 3 requirements for the majority of the subject areas are similar to MIL-STD-2000, “Detail Requirements.” Since the deactivation of MIL-STD-2000 and the associated revisions, many contract performance requirements have been transitioned to this document and family of IPC standards. As with the predecessor documents, it should be recognized that a successful soldering process requires consistent materials and the ability to select the materials for a given process that will perform well in combination with compatibility for the application. As with acceptability, users may have the flexibility to establish their own requirements for these materials, but it would be difficult to find suppliers willing to create materials qualifications for anything other than a standardized definition. The following discussion provides a brief overview of the “family of standardized criteria” for materials associated with acceptable production standards.

52.1.2.3.2 *J-STD-002, “Solderability Tests for Component Leads, Terminations, Lugs, Terminals, and Wires.”* This standard prescribes the recommended test methods, defect definitions, acceptance criteria, and illustrations for assessing the solderability of electronic component leads, terminations, solid wire, stranded wire, lugs, and tabs.

Solderability evaluations are made to verify that the solderability of component leads and terminations meets the requirements established in J-STD-002 and that subsequent storage has had limited adverse effect on the ability to solder components to an interconnect. Determination of solderability can be made at the time of manufacture, at receipt of the components by the user, or just prior to assembly and soldering.

Similar to J-STD-001, J-STD-002 has its origin with military standards, which in this case was MIL-STD-202, Method 208. It defines standardized methods of evaluating the ability of a surface to accept solder and in addition defines the durability of the solderable surface with three categories of product and related conditioning to determine the product performance before soldering. Category 1 is the least demanding performance, where the product would be used soon after testing, and Category 3 is applied where the product may be stored for extended periods of time before soldering. The intent is to identify solderability problems before the expense of production is added or the production schedule is delayed while waiting for solderable replacement parts.

For a more detailed discussion of solderability and the related issues, refer to Sec. 52.5.

52.1.2.3.3 *J-STD-003, “Solderability Tests for Printed Boards.”* J-STD-003, “Solderability Tests for Printed Boards,” was released in April 1992 to complement the requirements of J-STD-001. This standard prescribes the recommended test methods, defect definitions, and illustrations for assessing the solderability of printed board surface conductors, attachment lands, and plated-through holes.

The solderability determination is made to verify that the PCB fabrication processes and subsequent storage have had no adverse effect on the solderability of those portions of the PCB intended to be soldered. This is determined by evaluation of the solderability specimen portion of a board, or representative coupon, that has been processed as part of the panel of boards and subsequently removed for testing per the method selected.

The objective of the solderability test methods described in J-STD-003 is to determine the ability of printed board surface conductors, attachment lands, and plated-through holes to wet easily with solder and to withstand the rigors of the PCB assembly processes.

For a more detailed discussion of solderability issues, refer to Sec. 52.5.

52.1.2.3.4 *J-STD-004, “Requirements for Soldering Fluxes.”* J-STD-004 prescribes general requirements for the classification and testing of soldering fluxes for high-quality interconnections. This standard is a flux characterization, quality control, and procurement document for solder flux and flux-containing material.

This standard defines the classification of soldering materials through specifications of test methods and inspection criteria. These materials include liquid flux, paste flux, solderpaste

flux, solder-preform flux, and flux-cored solder. It is not the intent of this standard to exclude any acceptable flux or soldering aid material; however, these materials must produce the desired electrical and metallurgical interconnection.

**52.1.2.3.5 J-STD-005, “Requirements for Soldering Paste.”** This standard prescribes general requirements for the characterization and testing of the solderpastes used to make high-quality electronic interconnections.

**52.1.2.3.6 J-STD-006, “Requirements for Electronic Grade Solder Alloys and Fluxed and Non-Fluxed Solid Solders for Electronic Soldering Applications.”** This standard prescribes the nomenclature, requirements, and test methods for electronic grade solder alloys; for fluxed and non-fluxed bar, ribbon, and powder solders, for electronic soldering applications; and for “special” electronic grade solders.

**52.1.2.3.7 Other Standards.** There are many standards that comprise the necessary content for successful production practices that lead to acceptability. Each represents an element of the foundation that supports a complete and successful production effort. One example is moisture susceptibility and the procedures to ensure that the components are not damaged by popcorning during reflow. J-STD-020 and J-STD-033 provide classification and control for moisture-sensitive components. Others, such as IPC-CC-830, “Qualification and Performance of Electrical Insulating Compound for Printed Wiring Assemblies,” deal with material acceptability of conformal coating. Each of the elements is important and should be considered as a package for overall acceptability.

Many of the material specifications reference test methods. Rather than include the actual test method with the publication of the specification, the IPC posts them on its web site, where they can be easily accessed and kept current without extensive revision of the various reference standards. This prevents possible conflict with outdated procedures. Criteria for the acceptance levels, however, are provided by reference standards such as J-STD-001, J-STD-004, and so on.

**52.1.2.4 IPC-A-610, “Acceptability of Electronic Assemblies”.** Many companies use IPC-A-610, “Acceptability of Electronic Assemblies,” as the standalone workmanship standard for their products. J-STD-001 establishes the requirements for soldering processes, whereas IPC-A-610 depicts the pictorial acceptability criteria for production, including soldering as identified in the J-STD-001 document. IPC-A-610 also addresses additional, broad criteria to define handling and mechanical workmanship requirements, among others. A large percentage of the acceptability criteria defined in this chapter is that which is illustrated in the IPC-A-610 standard.

The popularity of IPC-A-610 is apparent considering that it is available in many different languages and used throughout the world as the acceptance reference of choice for electronics.

The IPC-A-610 standard describes the acceptability criteria for quality electronic assemblies. It does not define process requirements, although the methods used must produce a completed solder joint conforming to the acceptability requirements as defined. Consistent with other IPC standards, the IPC-A-610 document details the acceptance criteria for each of three classes.

The three classes of product allow flexible application of the conditions for which the standard provides acceptance criteria. The customer should provide the inspector with the intended class for acceptability before the product is considered for acceptance. The three classes are 1, 2, and 3 and are the equivalents of the definitions provided by J-STD-001.

In addition, this standard discusses and visually illustrates degrees of compliance, such as “Target,” “Acceptable,” “Defect,” and “Process Indicator,” for each condition relative to the three classes of product. The importance of the condition varies with the expected performance of the class based on the preceding class criteria.

Acceptance definitions are summarized as:

- **Target** This condition is close to perfect or preferred; however, this desirable condition is not always achievable and may not be necessary to ensure reliability of the assembly in its

service environment. Although this condition is not a requirement for performance based on the standard, it is provided to illustrate to users the desired condition that the creators of the criteria thought they should strive to achieve.

- **Acceptable** This condition, although not necessarily perfect, will maintain the integrity and reliability of the assembly in its service environment.
- **Defect** This condition may be insufficient to ensure the form, fit, or function of the assembly in its end-use environment. Defect conditions need to be dispositioned by the manufacturer based on design, service, and customer requirements. Disposition may be to rework, repair, scrap, or use as is. Repairing or using the assembly as is may require customer concurrence. A defect for Class 1 automatically implies a defect for Class 2 and 3. A defect for Class 2 implies a defect for Class 3.
- **Process indicator** A process indicator is a condition (not a defect) that identifies a characteristic that does not affect the form, fit, or function of a product. Such condition is a result of material, design, and/or operator- or machine-related causes that create a condition that neither fully meets the acceptance criteria nor is a defect.

As established by the predecessor military standards, process indicators are not intended to be reworked or even dispositioned, and they can be included in product delivery without correction of the product. They are, however, not desirable and indicate the relative success of the process and materials; if the process or materials could lead to defect conditions, the process may need to be adjusted or corrected for future production. Process indicators should be monitored as part of the process control system. Should the number of process indicators indicate abnormal variation in the process or identify an undesirable trend, the process should be analyzed. This analysis may result in action to reduce the variation and improve yields before there is a defect trend that may require rework or scrap or, worst of all, result in customer dissatisfaction.

### 52.1.3 Workmanship Manuals

Many companies use a workmanship document of some sort to describe what the operations should achieve during production. IPC-A-610 is used frequently by manufacturing and also quality personnel to determine acceptable quality levels of their product. Some companies have also developed very good workmanship manuals for their own use, especially to cover unique or uncommon design requirements. If a need exists to develop a unique workmanship manual, then this manual should reflect the intended contract requirements. It is certainly desirable to use a manual already in existence since it can become extremely costly to develop your own, and because customer review is unnecessary since the customer should already be aware of the common requirements definition. If minor changes are necessary to standard performance due to process, product or material limitations, they can often be addressed as a contractual waiver, addition, or exception to the standard definition.

## 52.2 HANDLING TO PROTECT THE PCBA

---

The handling of PCBs both before and after the soldering operation can be very important in terms of inducing possible damage to the board or contaminating the board such that subsequent operations are affected. There are three subjects that should be well thought out and controlled in an assembly operation for PCBAs: electrostatic discharge (ESD) protection, contamination prevention, and physical damage prevention.

### 52.2.1 ESD Protection

ESD is the rapid discharge of a voltage potential into an electronic assembly from a static energy source. The presence of a static discharge in the area of a sensitive device can damage the device even without actual contact. ESD-sensitive (ESDS) components found on the assembly and the amount of current generated by the discharge will determine whether immediate failure takes place. All types of ESD damage can be difficult to troubleshoot, but the most costly scenario is one in which the component is assembled and passes functional test only to fail later due to latent conditions resulting from ESD. This could cause the loss of a customer and even in some cases recall of the product.

Some electronic devices are more sensitive to electrostatic overstress (EOS) damage than others. The degree of such sensitivity within a particular device is related directly to the manufacturing technology employed. The trend for electronic components is smaller size, wider band pass, and lower voltage. These are all contributors to the ESD protection problem and increased sensitivity of the component.

Where sensitive components are handled, protective measures must be taken to prevent component damage. Improper and careless handling accounts for a significant portion of ESD damage to components and assemblies. Before handling ESD-sensitive components, equipment should be carefully tested to ensure that it does not generate damage-causing spikes. The preferred workstation to be utilized in electronic assembly is shown in Fig. 52.1.

**FIGURE 52.1** Target condition for EOS/ESD workstation (1) Personal wrist strap (2) EOS protective trays, shunts, etc. (3) EOS protective table top (4) EOS protective floor mat (5) Building floor (6) Common ground point (7) Ground. (IPC)

Static charges are created when nonconductive materials are separated. Destructive static charges are often induced on nearby conductors, such as human skin, and discharged as sparks passing between conductors. This can happen when a person having a static charge potential touches a PCBA. The electronic assembly can be damaged as the discharge passes through the conductive pattern to a static-sensitive component. Static discharges may be too low to be felt by humans (less than 3,500 volts) and still damage ESD-sensitive components.

Sensitive components and assemblies must be enclosed in conductive, static-shielding bags, boxes, or wraps when not being worked on, unless otherwise protected. ESD-sensitive items must be removed from protective enclosures only at static dissipative or antistatic workstations.

For ESD safety, a path to ground must be provided for static charges that would otherwise discharge on a device or board assembly. Provisions are made for grounding the worker, preferably via a wrist strap or a heel strap, provided conductive flooring is used.

### 52.2.2 Contamination Prevention

The key to any contamination problem is to prevent it from happening. The cost of subsequent operations required to clean a product or rework a product is orders of magnitude more than any cost associated with preventing the contamination from occurring. These contaminants can cause soldering and solder mask or conformal coating problems. There are any number of possibilities for inducing contamination in an assembly environment, such as dirt, dust, machine oils, and process residues; however, in many cases, contamination is caused by the human body, specifically the salts and oils on the skin.

In a high percentage of assembly areas, good housekeeping will take care of contamination from the environment. It should be a common event on each shift to clean workstations, sweep floors, dust fixtures, empty trash, and so on. This not only prevents contamination, but it also helps to keep personnel morale at a higher level. After all, we all desire to work in a nice, clean environment. It will also serve as a positive point if visitors or possible customers visit the assembly area.

To prevent contamination from the human body, every individual must be aware of the possibility of contaminating the PCBA. Printed circuits should be touched only on the edges away from any edge connectors prior to the soldering operation (see Fig. 52.2). Where mechanical assembly procedures require a firm grip on the board, gloves or finger cots should be worn. If the PCBA is to be conformal coated after the soldering operation, the handling of the assembly should be prevented. In some cases, using finger cots, gloves, or fixtures can reduce the contamination. Many producers utilize cleanliness testing to ensure that contamination levels remain within an acceptable range before the coating process, and to ensure adhesion and eliminate localized contaminants that could impact circuit operation and long-term performance. J-STD-001 provides levels for cleanliness acceptability.

**FIGURE 52.2** Appropriate method of handling board to avoid contamination and electrostatic discharger damage. Note position of fingers and the use of a grounding wrist strap.

### 52.2.3 Physical Damage Prevention

Improper handling can damage components and assemblies. Typical defects associated with handling are cracked, chipped, or broken components; bent or broken terminals; scratched

board surfaces; damaged traces or lands; fractured solder joints; and missing surface-mount technology (SMT) components.

Physical damage caused by handling can ruin assemblies and cause a high scrap rate of components or assemblies. Scrap is costly and must be avoided to achieve an efficient and high-quality operation.

Well-maintained handling equipment is also very important in preventing physical damage. One good example is conveyor systems. PCBAs can be caught in conveyors and damaged beyond rework or repair capability and, unless the area of operation is staffed, the conveyor system can damage many assemblies in a very short period of time.

Care must be taken during assembly and acceptability processes to ensure product integrity at all times. The following guidelines provide general guidance:

- Keep workstations clean and neat. There must not be any eating, drinking, or use of tobacco products in the work area.
- Minimize the handling of electronic assemblies and components to prevent damage.
- When gloves are used, they need to be changed as frequently as necessary to prevent contamination from dirty gloves.
- Solderable surfaces are not to be handled with bare hands or fingers. Body oils and salts reduce solderability and promote corrosion and dendritic growth. They can also cause poor adhesion of subsequent coatings or encapsulant.
- Do not use hand creams or lotions containing silicone, because they can cause solderability and conformal coating adhesion problems.
- Never stack electronic assemblies, because physical damage may occur. Special racks need to be provided in assembly areas for temporary storage.
- Always assume the items are ESDS even if they are not marked.
- Personnel must be trained and follow appropriate ESD practices and procedures.
- Never transport ESDS devices unless proper packaging is applied.

## 52.3 PCBA HARDWARE ACCEPTABILITY CONSIDERATIONS

---

Most electronic assembly designs include a small percentage of mechanical assembly that requires hardware of various types. Some of the more common component types and the acceptability criteria associated with each are discussed in the following sections.

### 52.3.1 Component Types

**52.3.1.1 Threaded Fasteners.** Hardware stack-up for all threaded fasteners must be identified on engineering documentation. The stack-up can be critical, depending on the types of material used for both the hardware and the PCB. Any missing hardware must be found or replaced. Any damage to hardware that prevents it from accomplishing what it was designed to do is unacceptable. A good example of this is any screw or nut that has been stripped, cross-threaded, or damaged to the point that a screw or nut driver is no longer able to tighten or loosen the part (see Fig. 52.3).

A minimum of  $1\frac{1}{2}$  threads should extend beyond the threaded hardware unless the hardware could interfere with other components. The maximum extension of threaded hardware is 3 mm plus  $1\frac{1}{2}$  threads for hardware up to 25 mm long and 6.3 mm plus  $1\frac{1}{2}$  threads for hardware greater than 25 mm long.

**FIGURE 52.3** Hardware mounting for threaded fasteners (1) Lock washer (2) Flat washer (3) Nonconductive material (base laminate) (4) Metal (not conductive pattern or foil). (IPC)

Threaded fasteners should be tight to the specified torque on engineering documentation. If torque is not specified on engineering documentation, a generic torque table should be available for use in the assembly environment. Such a table is sometimes included in a workmanship manual.

**52.3.1.2 Mounting Clips.** Uninsulated metallic components, clips, or holding devices must be insulated from underlying circuitry. Minimum electrical spacing between land and uninsulated component body must not be violated (see Fig. 52.4).

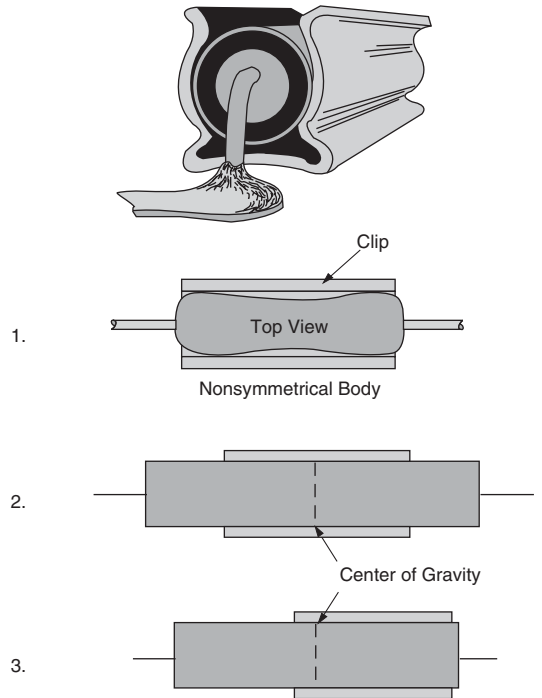

The clip or holding device must make contact with the component sides on both ends of the component. The component must be mounted with its center of gravity within the confines of the clip or holding device. The end of the component may be flush or extend beyond the end of the clip or holding device if the center of gravity is within the confines of the clip or holding device (see Fig. 52.5).

**52.3.1.3 Terminals.** Terminals that are to be soldered to a land may be mounted such that they can be turned by hand, but should be stable in the z-axis. Terminals may be bent if the top edge does not extend beyond the base and no other mechanical damage such as fractures or breakage to the terminal or the solder joint have occurred (see Fig. 52.6). Common terminals utilized are turret, bifurcated, hooked, and pierced or perforated terminals. See Fig. 52.7 for an example of a damaged turret terminal and a cross section of an assembled board.

**52.3.1.4 Swaged Hardware, Flared Flange.** The shank extending beyond the land surface is swaged to create an inverted cone, uniform in spread and concentric to the hole. The flange should not be split, cracked, or otherwise damaged to the extent that mechanical strength is compromised or allows contaminating materials to be entrapped in the rivet or funnel (see Fig. 52.8).

**FIGURE 52.4** Component mounting clip insulation requirements (1) Conductive patterns (2) Metallic mounting clip (3) Insulation material (4) Clearance. (IPC)

**FIGURE 52.5** Component mounting requirements (1) Clip (2) Nonsymmetrical body (3) Top view (4) Center of gravity. (IPC)

**FIGURE 52.6** Bifurcated terminal (1) top edge and (2) base, swaged. Post is broken, but sufficient material is left to attach the specified wires/leads for class I. If both posts are broken, it is unacceptable. (IPC)

**FIGURE 52.7** Acceptable installed turret terminal and cross section of assembled board. Terminal is intact and straight. (IPC)

**FIGURE 52.8** Flared flange. Acceptable for all Classes.

After swaging, the area should be free of circumferential splits or cracks. It may have a maximum of three radial splits or cracks, provided that the splits or cracks are separated by at least  $90^\circ$  and do not extend into the barrel of the rivet or funnel (see Fig. 52.9).

**52.3.1.5 Connectors, Handles, Extractors, and Latches.** Ejectors, handles, and connectors should not exhibit any cracks in the component material emanating from the roll pin or rivet that mounts the component to the PCBA.

Roll pins should not protrude more than 0.015 in. from the surface of the ejector, handle, or connector. The major consideration for roll pins should be to ensure that any protrusion does not mechanically interfere with any other assembly. Damage to the part, PCB, or securing hardware is unacceptable.

(a)

(b)

**FIGURE 52.9** (a) Shows an example of acceptable flared swage-split while (b) shows an unacceptable split into barrel.

Connector damage can also affect the pins of the connector being pushed or bent out of specification. When connectors are mated, there is the chance that the female portion of the connector pin will be pushed backward and bent. This prevents adequate contact area between the male and female pins of the connector, if they will mate at all. This circumstance is an unacceptable condition.

The male connector pins might also be bent. When the male pin is bent significantly, the mating of the female and male connectors can cause mechanical damage to the connector casing due to the male pin being forced into the wrong female connector slot. In most cases, the damage is deformation, cracking, or breaking of the connector casing material, all of which are unacceptable.

When connector pins are installed (such as compliant pin, press fit), the pins must be straight within 50 percent of the pin thickness from the perpendicular. For Class 1 and 2 equipment, the PCB land may be lifted less than or equal to 75 percent of the annular ring width. Any land that is lifted across more than 75 percent of the annular ring or has been fractured is unacceptable. For Class 3 equipment, no lifted or fractured lands are acceptable. For all classes, visibly twisted pins, damaged pins, or pins inserted such that there is a nonstandard pin height beyond a specified engineering tolerance is unacceptable.

**52.3.1.6 Faceplates.** Faceplates must be clean and free of scratches or damage on the front surface. This is important since this is the surface that is commonly viewed by the customer and presents the cosmetic appeal to the product being purchased. An exaggerated example of this is the purchase of an automobile. Few if any consumers would be willing to accept a new automobile with noticeable scratches in the painted surface.

A good rule of thumb for scratch criteria that some companies have adopted as a workmanship standard includes the following:

1. A scratch must be visible when viewed under the following conditions to be considered a defect:
  - a. From a distance of 18 in.
  - b. With no magnification utilized
  - c. With normal room lighting used in the assembly area
2. A scratch must be visible from more than one angle to be considered a defect.
3. Metal or plastic faceplate scratches that exceed 0.125 in. in length are considered defects.

Surfaces exposed to frequent viewing should be free of blisters, runs, nicks, gouges, blemishes, or other abrasions that would detract from the general appearance of the finish. Faceplates must also be securely fastened to the PCB, that is, tightly enough to prevent physical movement.

**52.3.1.7 Stiffeners.** Stiffeners are commonly used on PCBA designs that are large in dimension to prevent warpage of the PCBA before, during, or after assembly operations. If a stiffener has kept a PCBA from warping outside acceptability criteria, it has done its job; however, the stiffener must meet the following criteria to be acceptable:

- Any marking or color coatings must be permanent. Loss of marking such that it is not legible, or fading or loss of color outside the color standard being used, is unacceptable.
- The stiffener must be properly seated and mechanically fastened. If the soldering operation is used to mechanically fasten the stiffener to the PCBA, then good wetting to the stiffener such that the stiffener is mechanically sound is required.
- It is unacceptable to have a loose stiffener on a PCBA. The stiffener must be securely fastened to the PCBA.

## 52.3.2 Electrical Clearance

Electrical clearance of hardware to components or electrical traces must be controlled by the design based on the expected voltage and environment's exposure. As a default, design standards

such as IPC-2221 create a spacing requirement unless it is specifically defined for the particular PCBA (see Fig. 52.10 for examples). Minimum electrical clearance can be referenced throughout the acceptability requirements such as with contaminants or board laminate defects related to the conductors. Any violation of minimum electrical clearance is cause for a defect disposition consideration for any class, since it will directly impact the electrical performance of the product. Any condition that compromises the clearance should be verified by assemblers or inspectors to ensure that a shorting condition does not occur.

**FIGURE 52.10** Examples of acceptable and unacceptable electrical clearance-hardware. (a) Acceptable where: (1) Metallic hardware; (2) Conductor pattern; (3) Specified minimum electrical clearance; (4) Mounted component; (5) Conductor; (b) Unacceptable where hardware reduces clearances to less than specified electrical clearance; (1) Metallic hardware; (2) Conductor pattern; (3) Spacing less than minimum electrical requirements; (4) Mounted component; (5) Conductor; (c) Unacceptable as lead is clinched toward a noncommon electrical conductor (1) and violates clearance; (C) requirement.

### 52.3.3 Physical Damage

Physical damage to hardware components in most cases refers to enough damage to a component to render it unusable in its application—for example, threads that are damaged to the point that mechanical fastening cannot be performed or a component that is fractured or broken such that it cannot perform the function for which it was intended.

Subjective judgments are common in this area since it is very much dependent on the application of the hardware in the given design, the environment in which the final product will be used, and life cycle expectations of the product.

## 52.4 COMPONENT INSTALLATION OR PLACEMENT REQUIREMENTS

Component installation or placement is the first step in the assembly of the PCBA. It may begin by preparation of the leads of a given package type in order to provide the correct lead

protrusion, form the leads to fit the PCB plated-through holes or pads, or put a bend in the leads that will serve as a standoff from the component to the PCB.

#### 52.4.1 Plated-Through Hole (PTH) Lead Installation

Several requirements apply to all PTH components. When using a polarized component, it must be oriented correctly. In all cases, if the orientation is incorrect, the board is unacceptable (see Fig. 52.11). When lead forming is required, the lead form must provide clearance and

FIGURE 52.11 Component orientation-polarity. (IPC)

stress relief (see Fig. 52.12). Physical damage to the lead itself cannot exceed 10 percent of the diameter of the lead. Exposed basis metal as a result of lead deformation is a process indicator but does not render the board unacceptable.

**52.4.1.1 Axial Leaded Components.** The target condition for axial components is that the entire body length of the component should be parallel and in contact with the board surface (see Fig. 52.13 for tolerances). If the component is required to be spaced above the board to avoid overheating the laminate, it must be mounted a minimum of 1.5 mm above the PCB surface. The maximum space between the component and the PCB surface should not violate the requirements for lead protrusion and cannot be greater than 3.0 mm for Class 1 and 2 and 0.7 mm for Class 3 equipment (see Fig. 52.13).

Leads must extend from the component body at least one lead diameter ( $L$ ) or thickness, but not less than 0.8 mm from the body or weld, before the start of the lead bend radius (see Fig. 52.14).

**FIGURE 52.12** Examples of acceptable clearance and stress relief for PTH components. (IPC)

**FIGURE 52.13** Amount of nonparallel allowed varies by class but is measured: (H) is component height, (C) is clearance between component body and board, and (D) is the farthest distance between the component body and the board.

No physical damage, such as chips or cracks to axial components, should be allowed; however, it is acceptable to allow minor damage. It becomes unacceptable if the insulating cover is damaged to the extent that the metallic element is exposed or the component shape is deformed (see Fig. 52.15).

**52.4.1.2 Radial Leaded Components.** The target condition for vertical radial components is that the body is perpendicular to the PCB and the component base is parallel to the PCB. It is an acceptable condition to have the component tilt from the perpendicular as long as it does not violate electrical clearance. The space between the component base and PCB should be between 0.3 and 2.0 mm (see Fig. 52.16) but it is considered a process indicator only if it exceeds that dimension. Some components, such as light-emitting diodes (LEDs) and switches, may need to be perpendicular due to mating requirements.

**FIGURE 52.14** Lead extension from component body, where (1) is solder bead, (2) is weld. L is the distance from the effective component body to the bend. (IPC)

**FIGURE 52.15** Example of physical damage to component after insertion. This is a “defect” condition and cause for rejection. (a) Axial lead component, (b) Chip component. (IPC)

**FIGURE 52.16** Radial ledged components spacing. Component is perpendicular and base is parallel to board. Acceptable clearance varies with Class. (IPC)

### 52.4.2 SMT Placement

Coplanarity is very important in the placement of SMT components with leads. Occasionally, lead preparation to form the leads of SMT components is necessary to achieve the proper coplanarity for manual or automatic placement of components on the PCB. Most times, however, the components are purchased packaged with leads prepared and ready to be automatically placed by pick-and-place equipment. Another critical parameter for all surface-mounted components is the accuracy of placement of the components onto the pads of the PCB.

**52.4.2.1 Chip Components.** Side overhang is acceptable up to one-half (one-quarter for Class 3) the width of the component end cap or PCB pad. End-cap overhang is not acceptable for all classes. The end-cap solder joint width is acceptable with a minimum solder joint length of one-half (three-quarters for Class 3) the component end cap or PCB land, whichever is less.

A side solder joint length is not required; however, a properly wetted fillet must be evident. The maximum solder fillet height may overhang the land or extend onto the top of the end-cap metallization; however, the solder should not extend farther on the component body.

The minimum solder fillet height must cover one-quarter the thickness, or height, of the component end cap for Class 3 but is required to be evident only for Classes 1 and 2. The component end cap must have overlap contact with the PCB pad. There is no minimum contact length specified see (see Fig. 52.17 and Table 52.1 for an example and list of specifications).

**FIGURE 52.17** Example placement and solder fillet for surface mount chip component. Evidence of overlap of contact (J) between the component termination and the land is required. (IPC)

**52.4.2.2 Metal Electrode Leadless Face (MELF) or Cylindrical Termination.** Side overhang is acceptable up to one-quarter the diameter of the end cap. This dimension is different from the other SMT components due to the cylindrical feature of the component. End-cap overhang is not acceptable for all classes. The end-cap solder joint width is acceptable with a minimum solder joint length of one-half the diameter of the component end cap for Classes 2 and 3 but is required to be discernable only for Class 1. A side solder joint length must be a minimum of one-half (three-quarters for Class 3), but again is required to be discernable only for Class 1. The maximum solder fillet height may overhang the land or extend onto the top of the end-cap metallization; however, the solder should not extend farther on the component body. The minimum solder fillet height must cover one-quarter the thickness, or height, of the component end cap for Class 3, and for Classes 1 and 2 the minimum solder fillet must exhibit proper wetting. The component end cap must have 75 percent of the cap dimension overlapping the land for Class 3 and 50 percent for Class 2. There is no minimum contact length specified for Class 1 (see Fig. 52.18 and Table 52.2).

**52.4.2.3 Castellated Terminations.** Side overhang is acceptable up to one-half (one-quarter for Class 3) of the castellation width. End overhang of the castellation is not acceptable for all classes. The castellation end solder joint width is acceptable with a minimum solder joint length of one-half (three-quarters for Class 3) of the castellation width (see Table 52.3). A minimum side solder joint length is required to extend beyond the edge of the component for all classes. The maximum solder fillet height is not a specified parameter for this type. The minimum solder fillet height must be 50 percent of the castellation height for Class 3 and 25 percent for Class 2. The only height requirement for Class 1 is that at least one fillet is visible.

**TABLE 52.1** Dimensional Criteria for Chip Components, Rectangular or Square End Components—One-, Three-, or Five-Side Terminations

Feature	Dim.	Class 1	Class 2	Class 3
Maximum Side Overhang	A	50% (W) or 50% (P) whichever is less <sup>a</sup>		25% (W) or 25% (P), whichever is less <sup>a</sup>
End Overhang	B	Not permitted		
Minimum End Joint Width	C	50% (W) or 50% (P), whichever is less <sup>b</sup>		75% (W) or 75% (P), whichever is less <sup>b</sup>
Minimum Side Joint Length	D	Wetting is evident		
Maximum Fillet Height	E	The maximum fillet may overhang the land and/or extend onto the top of the end-cap metallization; however, the solder does not extend further onto the top of the component body		
Minimum Fillet Height	F	Wetting is evident on the vertical surface(s) of the component termination <sup>c</sup>		(G) + 25% (H) or (G) + 0.5 mm (0.02 in.), whichever is less <sup>c</sup>
Solder Thickness	G	Wetting is evident		
Termination Height	H	Unspecified dimension, determined by design		
Minimum End Overlap	J	Required		
Width of Land	P	Unspecified dimension, determined by design		
Termination Width	W	Unspecified dimension, determined by design		
Side mounting/billboarding <sup>d,e</sup>				
Width to Height Ratio		Does not exceed 2:1		
End Cap and Land Wetting		100% wetting land to end metallization contact areas		
Minimum End Overlap	J	100%		
Maximum Side Overhang	A	Not permitted		
End Overhang	B	Not permitted		
Maximum Component Size		No limits		1206
Termination Faces		Three or more faces		

**Notes:**<sup>a</sup> Does not violate minimum electrical clearance.<sup>b</sup> C is measured from the narrowest side of the solder fillet.<sup>c</sup> Designs with via in pad may preclude meeting these criteria. Solder acceptance criteria should be defined by the user and the manufacturer.<sup>d</sup> These criteria are for chip components that may flip (rotate) onto the narrow edge during assembly.<sup>e</sup> These criteria may not be acceptable for certain high-frequency or high-vibration applications.**FIGURE 52.18** Cylindrical end cap (MELF) termination. “J” represents the overlap between component termination and land, “R” is length of component termination. (IPC)

**52.4.2.4 Flat Ribbon, L, and Gull-Wing Leads.** Side overhang is acceptable up to one-half (one quarter for Class 3) of the width of the component lead. Lead toe overhang is acceptable for all classes provided it does not violate minimum electrical clearance. The end-joint solder width is acceptable for Class 2 with a minimum solder-joint length of one-half (three-quarters for Class 3) of the component lead width. The lead-side solder-joint minimum length is one-time the lead width for Class 1. It must be three times the width when the lead length is greater than three times its width. If the lead length is less than three times its width, the side joint width must be equal to the length. For Classes 2 and 3, the maximum solder fillet height on components such as small-outline integrated circuits (SOICs) or small-outline transistors (SOTs) may touch the package body or end seal, but not that of ceramic or metallic components. The minimum solder heel fillet height must cover one-half of the lead thickness for Class 2 and must be equal to the lead thickness for Class 3 (see Table 52.4).

**TABLE 52.2** Dimensional Criteria: Cylindrical End-Cap MELF Termination

Feature	Dim.	Class 1	Class 2	Class 3
Maximum Side Overhang	A	25% (W) or 25% (P), whichever is less <sup>a</sup>		
End Overhang	B	Not permitted		
Minimum End Joint Width <sup>b</sup>	C	Wetting is evident	50% (W) or 50% (P), whichever is less	
Minimum Side Joint Length	D	Wetting is evident <sup>c</sup>	50% (R) or 50% (S), whichever is less <sup>c</sup>	75% (R) or 75% (S), whichever is less <sup>c</sup>
Maximum Fillet Height	E	The maximum fillet may overhang the land or extend onto the top of the component termination; however, the solder does not extend further onto the component body		
Minimum Fillet Height (End and Side)	F	Wetting is evident on the vertical surface(s) of the component termination <sup>d</sup>		(G) + 25% (W) or (G) + 1.0 mm (0.0394 in.), whichever is less <sup>d</sup>
Solder Thickness	G	Wetting is evident		
Minimum End Overlap	J	Wetting is evident <sup>c</sup>	50% (R) <sup>c</sup>	75% (R) <sup>c</sup>
Land Width	P	Unspecified dimension, determined by design		
Termination/Plating Length	R	Unspecified dimension, determined by design		
Land Length	S	Unspecified dimension, determined by design		
Termination Diameter	W	Unspecified dimension, determined by design		

*Notes:*<sup>a</sup> Does not violate minimum electrical clearance.<sup>b</sup> C is measured from the narrowest side of the solder fillet.<sup>c</sup> Does not apply to components with end-only terminations.<sup>d</sup> Designs with via in pad may preclude meeting those criteria. Solder acceptance criteria should be defined by the user and the manufacturer.**TABLE 52.3** Dimensional Criteria: Castellated Terminations

Feature	Dim.	Class 1	Class 2	Class 3
Maximum Side Overhang	A	50% (W) <sup>a</sup>		25% (W) <sup>a</sup>
End Overhang	B	Not permitted		
Minimum End Joint Width	C	50% (W)		75% (W)
Minimum Side Joint Length	D	wetting is evident	Depth of castellation	Depth of castellation
Maximum Fillet Height	E	G + H		
Minimum Fillet Height	F	wetting is evident	(G) + 25% (H)	(G)+50% (H)
Solder Thickness	G	Wetting is evident.		
Castellation Height	H	Unspecified dimension, determined by design		
Land Length	S	Unspecified dimension, determined by design		
Castellation Width	W	Unspecified dimension, determined by design		

*Note:*<sup>a</sup> Does not violate minimum electrical clearance.

**52.4.2.5 J-Leaded Components.** Side overhang is acceptable up to one-half (one-quarter for Class 3) of the width of the component lead. Lead toe overhang is not specified for any class.

The end lead solder-joint width is acceptable with a minimum solder-joint length of one-half (three-quarters for Class 3) of the component lead width. A side solder-joint length must be a minimum of  $1\frac{1}{2}$  times the lead width for both Class 2 and 3, but Class 1 requires only a visible fillet. The maximum solder fillet height is not specified; however, the solder fillet may not touch the component package body. The minimum heel solder fillet height must cover one-half of the thickness of the component lead or the lead thickness for Class 3 (see Table 52.5).

**TABLE 52.4** Dimensional Criteria: Flat Ribbon, L, and Gull-Wing Leads

Feature	Dim.	Class 1	Class 2	Class 3
Maximum Side Overhang	A	50% (W) or 0.5 mm (0.02 in.), whichever is less <sup>a</sup>		25% (W) or 0.5 mm (0.02 in.), whichever is less <sup>a</sup>
Maximum Toe Overhang	B	Does not violate minimum electrical clearance		
Minimum End Joint Width	C	50% (W)		75% (W)
Minimum Side Joint Length <sup>b</sup>	When (L) Is $\geq 3$ W	D	(1W) or 0.5 mm [0.02 in.], whichever is less	3 (W) or 75% L, whichever is longer
	When (L) Is $< 3$ W			100% (L)
Maximum Heel Fillet Height	E	See Section 52.4.2.1

Solder Thickness	G	Wetting is evident		
Formed Foot Length	L	Unspecified dimension, determined by design		
Lead Thickness	T	Unspecified dimension, determined by design		
Lead Width	W	Unspecified dimension, determined by design		

*Notes*<sup>a</sup> Does not violate minimum electrical clearance.<sup>b</sup> Fine-pitch leads require a minimum side fillet length of 0.5 mm (0.02 in.).<sup>c</sup> In the case of a toe-down lead configuration, the minimum heel fillet height (F) extends at least to the midpoint of the outside lead bend.**TABLE 52.5** Dimensional Criteria: J-Leads

Feature	Dim.	Class 1	Class 2	Class 3
Maximum Side Overhang	A	50% (W) <sup>a</sup>		25% (W) <sup>a</sup>
Maximum Toe Overhang	B	Unspecified dimension, determined by design <sup>a</sup>		
Minimum End Joint Width	C	50% (W)		75% (W)
Minimum Side Joint Length	D	Wetting is evident	150% (W)	
Maximum Fillet Height	E	Solder does not touch package body		
Minimum Heel Fillet Height	F	(G) + 50% (T)		(G) + (T)
Solder Thickness	G	Wetting is evident		
Lead Thickness	T	Unspecified dimension, determined by design		
Lead Width	W	Unspecified dimension, determined by design		

*Note:*<sup>a</sup> Does not violate minimum electrical clearance.

**52.4.2.6 Ball Grid Array (BGA) Components.** BGA package components are a very popular design due to significant packaging density. This allows designers to get more function in a smaller space. The component package is virtually impossible to inspect visually as traditionally allowed with other components since the solder spheres are located beneath the component. If cost justification exists, either due to volume or reliability provisions such as could be the case on Class 3 equipment, x-ray equipment can be used to verify the position quality and integrity of the solder joints. This could be costly in terms of the upfront capital investment of the x-ray equipment, but may pay for itself many times over in customer satisfaction or the prevention of defective product. Other options may use the x-ray as a process development tool where once the process is stabilized, the inspection is reduced to sampling or eliminated completely.

X-ray inspection can provide a visual depiction of the solder connection that must not contain solder bridges, incomplete reflow, attachment fractures, misalignment that violates minimum electrical clearance, or missing or damaged spheres. It's also considered defective for solder voids to displace more than 25 percent of a sphere (see Fig. 52.19).

**FIGURE 52.19** Ball grid array (BGA), bottom view showing solder ball connection. (IPC)

### 52.4.3 Use of Adhesives

Adhesives can often be used in SMT and PTH applications.

For SMT components, adhesive may be used to attach components to the bottom side of the PCB for mixed technologies (those containing both through-hole and SMT components). In some process flows, the SMT components are placed with adhesive between the solder pads; the PCB is processed through an adhesive curing cycle; then the components are wave soldered or reflowed onto the PCB along with the PTH components. In some processes, the adhesive is a temporary (soluble) attachment to stabilize the components during soldering and is to be removed after the solder is attached. In some extreme cases, the adhesive is used for both through-hole and SMT components to support the physical attachment of the components for severe operational conditions such as physical shock or vibration. Where intended to support the component physically, the attachment is specifically defined by drawing or individual requirements. The SMT components are acceptable as long as the adhesive has not contaminated the solder joint. If adhesive has contaminated the component solderable surface, lead, end cap, or PCB pad such that an acceptable solder joint is not achieved, the PCBA is not acceptable (see Fig. 52.20).

Normally in PTH component applications, adhesive is used to give large-profile and/or heavy components more mechanical stability. When adhesives are used in this manner, the following adhesive acceptance criteria apply:

- The adhesive must adhere to a flush-mounted axial component for 50 percent of the component length and 25 percent of its diameter on one side. The build-up of adhesive should

**FIGURE 52.20** Adhesive visibly extended from under the component and visible in the terminal area. (IPC)

not exceed 50 percent of the component diameter, and adhesion to the mounting surface must be evident (see Fig. 52.21).

- The adhesive must adhere to a vertically mounted axial component for 50 percent of the component length and 25 percent of its circumference, and adhesion to the mounting surface must be evident (see Fig. 52.22).

**FIGURE 52.21** Adhesive on horizontal and vertically mounted components. (1) Adhesive, (2) Top view, (3) 25 percent circumference.

**FIGURE 52.22** Adhesive on vertically mounted components. (1) Top view, (2) Adhesive. (IPC)

## **52.5 COMPONENT AND PCB SOLDERABILITY REQUIREMENTS**

---

Component solderability, which includes the solderability of the PCB, is probably the most important single characteristic to consider when building PCBAs. To be successful in soldering PCBAs, good wetting must be achieved. It is an ongoing effort to ensure that all boards and electrical components purchased and received from suppliers maintain good solderability.

The key to success in this all-important task is to have an excellent working relationship with the suppliers and manufacturers of the components to ensure good, solderable components.

Until partnership relationships are achieved, there should be a sample of each lot or batch of components received that are subjected to solderability testing. This testing should be conducted in accordance with J-STD-002 and J-STD-003. These documents were written specifically to address solderability requirements for electronic assembly components and PCBs. The intent of the solderability testing is to qualify the surface to accept solder with less-than-optimum conditions. Additionally, artificial conditioning (aging) is used to simulate a normal aging period that the components might experience before use. Identification of weaker components can reduce the possibility of a solderability problem or production issues later on in the production cycle. Based on this lack of lead solderability, the components should be rejected and returned to the supplier, before they can be placed in the assembly process.

Packaging and handling of components are also important to maintain good solderability since many contaminants that could affect solderability can be transferred to solderable surfaces as a result of handling by equipment or personnel or the storage environment. Storage contamination may result from airborne contaminants, moisture, temperature, and also time. As tin-lead or lead-free component lead finishes age, they can oxidize, and this oxidation will affect solderability of the component. A rule of thumb used by many companies is to suspect the solderability of components two or more years old. In some cases, this age can be tracked easily for components marked with a date code. Other components too small to mark or that for some other reason are not marked with a date code cannot be traced as easily. Often companies keep records on the date of receipt and base the age of the component on this date. Although these records may not be completely accurate, they still serve the purpose. If components are known to be over two years old, a new solderability sample may be pulled to determine whether the components are still usable before production. Often they are not usable due to oxidation, intermetallic growth, or some other contaminant that the component has been exposed to over time.

## **52.6 SOLDER-RELATED DEFECTS**

---

All solder joints should exhibit wetting as shown by a concave meniscus between the component and PCB being soldered. The outline of the component being soldered should be easily determined. The most common solder defects produced by the soldering process are discussed in the following sections.

### **52.6.1 PTH Solder-Joint Minimum Acceptable Conditions**

Table 52.6 shows the minimum acceptable PTH solder-joint criteria. Fig. 52.23 shows the basic elements of solder fill for all classes.

**TABLE 52.6** PTHs with Component Leads: Minimum Acceptable Solder Conditions<sup>a</sup>

Criteria	Class 1	Class 2	Class 3
A. Vertical fill of solder <sup>b,c</sup> Note: Less than 100 percent solder fill may not be acceptable in some applications: e.g., thermal shock. The user is responsible for identifying these situations to the manufacturer	Not Specified	75%	75%
B. Wetting on primary side (solder destination side) of lead and barrel Target for Classes 1,2, and 3 is 360° wetting present on land and barrel	Not Specified	180°	270°
C. Percentage of land area covered with wetted solder on primary side (solder destination side) The land area does not need to be wetted with solder on the primary side	0	0	0
D. Fillet and wetting on secondary side (solder source side) of lead and barrel	270°	270°	330°
E. Percentage of land area covered with wetted solder on secondary side (solder source side)	75%	75%	75%

*Notes:*

<sup>a</sup> Wetted solder refers to solder applied by the solder process.

<sup>b</sup> The 25 percent unfilled height includes both source and destination side depressions.

<sup>c</sup> Class 2 may have less than 75 percent vertical hole fill.

**FIGURE 52.23** (1)–Vertical fill meets requirements of Table 52.6 (2)–Solder destination side (3)–Solder source side. (IPC)

**52.6.2 Solder Balls or Solder Splash**

Solder balls and splashes that violate minimum electrical design clearance, are not encapsulated in a permanent coating, or are not attached (soldered) to a metal surface are unacceptable (see Fig. 52.24).

**52.6.3 Dewetting and Nonwetting**

Dewetting is a condition that results when molten solder coats a surface and then recedes to leave irregularly shaped mounds of solder that are separated by areas that are covered with a

**FIGURE 52.24** Solder ball causing a short circuit between pins in SOIC.

thin film of solder and with the basis metal not exposed (see Fig. 52.25). Nonwetting is the partial adherence of molten solder to a surface that it has contacted, while the basis metal remains exposed (see Fig. 52.26).

**FIGURE 52.25** Example of dewetting. (IPC)

**FIGURE 52.26** Example of non wetting. (IPC)

Dewetting and nonwetting of solder joints is generally caused by contaminants on either the component leads or on the PCB PTH or pads. A minimum of dewetting is allowed on solder joints assuming that the solder joint meets minimum requirements as defined in Table 52.6 and Sect. 52.4.2 by component package type, and good wetting is evident on the portion of the solder joint that does not display dewetting. Nonwetting is unacceptable since adequate wetting is not achieved and indicates a serious solderability problem on the component or the PCB.

#### 52.6.4 Missing and Insufficient Solder

Missing solder is an obvious unacceptable condition since solder provides electrical continuity and some measure of mechanical attachment of the component to the PCB.

Insufficient solder becomes an unacceptable condition for SMT components when the minimum solder fillet requirements defined in Sec. 52.4.2 are not achieved. Insufficient solder becomes unacceptable for PTH components when the minimum requirements of section 52.6.1 and Table 52.6 are not achieved.

#### 52.6.5 Solder Webbing and Bridging

Solder bridged between electrically noncommon conductors creates a shorting condition and is an unacceptable condition (see Fig. 52.27). Solder webbing is a continuous film of solder that is parallel to, but not necessarily adhering to, a surface that should be free of solder. Solder webbing is also an unacceptable condition (see Fig. 52.28).

**FIGURE 52.27** Solder connection across conductors that should not be joined. (*IPC*)

For components with leads, with the exception of criteria stated in sec. 52.4.2.4, solder cannot come into contact with the component body or end seal. Solder contacting the component body or end seal is generally unacceptable.

#### 52.6.6 Lead Protrusion Problems

Measurement of lead protrusion is defined as the distance from the top of the PCB land to the outermost part of the component lead, which can include any solder projection from the lead.

**FIGURE 52.28** Examples of solder splashes and webbing. (IPC)

Solder projections (icicles) are unacceptable if they violate lead protrusion maximum requirements or electrical clearance, or if they pose a safety hazard; otherwise, solder projections are an acceptable condition on both SMT and PTH components (see Fig. 52.29).

**FIGURE 52.29** Projection violates minimum electrical clearance (1). (IPC)

For single-sided PCBAs, lead or wire protrusion must be visible in the solder for Classes 1 and 2, and must allow a clinch for Class 3. For double-sided and multilayer PCBAs in all classes, the minimum lead protrusion is for the lead end to be visible in the solder. The maximum lead protrusion for Class 1 is that there be no danger of shorts when the PCBA is used in its assembly application. For Class 2, the maximum lead protrusion is 2.5 mm, and for Class 3 the maximum lead protrusion is 1.5 mm (see Fig. 52.30).

**FIGURE 52.30** Lead protrusion violates minimum clearance requirements. Lead protrusion exceeds maximum design height requirements. (IPC)

### 52.6.7 Voids, Pits, Blowholes, and Pinholes

Solder cavities (voids, pits, blowholes, pinholes) are acceptable for Class 1 and process indicators for Classes 2 and 3, provided the lead and land/pad are wetted and solder fillets meet requirements specified in Table 52.6.

### 52.6.8 Disturbed or Fractured Solder Joints

Solder joints may not be disturbed due to movement of the solder connection during solidification. However, a rough, granular, or uneven appearance, provided the wetting coverage criterion in Table 52.1 is met, is acceptable. Solder connections accomplished using many of the lead-free solder alloys and surface preparations will normally exhibit the rough or granular appearance more than eutectic tin-lead. Solder joints that are fractured or cracked are unacceptable for all classes of equipment.

Cutters cannot damage solder joints in which leads have been trimmed after soldering, due to physical shock transmitted through the lead. If lead cutting is required after soldering, the solder joint must be reflowed or visually inspected at  $10\times$  magnification to ensure that the cutting operation did not damage the solder connection. No fractures or cracks are allowed between the lead and solder (see Fig. 52.31).

**FIGURE 52.31** Example of disturbed solder joint on through-hole component joint. Note evidence of fracture between lead and solder fillet. (IPC)

### 52.6.9 Excess Solder

Excess solder conditions that produce a solder fillet that is slightly convex or bulbous and in which the lead is no longer visible are considered defects for unsupported hole lead termination.

The solder should not flow onto the body of SMT components or touch the component body for through-hole components.

FIGURE 52.32 Via hole solder fill requirements. (IPC)

### 52.6.10 Solder Requirements for Vias

Plated-through via holes used only for interfacial connection do not need to be filled with solder. To prevent solder fill, manufacturers usually place temporary or permanent masks over the vias during the soldering process. PTHs or vias without leads when exposed to solder should meet the following acceptability requirements:

- The target condition is to have the holes completely filled with solder and the top of the lands showing good wetting.
- The minimum acceptable condition is to have the sides of the PTH wetted with solder.
- Solder that has not wet the sides of the PTH is considered a process indicator and product is not rejected (see Fig. 52.32).

### 52.6.11 Soldering to Terminals

When soldering wires to terminals, the lead outline must be visible and good wetting between the wire and terminal must be evident to be acceptable. The wire insulation gap can be near zero if the insulation has not melted into the solder joint. Slight melting of the insulation is acceptable. If the insulation gap is too large and allows potential shorting of wire to an electrically noncommon conductor, the joint is unacceptable. If the wire insulation is severely burned and the melt by-product intrudes into the solder joint, the joint is unacceptable.

For round post terminals, the contact of wrap must be  $180^\circ$  for Class 3 and  $90^\circ$  for Classes 1 and 2. Most of the other terminal types, such as pierced terminals, require  $90^\circ$  of wire wrap (see Fig. 52.33).

FIGURE 52.33 Minimum requirements for wrap of exposed wire on terminal for acceptable solder joint by class.

For solder cup terminations, the wire should be fully inserted to the bottom of the cup and solder fill must be greater than 75 percent of the milled edge.

## 52.7 PCBA LAMINATE CONDITION, CLEANLINESS, AND MARKING REQUIREMENTS

---

### 52.7.1 Laminate Conditions

Laminate defect conditions may be caused by the laminator, PCB fabricator, or assembly of the PCB. The major laminate conditions seen are measling, crazing, blistering, delamination, weave exposure, and haloing.

**52.7.1.1 Measling and Crazing.** Measling is an internal condition occurring in laminated base material in which the glass fibers are separated from the resin at the weave intersections. This condition manifests itself in the form of white spots or crosses below the surface of the base material and is usually related to thermally induced stress.

Crazing is an internal condition occurring in laminated base material in which the glass fibers are separated from the resin at the weave intersections. This condition manifests itself in the form of connected white spots or crosses below the surface of the base material and is usually related to mechanically induced stress (see Fig. 52.34).

**FIGURE 52.34** Crazing in base laminate. Crazing exceeds 50 percent of the physical space between internal conductors. (IPC)

Measling or crazing that occurs as a result of an inherent weakness in the laminate is a warning of a potentially more serious problem. If measling or crazing occurs in the assembly process, it usually will not propagate further. Measling is considered a defect for Classes 2 and 3 if the measle condition extends more than 50 percent of the span between internal conductors. The concern is in regard to the ability of the laminate to maintain dielectric integrity after exposure to high humidity and active chemistries and environments.

By the time that a PCB enters an assembly process, the operator who observes measling or crazing cannot determine the source of the problem. This fact places even more importance

on getting high-quality PCBs from suppliers. This can be done through increased receiving inspection, source inspections, or a comprehensive qualification program and partnership with suppliers. In such a program, process control is exercised in the PCB fabrication, and parametric data from the supplier are sent to the buyer to review for compliance with requirements. This kind of information can also be used to justify a dock-to-stock program if desired.

**52.7.1.2 Blistering and Delamination.** Blistering is a localized swelling and separation between any of the layers of the base material or between the material and the metal cladding. Delamination is a separation between any of the layers of the base material or between the base material and the metal cladding. In contrast to measles that do not propagate, blisters and delamination conditions can increase in size with use.

Blistering and delamination cannot exceed 25 percent of the distance between PTHs or subsurface conductors (see Fig. 52.35).

**FIGURE 52.35** Example of blister in base material. (IPC)

**52.7.1.3 Weave Exposure.** Weave exposure is a surface condition of base material in which the unbroken fibers of woven glass cloth are not completely covered by resin. Weave exposure is acceptable if it does not reduce dielectric spacing below the minimum electrical clearance.

**52.7.1.4 Haloing and Edge Delamination.** Haloing occurs on or below the surface of the base material, appearing as a light area around holes or other machined areas. This condition is acceptable if the penetration of the haloing or edge delamination does not reduce edge spacing more than 50 percent of that specified in the drawing or other documentation or 2.5 mm maximum.

## 52.7.2 PCBA Cleanliness

Board cleanliness is needed to ensure sufficient removal of contaminants that could affect functionality at present or in the future. Some contaminants can actually promote growth of undesirable substances on the PCBA that can cause shorting or corrosion that would affect the PCBA's electrical functional integrity and dielectric properties over a period of time. These contaminants can be in the form of surface dendrites, internal conductive anodic filaments, and so on.

No visible residue from cleanable or any activated fluxes is allowed. Production operations may not be required to remove cleanable residues if qualification testing is performed that demonstrates no need for cleaning the assembly. No-clean or low-residue flux chemistries may be allowed during the soldering process. However, it is critical that the cleanliness of the elements such as the bare boards and components be specified, controlled, and closely monitored; otherwise, the contaminant build-up can far exceed allowable limits for the end item's functional performance.

For processes utilizing potentially corrosive rosin based fluxes, simple test options to determine cleanliness such as resistance of solvent extract (ROSE) tests can be used. Other more significant tests may be required to determine the residue properties of organic residue fluxes, such as those commonly used during hot air solder leveling (HASL) of boards. The most common of these are ion chromatography tests that can characterize the residuals and their potential hazards to the product.

In the event of test failure, immediate process corrections for the cleaning process or elimination of the source of residues must be accomplished before any additional product is assembled.

Particulate matter such as dirt, lint, dross, lead clippings, and such is not acceptable on PCBAs. Metallic areas or hardware on the PCBAs may not exhibit any crystalline white deposits, colored residues, or rusty appearance.

### 52.7.3 PCBA Marking Acceptability

Marking provides both product identification and traceability. It aids in assembly, in-process control, and field repairs. The methods and materials used in marking must serve the intended purposes and must be readable, durable, and compatible with the manufacturing processes as well as the end use of the product.

Fabrication and assembly engineering drawings should be the controlling documents for the locations and types of markings on PCBAs. Marking on components and fabricated parts should withstand all tests, cleaning, and assembly processes to which the item is subjected and must remain legible. Acceptability of marking is based on whether it is legible. If a marking is legible and cannot be confused with another letter or number, it is acceptable. Components and fabricated parts do not have to be installed so that reference designators are visible after installation. Missing, incomplete, or illegible characters in markings are unacceptable.

## 52.8 PCBA COATINGS

---

It should be noted that not all PCBA designs use conformal coating; however, when used, conformal coating must meet the following acceptability criteria. All PCBAs that utilize top- or bottom-layer etch (trace) runs have a solder mask over them if a solder wave or static solder bath process is used to solder components onto the PCB. Without the solder mask, the solder would bridge between many solder wettable surfaces, causing short circuits.

### 52.8.1 Conformal Coating

Conformal coating is an insulating protective covering that conforms to the configuration of the objects coated when it is applied to a completed PCBA. The purpose of conformal coating is to provide a temporary barrier to environmental exposure of chemicals, humidity, and condensation. It is also a barrier from surface contact of contaminants caused by handling, and can provide physical support for components from shock and vibration. It is not, however, a hermetic seal and is eventually permeable. To be most effective, conformal coatings should

be homogeneous and transparent. Most coatings will contain an ultraviolet (UV) tracer to make inspection easier through the use of a black light. The conformal coating should be properly cured and not exhibit tackiness. Defects associated with conformal coating are as follows:

- Applied where not required
- Not applied where required
- Bridging of conductors due to:
  - Mealing (adhesion)
  - Voids
  - Dewetting
  - Cracks
  - Ripples
  - Orange peel/fisheye
- Inclusions
- Discoloration
- Incompletely cured
- Wicking into connectors or mating surfaces

Conformal coating thickness requirements for five types of coatings are listed in Table 52.7. The thickness is commonly measured on a coupon that has been processed with the assembly.

**TABLE 52.7** Coating Thickness

Type	Material	Thickness
AR	Acrylic Resin	0.03–0.13 mm (0.00118–0.00512 in.)
ER	Epoxy Resin	0.03–0.13 mm (0.00118–0.00512 in.)
UR	Urethane Resin	0.03–0.13 mm (0.00118–0.00512 in.)
SR	Silicone Resin	0.05–0.21 mm (0.00197–0.00827 in.)
XY	Paraxylyene Resin	0.01–0.05 mm (0.00039–0.00197 in.)

### 52.8.2 Solder Resist

Solder resist or solder mask is a heat-resistant film coating used to provide mechanical shielding during soldering operations. Solder resist material may be applied as a liquid or a dry film.

Solder resist would be ineffective and considered a defect when there are blisters, scratches, or voids that bridge noncommon circuits, or if the exposure has the potential to allow solder bridges. It could be considered a process indication if blisters or flaking expose bare copper.

## 52.9 SOLDERLESS WRAPPING OF WIRE TO POSTS (WIRE WRAP)

Many applications of wire wrap are still utilized in equipment design, and standards of acceptance should be consistent. Standards of acceptance in this area are shown in IPC-A-610 and in other standards.

### 52.9.1 Wrap Post

The wrap post cannot be bent or twisted before or after the wire is wrapped to the post. The wrap straightness may not exceed approximately one post diameter or thickness from its perpendicular position.

### 52.9.2 Wire Wrap Connection

Table 52.8 shows the number of wire wrap turns of insulated and uninsulated wire used on the wrapped connection. The connection is made using automatic or semiautomatic wire wrapping devices. For this requirement, countable turns are those turns of bare wire or insulated wire in intimate contact with the corners of the terminals starting at the first contact with a terminal corner and ending at the last contact with a terminal corner (see Fig. 52.36).

**TABLE 52.8** Minimum Turns of Bare Wire

Wire Gauge	Turns
30	7
28	7
26	6
24	5
22	5
20	4
18	4

**FIGURE 52.36** Solderless wrap acceptability. (IPC)

Maximum turns of bare and insulated wire are governed by the tooling configuration and space available on the terminal. The minimum countable turns must be as stated in Table 52.8. Electrical clearance between terminals as specified by engineering documentation must be maintained. Wire ends should in no case project to the extent that the required electrical clearance is compromised. The wire end should never project more than 0.12 in. (one wire diameter for Class 3) away from the terminal.

The wrapped conductors should be free of gaps (that is, each wrap should be in contact with the previous wrap), with turns not overlapping. The first and last one-half turns may have a space between turns, provided that the space does not exceed one diameter of the conductor wire. Excluding the first and last one-half-turns, the wrapped conductors may have a single space between them, if the opening does not exceed one-half the nominal diameter of uninsulated wire (see Fig. 52.37).

### 52.9.3 Multiple Wire Wrap Spacing

Typically no more than three wires are wrapped to a single post. When more than one wrap is used on a single post, there should be visible clearance between consecutively wrapped wires. The final wire wrap turn on a post must not extend beyond the working length of the post (see Fig. 52.38). The first insulated turn of a higher-level wire wrap may overlap the last turn of uninsulated wire on a lower-level wrap by a maximum of 1 turn for Class 3.

**FIGURE 52.37** Solderless wrap with more than one space. Acceptability depends upon Class of product. (IPC)

**FIGURE 52.38** Multiple solderless wrap example. (IPC)

## 52.10 PCBA MODIFICATIONS

---

All modifications to PCBAs should be defined and detailed in approved engineering and/or methods documents. Jumper wires are considered components and are defined by engineering documentation for routing, termination, staking, and wire type.

### 52.10.1 Cut Traces

Trace cuts should be at least 0.030 in. wide, with all loose material removed. They should also be sealed with an approved sealant to prevent absorption of moisture.

Care should be taken when removing etch from PCBs to prevent damaging the laminate material.

### 52.10.2 Lifted Pins

Lifted pins should be cut short enough to prevent the possibility of being shorted to the pad from which they were lifted should they be pushed back down. If the component hole from which the pad was lifted does not contain a jumper wire, it should be filled with solder.

### 52.10.3 Jumper Wires

Jumper wires may be used on all classes of equipment electronic assemblies and in thick-film hybrid technology. The wire may be terminated in PTHs, on terminal standoffs, on circuit lands, or on component leads. It should be noted for Class 3 equipment that a wire cannot be placed into the same PTH with a component lead.

Recommended jumper wire is solid, insulated, plated copper wire. It should be the smallest wire diameter that can reliably carry the required current, and the insulation should be capable of withstanding soldering temperatures.

Jumper wires should be routed in the shortest x-y route possible (see Fig. 52.39). Wire routing must be documented for each part number. Assemblies having the same part number must be routed in the same pattern.

**FIGURE 52.39** Example of X-Y routing of jumper wires. (IPC)

When jumper wires are used on the primary side (component side) of the PCBA, no wire is to pass over or under any components for Class 2 or 3. The wire may pass over lands, provided the wire can be moved away from the land for component replacement. To prevent damage to the wire from excessive heat, care must be taken to avoid running wires near heatsinks or components that generate high temperatures.

When jumper wires are used on the secondary side of the PCBA, the jumper wire should not pass through component footprints unless the layout of the assembly prohibits routing in other areas. If this condition occurs, it should be considered a process indicator. There is an exception to this is rule for edge connectors on the PCBA. Jumper wires should not pass over test points or vias used as a test point.

Jumper wires should be staked to the base material with an approved adhesive or tape dots or strips intended for this purpose. If adhesives are used, they must be fully cured as part of

the completed PCBA. The wire should be spot-bonded along its route and must not be applied to lands, pads, or components. The interval of staking must be defined in the applicable engineering documentation, but the wire must be staked at all changes in direction of the wire. No jumper wires may be staked to components that are socketed or any moving part. Jumper wires must be staked or taut enough to prevent the wire from rising above the height of adjacent components. No more than two jumper wires may be stacked on a given route.

When a jumper wire is attached to leads on the secondary side of the PCBA or to axial components on the primary side of the PCBA, it must form a full 180 to 360° loop around the component lead. When a jumper wire is soldered to other component package styles, the wire should be lap-soldered to the component lead.

Jumper wires may be installed into a PTH with another component lead for Class 1 and 2 equipment; however, this is unacceptable for Class 3 equipment. Jumper wires may also be installed into via holes (see Fig. 52.40).

**FIGURE 52.40a** Example of jumper wire connected to plated through-holes (IPC).

**FIGURE 52.40b** Example of wire connected to a via hole with a lead installed.

## 53.1 INTRODUCTION

---

This chapter covers why manufacturers inspect printed circuit assemblies, how they have implemented and enhanced visual inspection, what automated inspection systems they are using, and how they have implemented these automated systems. The scope of this chapter includes only inspection of printed circuit assemblies during the assembly process, as typically shown in Fig. 53.1. Thus, it includes inspection of solder paste after the paste printing process step, components after the component placement process step, and solder joints after the solder reflow process step. Not included, however, is incoming inspection of components and the bare printed circuit board (PCB). The focus of this chapter is on production use of inspection, not the collection of measurements during process development in a research and development (R&D) environment.

### 53.1.1 Visual Inspection

Manufacturers of printed circuit assemblies have always visually inspected their boards at various points in the assembly process. There are a variety of reasons for visual inspection of assemblies, including eliminating obvious process defects quickly and meeting military specifications. With the advent and growth of surface-mount technology (SMT), visual inspection of printed circuit assemblies has also grown in importance and prevalence. SMT solder joints must carry a much bigger burden for mechanical or structural reliability than do plated-through-hole (PTH) solder joints. The pin-in-through-hole solder joint carries much of the mechanical burden, helping to keep the component attached to the printed circuit board. However, with SMT solder joints, it is often only the solder that keeps the component attached to the board. In some cases, only visual inspection could judge the mechanical reliability of an SMT solder joint.

As SMT geometries have continued to shrink and solder joints have become denser on printed circuit boards, visual inspection has become more difficult and thus its results have become less consistent and reliable. In addition, components such as pin grid arrays (PGAs)

Side A:

**FIGURE 53.1** Generic manufacturing process for surface-mount technology printed circuit assemblies, including the possible locations within the process for inspection or testing of mechanical or structural attributes and electrical characteristics of an assembly.

or ball grid arrays (BGAs) completely hide their solder joints from view, which makes visual inspection not possible at all for those joints. As Fig. 53.2 indicates, achieving a high assembly process yield is more important as the number of solder joints per assembly increases.

**FIGURE 53.2** Printed circuit board yield decreases dramatically with increases in the number of solder joints per assembly if the defect rate per solder joint remains constant. For instance, at a 40 defects per million opportunities (DPMO) defect rate, the yield drops from 96 percent at 1,000 joints per assembly to 45 percent at 20,000 joints.

### 53.1.2 Automated Inspection

Inspection is an important source of process information without which high yields are difficult to obtain. Consequently, manufacturers have employed the following range of techniques either simply to enhance visual inspection or automate inspection fully:

- Microscopes, mono- and stereoscopic, with magnification from 4× to 10×
- Real-time video images created using simple light, x-rays, thermal imaging, or acoustics
- Fully automated inspection systems using light, laser, or x-ray imaging

The automation of inspection has evolved into systems that resemble the automated test equipment used to make electrical measurements and find electrical defects (faults). These automated inspection systems acquire real-time images, process the images to find and measure features within the image, and make accept/reject decisions based on this image processing. Additionally, they provide data that can be used for long-term statistical process analysis. Thus these automated systems remove the human—and human judgment—from the inspection process altogether.

### 53.2 DEFINITION OF DEFECTS, FAULTS, PROCESS INDICATORS, AND POTENTIAL DEFECTS

---

*Faults, defects, process indicators, and potential defects* are terms that are important when discussing test and inspection, so this section will define and explain them:

- **A fault is a manifestation of a defect** An example is a digital device output pin that does not toggle correctly. For simplicity, think about a two-input OR-gate whose output is stuck high. This is a fault and is a manifestation of a defect. The causing defect can be any one of several, including a defective component, an incorrectly placed component, an open input pin, or an open output pin. The fault class is a subset of the defect class. Electrical tests such as in-circuit test (ICT), boundary-scan, built-in-self-test (BIST), functional test (FT), and system test mainly detect faults.
- **A defect is, at the end of the manufacturing process, an unacceptable deviation from a norm** There may be defects that do not show up as faults. Examples are insufficient solder, a misaligned component, a missing bypass capacitor, and an open power pin. Inspection systems such as automated optical inspection (AOI) and automated x-ray inspection (AXI) detect many of the defects and also some of the same faults as electrical test. The definition includes the phrase “at the end of the manufacturing process,” which is important when compared with “potential defect.”

All defects, which also include the faults, need to be corrected before the product is shipped, if high quality standards are to be followed.

- **A process indicator is, at the end of the manufacturing process, an acceptable deviation from a norm** Good examples are insufficient solder or misaligned components. The insufficient solder may not be so lacking that it requires a repair action. However, if many of these conditions exist, a process improvement action may be required.
- **A potential defect is, in the manufacturing process, a deviation from a norm, that may or may not be a defect at the end of the manufacturing process** This category needs to be understood. An example is a pre-reflow misaligned chip component. This component may or may not self-align in the reflow oven. Another example is an insufficient paste volume that may not end up as a defective solder joint at the end of the manufacturing process.

Test and inspection engineers at the end of the line are mainly interested in finding faults and defects. Process engineers responsible for improving the manufacturing process are mainly interested in potential defects, process indicators, and systematic defects. Systematic defects are typically defects that occur on a larger number of boards and are due to some systematic problem, such as a bent nozzle on a pick-and-place machine, soldering issues with one type of component, or a design for manufacturing (DFM) issue.

It is important to realize that electrical test at the end of the manufacturing line only finds faults. It is therefore important to complement the test strategy with steps that find all defects. Finding all defects is critical if shipping high-quality, reliable products is a priority. Identifying potential defects and process indicators can also help in adjusting the manufacturing process to result in lower defect levels, higher yields, and lower cost. Inspection is therefore a very important complement to electrical test.

### 53.3 REASONS FOR INSPECTION

Manufacturers inspect printed circuit assemblies during production for a variety of reasons. Most of these reasons fall into the following categories:

- Improvement of process defect coverage
- Improvement in ability to meet customer specifications
- Detection of process defects as quickly as possible after they occur
- Ability to decrease process defect rates through statistical process control (SPC)

#### 53.3.1 Process Defect Coverage

The goal of higher defect coverage is to prevent any defective printed circuit assemblies from reaching assembly of the board and making it into the final product, whether final assembly is at the same site or at a separate customer site. Figure 53.3 shows a typical spectrum of SMT process defects. Some of these defects, such as misaligned solder joints and solder balls, can be discovered only by inspection, not by electrical, functional, in-circuit, or boundary-scan test. For instance, marginal solder joints are those that pass electrical tests just after assembly completion, but eventually fail because of inferior mechanical strength. Insufficient solder and components partially misaligned with printed circuit pads are the two most common causes of low mechanical strength.

**FIGURE 53.3** Typical process defect spectrum for surface-mount assemblies. Process defects marked “E” can be detected by electrical tests, those marked “M” can be detected by mechanical or structural inspection or testing, and those marked by “E” and “M” can be detected by either method.

Voids in solder joints, solder balls away from solder joints, and “cold” or dull solder are other examples of defects that can be found only by some kind of inspection.

### 53.3.2 Customer Specifications

Many printed circuit assembly workmanship specifications—including MIL-STD-2000A, IPC/EIA J-STD-001C, and, more recently, IPC-A-610D—require inspection of solder joints to ensure conformance to these specifications. For instance, MIL-STD-2000A prescribes, for all defense and aerospace government contractors, the attributes of solder joints to be inspected and describes the conditions that result in nonconformance. Most commercial customers of contract manufacturers also have very specific solder joint specifications that require some type of inspection of printed circuit assemblies. Although process control is theoretically preferred over 100 percent inspection, practically speaking, a majority of printed circuit production lines include some kind of inspection to ensure conformance to specifications. As the inspection speeds of the automated inspection systems have improved in recent years, this has become even more prevalent. It is likely that this trend will continue in light of the continued usage of finer pitch devices and the dawn of material challenges, such as lead-free implementation.

### 53.3.3 Quick Defect Detection and Correction

Quick detection of process shifts or defects can lower rework costs.

**53.3.3.1 Preventing Defects.** If a particular process step has drifted out of its control limits or specification limits, discovering this fact as soon as possible will prevent more defects from occurring. If the problem is found quickly enough and corrected immediately, perhaps no actual defects will occur.

**53.3.3.2 Lowering Rework Costs.** Defects found earlier in the process are often easier to repair. For instance, if a defect in solder paste deposition is found before a component has been placed in the paste, it is fairly inexpensive to wipe the solder paste off and start over. If this same defect is found after the solder is reflowed, the solder joint itself will have to be touched up, a more difficult and expensive rework step. The same is true for repairing component placement defects before the solder is reflowed, particularly for missing or misaligned components. Additionally, when organic solderability preservative (OSP) boards are being utilized for lead-free soldering, for example, they cannot be reworked as easily. Using process control and defect prevention can prevent a large number of non-reworkable boards in this case.

**53.3.3.3 Making Defect Diagnosis Easier.** Defects found earlier in the assembly process are often more easily diagnosed, shortening the overall repair time. An example is the inspection of solder joints. Inspection of solder joints detects defects specific to the solder joints and quickly determines each defect's exact location and characteristic. Waiting until a later electrical test stage could make diagnosis more difficult because at that point there could be several causes of the defect, such as a defective component and defects in other connections, in addition to the actual defective solder joint.

### 53.3.4 Statistical Process Control

SPC requires reliable data that can be analyzed either in real time or historically. Visual inspection collects defect data, such as the number of solder joint defects per assembly right after the solder reflow process (either reflow or wave soldering). Some manual and automated inspection techniques also take quantitative measurements of key assembly parameters, such as solder paste volume or solder joint fillet height. To the extent that these data are repeatable, manufacturers use defect data or measurements to characterize the amount of process variation from assembly to assembly or from solder joint to solder joint. When the amount of variation starts to drift outside its normal range or outside its control limits, manufacturers can assess the assembly process and monitor or choose to take action until the process is adjusted to eliminate this drift. Historical analysis of the defect or measurement

FIGURE 53.4 Sample charts to display data from automated inspection.

data also helps discover the cause of process variation. Eliminating the sources of process variation reduces the process defect rate, thus creating savings in rework costs and increasing product reliability. As shown in Figure 53.4, various charts to display available data from the automated inspection can be made available for corrective action and process control.

### 53.4 LEAD-FREE IMPACT ON INSPECTION

Other chapters of this book have covered the lead-free process, but this section covers the lead-free process from an inspection point of view. In general, the lead-free process is a less forgiving one because the wetting forces for lead-free alloys are not as strong as for tin-lead, which means that defect levels are likely to increase and the need for inspection for process control and defect containment will increase. The figures illustrate wetting issues of the lead-free process. Figures 53.5 and 53.6 show x-ray close-ups of two gull-wing joints on the same type of quad flat pack (QFP) device.

A key issue for manufacturers is the lead-free alloy melting point of 217°C, higher than the 183°C for lead alloys. The higher melting point will have significant impact on manufacturing processes and potentially on component reliability.

During the transition to a lead-free process, it is important to understand all of the materials in use, as mixing lead-free and traditional tin-lead components will create many issues during the transition to a lead-free process. Ideally, all lead-free components and materials will be utilized, but this is not always possible.

Figure 53.5 is an x-ray image of a tin-lead example. A good heel formation and toe formation can be seen. The side fillets are approximately the same, indicating that the component pins are centered on the pad. Note also that very little solder appears on the pad below the toe in the photo; all solder is around the component pins.

Figure 53.6 is an x-ray image of a lead-free example and reveals a couple of wetting issues. Solder is over the full pad. The pad sizes on both boards (Figs. 53.5 and 53.6) are approximately the same. Also, note that the side fillet to the right is stronger than to the left, indicating that the component is misaligned on the pad. The toe fillet is insignificant. The heel fillet has formed correctly; a void can be seen in one of them. A void is also visible on the same pin further down on the pad.

During the transition to a lead-free process, expect to see many of these types of defects. Defect levels are expected to increase. The following types of defects are typically noticeable during lead-free transitions: opens, bridges, misalignment, tombstones, and voids. Because of the higher reflow temperatures, component defects are also expected to increase. Large variations in defect levels should be expected. For some board types, small increases or no increase will be seen, whereas for others a significant (more than 10 times) increase in DPMO values will be seen. These defect levels will vary from one manufacturing site to another.

Inspection and especially automated inspection will be a significant help in addressing the tighter process window acceptable for a lead-free process. For process control, pre-reflow inspection will provide the biggest benefit. The obvious benefit is that solder paste inspection (SPI) and pre-reflow automated optical inspection (AOI) systems provide early defect and potential defect detection and prevention specifically by identifying the defects that are expected to increase with the use of lead-free solder (opens, bridges, and so on, as previously mentioned in this chapter). An additional benefit—and perhaps the most valuable one—is the insight that the process engineer can gain by evaluating the results from SPI and AOI systems as lead-free materials are adopted. By integrating SPI and AOI systems in the manufacturing process as they move to lead-free materials, and then using the data for process optimization, the manufacturer can eliminate most of the process difficulties that a lead-free process creates. This implementation will in turn allow users to bring lead-free lines up to speed more quickly and efficiently, saving on labor, materials waste, and so on.

After reflow, the main objective is to identify defects so that repair action can take place. For this manual visual inspection, AOI post-reflow, or automated x-ray inspection, can be used. Even with good process control, defect levels are likely to increase, especially for higher-complexity boards. If defect levels are higher, then a good inspection strategy becomes more valuable.

**FIGURE 53.5** An x-ray image of a tin-lead example.

**FIGURE 53.6** An x-ray image of a lead-free example.

## 53.5 MINIATURIZATION AND HIGHER COMPLEXITY

---

Printed circuit board real estate continues to be coveted. Boards are getting smaller and smaller as more and more capabilities are built on them. To keep up with this trend, complex packages and devices and miniature devices are cropping up. Many would argue that a 0402 chip component is small, but “small” becomes subjective when you consider 0201s and 01005s. The 01005 component’s sizes typically range from 0.10 mm (0.004 in.)  $\times$  0.304 mm (0.012 in.) to 0.20 mm (0.008 in.)  $\times$  0.40 mm (0.016 in.), depending on the supplier. Note that the 0201 typical is 0.60 mm (0.0236 in.)  $\times$  0.30 mm (0.0118 in.), thus it’s quite a jump. With devices on this size order, the design considerations are large and the propensity for defects is higher. Inspection must catch the defects, but at these sizes, approaching the eye of a needle, it is not practical to conduct inspections visually, and thus such automated test and inspection become paramount. Automated test and inspection continues to spur the development of camera and algorithm technology to keep up with the throughput, coverage, and size requirements demanded by the industry. Miniaturization in itself is quite a driver for these technologies. Add this to the material changes that are going on with materials changes such as lead-free materials, and the need for automated test and inspection only increases. AOI systems including three-dimensional (3-D) and two-dimensional (2-D) solder paste and pre- and post-reflow component inspection are typically lead-free-ready, as are x-ray test systems, with a few minor programming updates.

The advancement of the miniaturization movement also drives technologies such as multi-chip modules (MCM), system-in-a-package (SIP), and so on. These devices or boards, depending on how one refers to them, have many interconnects among themselves in addition to the requirements that they pose when the entire MCM, SIP, etc., is adhered to a printed circuit board. The number of hidden joints increases, the types of hidden joints increase, and the complexity of the attachment to the SMT board in general increases. All of these are contributors to the ongoing need for increase defect containment and defect coverage that only automated inspection and testing bring.

## 53.6 VISUAL INSPECTION

---

Visual inspection is the visual comparison by a human of some attribute of the printed circuit assembly with specified standards that describe the acceptable range for that attribute. The inspector normally picks up the printed circuit assembly or places it under a microscope and carefully observes particular attributes, such as the condition or bend radius of component leads or the wetting of solder joints to a lead. Visual inspection always involves human judgment in comparing the attribute to its conditions of conformance to standards.

### 53.6.1 General Inspection Issues

As Fig. 53.1 indicates, visual inspection can occur after each of the several printed circuit assembly process steps. Visual inspection often has different purposes, depending on where in the assembly process it occurs. These purposes fall into the following major categories:

- Quick detection of an assembly process step that is not operating within its normal range
- Detection of process defects as specified by the customer or industry or internal standards

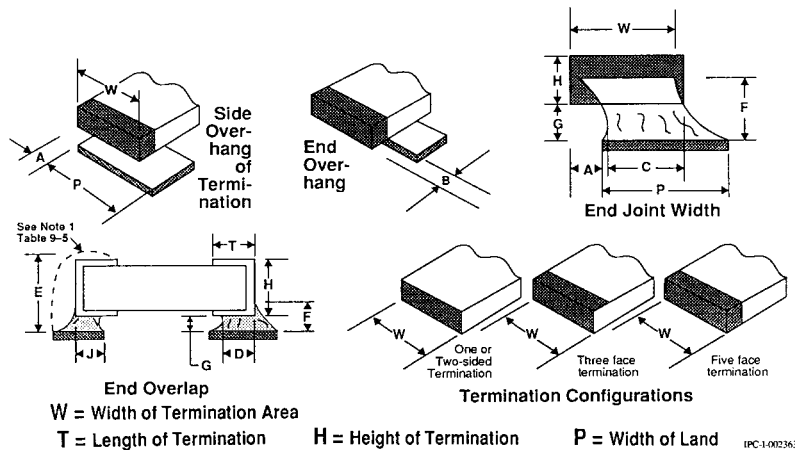

### 53.6.2 Solder Joint Inspection Issues

Visual inspection after the reflow and wave-soldering process steps can also be just a quick scan for obvious defects to detect a process condition outside of control limits. In this case, the operator visually inspects for solder bridges, large solder balls or solder splashes, lifted leads, and a

number of other improper conditions. Often, however, visual inspection after the soldering process steps is aimed at finding solder joints that do not meet specifications.

Visual inspection of solder joints against specification can cover 100 percent of the visual solder joints on an assembly. Inspecting samples of solder joints in conjunction with a documented process control system is also done. Inspecting for this purpose can be a lengthy process, taking as long as a half-hour for assemblies with 4,000 solder joints being measured against military specifications. As a rule of thumb, this kind of visual inspection has a throughput of about 5 joints per sec. compared to automated inspection techniques, which have capabilities of over 100 joints per sec. Thus, inspection of solder joints against specifications normally requires visual inspectors dedicated to this function with no other responsibilities. Visual inspection may still provide a low-cost alternative to automated inspection in some low-cost regions, which is one major factor contributing to its continued usage.

The visual inspector must be very familiar with the specifications of the attributes for each solder joint type. Each solder joint can have as many as eight different criteria for defects such as insufficient solder, misalignment, etc. Each assembly typically has more than six different solder joint types such as BGAs and QFPs, corresponding to different component packages with individual requirements for each. As an example, Fig. 53.7 shows the specification attributes for one component type (rectangular passive chips). Table 53.1 gives the corresponding conformance criteria for each attribute for this component type. More importantly, the visual inspector must be highly trained to make an accurate judgment of conditions on the borderline between good and bad. For instance, accurately determining whether a fillet height is one-quarter of the way up a component side that is only 0.05 mm high to begin with takes a lot of practice. Visual inspectors typically do not use any tools to help make these judgments. Rulers or calipers are very difficult or impossible to use to measure solder joint dimensions or thicknesses. Using reticules in microscopes in conjunction with coordinate-measuring machines is possible, but is usually much too time consuming to be done on a regular basis.

**FIGURE 53.7** Inspection attributes for solder joints of surface-mounted rectangular passive chips.

Visual inspection often occurs at the end of the assembly process or even after all of the electrical tests on the assembly have been completed. It is not possible, however, for invisible or hidden joints. The visual inspector looks for scratches, partial delaminations, solder splashes or solder balls away from solder joints, and any other condition that does not affect assembly performance but does make the assembly look as though it might not be a high-quality product.

**TABLE 53.1** Dimensional Criteria: Rectangular or Square End Components (Dimensions in Millimeters)

Feature	Dim.	Class 1	Class 2	Class 3
Maximum side overhang	A	50% (W) or 50% (P), whichever is less; Note 1	50% (W) or 50% (P), whichever is less; Note 1	25% (W) or 25% (P), whichever is less; Note 1
Maximum end overhang	B	Not permitted	Not permitted	Not permitted
Minimum end joint width	C	50% (W) or 50% (P), whichever is less	50% (W) or 50% (P), whichever is less	75% (W) or 75% (P), whichever is less
Minimum side joint length	D	Note 3	Note 3	Note 3
Maximum fillet height	E	Note 4	Note 4	Note 4
Minimum fillet height	F	Note 3	Note 3	(G) + 25% (H) or (G) + 0.5 mm (0.02 in), whichever is less
Solder fillet thickness	G	Note 3	Note 3	Note 3
Height of termination	H	Note 2	Note 2	Note 2
Minimum end overlap	J	Required	Required	Required
Width of land	P	Note 2	Note 2	Note 2
Width of termination	W	Note 2	Note 2	Note 2

Note 1. Shall not violate minimum electrical clearance.

Note 2. Unspecified parameter or variable in size as determined by design.

Note 3. Properly wetted fillet shall be evident.

Note 4. The maximum fillet may overhang the land or extend onto the top of the end cap metallization; however, the solder shall not extend further onto the component body.

### 53.6.3 Standards for Visual Inspection

Many standards cover printed circuit board assemblies. Most major electronics manufacturers have their own internally developed workmanship standards. Several industry and military standards also exist. However, the joint industry standard IPC-A-610D, "Acceptability of Electronic Assemblies," is the standard most often referenced for criteria defining reliable solder connections. This standard was developed by the Institute for Interconnecting and Packaging Electronic Circuits (IPC) ([www.ipc.org](http://www.ipc.org)).

The standard is a collection of visual quality acceptability requirements for electronic assemblies. It covers criteria for both pin through-hole and surface-mount technology solder connections. It also reflects requirements for three different classes of end products:

- **Class 1, general electronic products** These include consumer products and some computers and computer peripherals.
- **Class 2, dedicated service electronic products** This class includes communications equipment, critical business machines, and instruments where high performance is required and for which uninterrupted service is desirable.
- **Class 3, high-performance electronic products** These products include commercial and military equipment for which continued performance or performance on demand is imperative.

### 53.6.4 Capabilities of Visual Inspection

Visual inspection serves a number of important purposes well, but it also has several important limitations.

**53.6.4.1 Advantages.** Visual inspection can be an accurate and cost-effective method of defect detection for nonsubjective defects, such as larger missing components, larger misoriented or reversed components, or solder bridges. When low volume or lack of technical resources prevents the use of automation or more sophisticated tools, visual inspection is one alternative that finds many of the more subjective defects, such as solder joints with insufficient solder, lifted leads, or poor wetting. Finally, visual inspection can quickly detect when a process step has drifted significantly out of its control limits.

**53.6.4.2 Disadvantages.** Visual inspection also has many limitations, including the following:

- Low coverage of solder joint defect detection repeatability, particularly for fine-pitch parts, which results in high false accepts or defect escapes and high false reject rates
- Low coverage of component defect detection repeatability for smaller components such as 0402, 0201, or 01005 passive components
- Inability to see hidden solder joints in component types such as some connectors, PGAs, BGAs, chip-scale packages (CSPs), SIPs, or multichip modules (MCM)
- Inability to collect quantitative measurements in addition to defect data

**53.6.4.3 Repeatability Limitations.** Several studies have documented the low repeatability rate of visual inspection of solder joints. One such study was conducted by AT&T at its Federal Systems Division.<sup>1</sup> This study showed that even the same inspector inspecting the same assembly twice had a defect call repeatability rate of only about 50 percent. Two different inspectors inspecting the same assembly had a defect call repeatability rate of only about 28 percent. This study did not include any very-fine-pitch SMT solder joints or 0603 passive components, which are more difficult to inspect visually.

To alleviate this severe limitation somewhat, manufacturers have implemented the use of microscopes with a magnification level of 10×. Often, stereoscopic microscopes are used to provide visual inspectors a better three-dimensional view. Not as frequently, manufacturers have implemented light sources and cameras to capture real-time magnified video images of the assembly being inspected. The lighting and high-resolution video images can make it easier for visual inspectors to see the acceptance criteria for which they are searching. These enhancements do improve the repeatability rate of visual inspection. But the requirement for subjective human calls and the tedium of carefully inspecting thousands of connections per hour still results in repeatability rates much lower than desired. Low repeatability means many missed defects that escape to final assembly or to customers, impacting reliability and wasting and possibly damaging rework of good connections.

**53.6.4.4 Hidden Solder Joints.** Several component types used in printed circuit assemblies do not provide visual access to solder joints. These components include packages with bump arrays where the solder joints are distributed in a matrix under the entire component body, such as ball grid arrays and chip-scale packages. For these components, all of the joints except those on the edges of the array are completely hidden from view. Other packages, such as J-leaded components, where the connections are under the component body at the component edges, and 0.5 mm-pitch gull-wing components, where the solder joint heel is only 0.08 mm high and behind the component leads, also make visual inspection more difficult. Some manufacturers have attempted to solve this problem by using a penetrating imaging technique, such as x-ray, acoustics, or thermography, to acquire a live, magnified video image that the visual inspector can look at to make a defect call. However, the images resulting from

these techniques are either less consistent or less well defined than a visual image, still requiring the inspector to make a difficult judgment call. Therefore, a low repeatability rate persists.

**53.6.4.5 High-Complexity Boards.** Many printed circuit boards today are entirely too complex to allow accurate visual inspection. Components as small as 0402, 0201, or even 01005 passive components are simply too small for accurate visual detection of missing parts and particularly misalignment defects. Add to this the fact that many printed circuit boards have hundreds of these component types per board, and the opportunity for the visual inspector to make a mistake becomes enormous. Further obstacles to accurate inspection are “families” of boards, where the basic layout of each board type is the same, but specific board types vary by purposely not mounting specific components. In these cases, a missing component can be completely acceptable even in places where the board layout may provide for a component to be mounted.

**53.6.4.6 No Quantitative Measurements.** Accurate quantitative measurements of dimensions ranging from 0.05 to 0.5 mm are not possible with visual inspection. Quantitative measurements provide much more information about a process step, allowing much tighter process control and providing insight into the causes of process variation, without which process improvement is a hit-or-miss proposition. Some manufacturers have implemented semiautomatic measurement tools to allow operators to take quantitative measurements. Examples include optical-focusing microscopes and semiautomatic laser triangulation equipment. These tools do collect useful quantitative measurements, but are typically limited to sampling. Sampling is required because the tools are very slow. Measurement of solder paste height, volume, and registration with pads is possible because of easy visual access to solder paste depositions as well as their simple rectangular shape.

Automated inspection techniques using automated inspection equipment significantly overcome the repeatability and measurement limitations of visual inspection. It is for this reason that many manufacturers are implementing automated inspection.

## 53.7 AUTOMATED INSPECTION

---

The automation of inspection has evolved into systems that resemble the automated test equipment used to make electrical measurements and find electrical defects (faults).

Automated inspection systems generate images of the item to be inspected (normally solder paste, components, or solder joints), digitally analyze the image to locate and measure key features, and, based on these measurements, automatically decide whether a defect exists or not.

Just like visual inspection, automated inspection systems do not require physical contact with the printed circuit assembly to generate the desired images. Unlike visual inspection, however, automated inspection removes human subjectivity from defect detection, thereby increasing repeatability rates typically by an order of magnitude. Many of the automated inspection systems also provide accurate, repeatable, quantitative measurements that directly correspond to process parameters, thus providing the means for process control and improvement.<sup>2</sup>

### 53.7.1 Measurements by Automated Inspection Systems

Figure 53.8 shows examples of measurements made by automated inspection systems.

**53.7.1.1 Solder Paste Measurements.** Typical solder paste measurements, shown in Fig. 53.8(a), are volume, area of pad covered, height, and misalignment with the pad. These quantitative measurements provide information about the paste viscosity, stencil registration, cleanliness, snap-off, and squeegee speed and pressure that can lead to improvement in the paste printing process.

**FIGURE 53.8** Measurements made by automated inspection systems: (a) Typical solder paste measurements made by automated inspection systems, including the volume of paste deposition, area of the pad covered by paste, height of the paste deposition, and offset of the paste from the pad; (b) typical component placement attributes inspected by automated inspection systems, including missing component, components misaligned along or across the pads, and skewed components; (c) typical solder joint measurements made by automated inspection systems, including volume of solder, toe and heel fillet heights, distance between fillets, void volume, average solder thickness across the solder joint, and offset between the solder joint and pad.

**53.7.1.2 Pre-Reflow Measurements.** Typical pre-reflow component placement measurements, depicted in Fig. 53.8(b), include whether or not the component is missing, misaligned, or skewed. These measurements are usually attribute measurements, just separating good from bad. But quantitative dimensional measurement of the amount of misalignment, just after the placement process step, is also possible. Component placement measurements provide information about the rate of placement accuracy. Optical character recognition (OCR) and optical character verification (OCV) techniques allow for additional levels of verification, including correct part.

**53.7.1.3 Post-Reflow Solder Joint Measurements.** Solder joint measurements, such as fillet heights, average solder thickness across the pad, void volume, and pin-to-pad offsets, as shown in Fig. 53.8(c), provide information about the paste printing process, the component placement process, and the solder reflow process steps. Attribute measurements, such as solder bridges, opens, or insufficient solder, are most common. Quantitative measurements of solder

joints are also possible and provide greater insight into process parameters. For instance, the variation of heel fillet heights and void volume across an assembly provides insight into the oven temperature profile and spatial distribution. The variation of average solder thickness provides insight into squeegee speed and pressure and stencil cleanliness. And the pin-to-pad offsets measure the component placement accuracy.

### 53.7.2 Types of Inspection Systems

Inspection systems normally are dedicated to one type of measurement capability: solder paste, pre-reflow, or post-reflow inspection. For example, systems for solder paste measurements do not normally also make component placement measurements. The cost of combining different measurement capabilities into one system would typically make that system prohibitively expensive. More importantly, to reduce manufacturing costs, manufacturers want to implement linear, sequential production lines where an assembly always flows in one direction and goes through each machine only once per assembly side. So automated inspection systems fall into three major categories:

- Those that make three-dimensional solder paste measurements
- Those that make quantitative pre-reflow two-dimensional solder paste and/or component placement measurements
- Those that make post-reflow solder joint measurements and attribute component measurements

For all three types, the automated inspection system compares the measurements taken against a specified conformance range to accept or reject automatically a solder paste brick, component placement, or solder joint as being within specification.

## 53.8 THREE-DIMENSIONAL AUTOMATED SOLDER PASTE INSPECTION

---

### 53.8.1 Operating Principles

Automated inspection systems designed for 3-D solder paste measurements use structured light sources and cameras or digital light-emitting diode (LED) sensors to generate “three-dimensional images” of solder paste depositions. The structured light is normally some variation of a sheet of light or a laser line or spot. As Fig. 53.9 shows, the structured light sweeps across a solder paste brick, creating discontinuities and other features in the image that are calibrated to actual physical dimensions, such as height and area. In essence, the proportional nature of the deflection and height is turned into usable measurement results.

**53.8.1.1 View Magnification.** To achieve adequate accuracy, only a small portion of the assembly, called a *view*, is imaged at a single time. Magnification increases and digital quantization error decreases as the size of the view decreases. Views normally vary in size from 10 to 25 mm in diameter. So the automated inspection system may use more than 100 views to cover a typical assembly. The system moves the assembly or the image sensor on a positioning stage from view to view. The sum of move time plus image acquisition time normally makes up most of the total inspection time for a particular assembly.

**53.8.1.2 System Throughput.** The test speed for solder paste inspection systems varies anywhere from 2 to 22 cm<sup>2</sup>/sec. The high end of this speed range can be fast enough to keep

**FIGURE 53.9** Schematic of automated inspection system for solder paste measurement. The camera or LED sensor obtains images with discontinuities in the laser line scan; the image-processing software finds these discontinuities, measures them, and calibrates them to real physical dimensions.

up with many automated printed circuit production lines. But for the slower systems, or even for the fastest systems on very-high-volume production lines, manufacturers inspect a specific subset of paste depositions on every assembly coming down the production line.

### 53.8.2 Applications

Automated solder paste inspection systems typically reside in the fastest speed ranges on the system throughput scale and therefore are utilized as process control tools in addition to defect detectors. Manufacturers typically use these systems to monitor the process by tracking the key quantitative solder paste measurements, normally height and volume, against control limits. The systems then alarm any condition where control limits are exceeded or definite drifts are detected, allowing the manufacturer to assess the production line and monitor or choose to take action until appropriate adjustments have been made. (The alarm generated by the system is normally an obvious flashing message on a computer monitor.) Because the paste printing process step causes a large percentage of all production defects, tight production control of this process step using quantitative measurements can significantly lower the process defect rate. In fact, automated solder paste inspection systems have been linked through software to paste printing systems, allowing not only process control, but also closed-loop feedback for semiautomatic adjustment of paste printing parameters based on the paste measurements.

### 53.8.3 Advantages and Disadvantages

Automated 3-D inspection of solder paste depositions has the following major advantages:

- Real-time process control of paste printing to lower defect rates and rework costs
- Quantitative measurements, including volume, to help permanently eliminate the causes of paste defects

- Defect detection where rework is easiest, before component placement and solder reflow
- Process characterization during the lead-free conversion with minimal program tuning

Automated inspection of solder paste depositions has the following limitations:

- It is sometimes too slow to cover all paste depositions on an assembly.
- It does not measure or detect defects in component placement or solder reflow.

## 53.9 PRE-REFLOW AOI

### 53.9.1 Operating Principles

Automated inspection systems designed for 2-D component placement and solder paste quantitative measurements typically use optical techniques consisting of multi-angle light sources and charged-couple device (CCD) cameras to generate images. As Fig. 53.10 indicates, these systems extract specific features, such as edges of the components or solder paste deposits, in the images and then use these features to determine quantitative measurements of component and deposit misalignment or deposit area.

**FIGURE 53.10** Schematic of automated inspection systems for component placement defect detection. The camera sensor obtains images of component positions relative to the printed circuit board. The image processing software extracts features from the image and compares them to present position limits to flag a placement as defective.

Automated optical inspection systems also image only a small portion, or *view*, of the assembly at a time. These systems normally can use somewhat bigger views than the 3-D solder paste systems because the features being extracted often do not require as much magnification as do measurements of solder paste depositions. However, inspection of components, such as 0402, 0201, and 01005 passive components, or very-fine-pitch deposits, can require the same level of magnification and therefore views as small as the 3-D solder paste inspection systems.

In general, pre-reflow AOI systems are typically two to three times faster than 3-D systems and range in inspection speed between 10 and 40cm<sup>2</sup>/sec. The prices of 2-D component and solder paste placement automated inspection systems are typically somewhat less than those of the 3-D solder paste systems with the fastest inspection speed capability.

### 53.9.2 Applications

The majority of pre-reflow AOI systems are placed directly following the pick-and-place process step in the production line. These systems therefore only measure the amount of misalignment of components and are generally fast enough to cover all components on a printed circuit board and keep up with the production line's cycle time. So manufacturers often use these systems to detect all misalignment defects as well as missing components. But the most important purpose of these systems is process control, just as it is for the 3-D solder paste inspection systems. The intent is to discover process drift early enough to prevent defects by tracking the key quantitative misalignment measurements against control limits. The systems then alarm any condition where control limits are exceeded or process drifts are detected, allowing the manufacturer to assess the production line and monitor or choose to take action until appropriate adjustments have been made. Some system suppliers in conjunction with pick-and-place equipment suppliers can develop closed-loop feedback software links allowing semiautomatic adjustment of the pick-and-place equipment.

Pre-reflow AOI systems also have the ability to inspect 2-D solder paste; however, this ability is utilized only to inspect a small percentage of the solder paste deposits combined with the component misalignment measurements. Component misalignment measurements cover the passive components, whereas the solder paste measurements cover deposits for BGA, CSP, or fine-pitch QFP devices. Therefore, these systems are placed within production lines after the pick-and-place systems for passive devices but before the pick-and-place systems for the larger area-array and leaded devices. These systems serve the same purpose as those only meant for component placement measurement, both detecting defects and monitoring measurements within control limits to discover process drift as early as possible.

### 53.9.3 Advantages and Disadvantages

Pre-reflow AOI has the following major advantages:

- Real-time detection of systematic process defects where equipment is out of adjustment
- Detection of defects such as misalignment where rework is easier, before solder reflow
- Low-cost option for reasonable test coverage
- Process characterization during the lead-free conversion with minimal program tuning

Automated inspection of component placement has the following limitations:

- It does not measure or detect defects in solder reflow, and normally does not detect defects in solder printing.
- It does not measure 3-D for solder paste.

## 53.10 POST-REFLOW AUTOMATED INSPECTION

---

Solder joints have much more complex shapes than do solder paste depositions and components, so taking measurements of solder joints normally requires more complex imaging techniques than does measuring solder paste and components. Automated inspection systems for solder joints have used a variety of imaging technologies, including optical and x-ray imaging, thermography, cooling profiles of laser-heated solder joints, and ultrasonic imaging. But three technologies have dominated in these systems:

- Optical imaging using multiple light sources and cameras
- Transmission x-ray imaging
- Cross-sectional x-ray imaging

### 53.10.1 Post-Reflow AOI Systems

**53.10.1.1 Operating Principles.** Post-reflow AOI systems for solder joints are similar to, but more complex than, those for component placement. (Note that these systems also detect component defects such as missing, misaligned, or misoriented components, but their complex design is required for solder joint inspection.) Multicolor, multi-angled light sources are normally required to provide enough information in the images to allow sophisticated image-processing algorithms to detect the required features in the images accurately. If the light source is not multicolored or multi-angled, then many different cameras are usually used instead, each camera mounted at a different angle relative to the board being inspected.

The multiple light sources and cameras create and detect shadows from various angles to detect features of solder joints of all types oriented in different directions on the printed circuit assembly. These optical systems often use higher magnification, particularly for the smallest passive components and fine-pitch components, and therefore capture a smaller portion of the assembly at any one time. The smaller views allow more image pixels per solder joint feature, allowing more accurate image processing and corresponding defect calls. The use of smaller views renders the throughput of these systems slower than that of component placement inspection systems. However, in general these systems are faster than 3-D solder paste measurement systems. Their throughput typically falls in the range of 10 to 40 cm<sup>2</sup>/sec.

The systems' image-processing software uses sophisticated algorithms to extract specific features of solder joints, such as edges and areas of the solder joint in a specific range of angles relative to the board. Analysis of these extracted features then determines whether a defect exists or not. Defects detected include absence of solder, bridges, and grossly insufficient or excessive solder. These systems typically do not make quantitative measurements.

**53.10.1.2 Application.** These post-reflow AOI systems generate only attribute data. For instance, these systems detect the existence of a solder bridge between two joints or the absence or presence of a toe fillet on solder joints. But they do not measure the height of the heel fillet or the amount of solder in the solder joint. These systems typically do not measure how far a component is misaligned from its proper placement, but instead simply determine whether or not the component is misaligned more than a predetermined amount. These attribute data are not as useful for process control, and thus manufacturers use these systems strictly to detect defects. Normally these systems do, however, warn of a condition where the same defect has occurred several times consecutively or within a specific number of assemblies, indicating that some part of the process needs adjustment.

Post-reflow AOI systems cannot inspect hidden solder joints, such as those for ball grid arrays, pin grid arrays, and in some cases J-leaded devices, and can have high false accept or reject rates for some component types, such as fine-pitch components at or below 0.5 mm pitch or small outline transistor (SOT) devices. If tall components are placed on the board very close to smaller components, post-reflow AOI systems can also have difficulty inspecting these smaller components.

**53.10.1.3 Advantages and Disadvantages.** Post-reflow AOI systems of solder joints have the following advantages:

- They eliminate visual inspection by automating solder joint defect detection, thereby also reducing unnecessary rework due to false reject calls.
- They reduce rework analysis time by pinpointing defects to the exact solder joint.
- They afford real-time process control of all three process steps—paste printing, component placement, and solder reflow—to lower defect rates and rework costs.
- They can be used during the lead-free conversion with minimal program tuning.
- They are a low-cost option for reasonable test coverage.

Post-reflow AOI systems have the following limitations:

- Test throughput is not always fast enough to allow inspection of all solder joints within the manufacturing cycle time for the printed circuit assembly.
- A significant learning curve is required to become expert at developing solder joint tests with both low false accept and false reject rates.
- The ability to inspect hidden (or invisible) joints is not possible with post-reflow AOI.

## 53.10.2 Transmission X-Ray Systems

**53.10.2.1 Operating Principles.** Transmission x-ray systems radiate x-rays from a point source perpendicularly through the printed circuit assembly being inspected, as depicted in Fig. 53.11. An x-ray detector picks up a varying amount of x-rays depending on the thickness of metals that the x-rays are penetrating and converts the x-rays to light photons for a camera to create a grayscale image. The x-ray source is filtered so that metals of only a certain density range—lead, tin, gold, and silver—will absorb the x-rays. The copper leads and frames of components sitting on top of solder joints do not absorb the x-rays and are therefore practically invisible to the x-ray detector. Thus, x-ray systems can easily see the entire solder joint, no matter what component material may be on top of the joint blocking its optical or visual access. In other words, x-ray is the only automated inspection method equipped to inspect hidden joints such as those found in a BGA or CSP. The resulting x-ray image will be darker wherever the lead or tin solder or lead-free solder is thicker in the solder joint. The image processing capability of the system then searches for features, such as the heel and toe fillets, the sides of the solder joint, and even voids internal to the joint based on grayscale readings of the solder joint x-ray image. The system then uses predetermined decision rules to compare

**FIGURE 53.11** Schematic of transmission x-ray automated inspection system for solder joint defect detection. The x-ray detector converts a varying amount of x-rays to light, based on how much various parts of the solder joint absorb. The camera converts the light photons to an image, which is then processed to find solder joint features and flag defects accordingly.

the grayscale readings to acceptance criteria to accept or reject a solder joint automatically. For example, the system might compare the relative grayscale reading for the heel fillet region, the center of the solder joint, and the toe fillet region. The acceptance criteria might state that the heel fillet reading should be twice that of the center and that the toe fillet reading should be 50 percent higher than that of the center. If the actual readings do not meet these criteria, then the solder joint is reported as being defective.

The bottom of Fig. 53.11 shows an x-ray image of a gull-wing solder joint that shows the center of the joint as much darker than the heel fillet region. This solder joint is clearly defective, as the heel fillet region should always be darker and have a higher grayscale reading than the center of the joint, where the solder is thinnest for mechanically good solder joints. (The system's image processing capability is able to detect much more subtle changes in grayscales than can the human eye, allowing very accurate relative readings from one solder joint to the next.)

**53.10.2.2 Application.** Transmission x-ray technology works well for single-sided surface-mount assemblies. These automated inspection systems accurately detect solder joint defects such as opens, insufficient solder, excess solder, bridges, misalignment between pin and pad, and voids for most surface-mount solder joint types, including J-leads, gull-wings, passive chips, and small-outline transistors in hidden and nonhidden joints alike. These systems also detect missing components and reversed tantalum capacitors. Based on trends in grayscale reading, these systems also can accurately detect process drifts through real-time process control charting.

For double-sided assemblies, however, the transmission x-ray images of solder joints on the top side will overlap with the images of solder joints on the bottom side. The x-rays are absorbed by any solder in their path through the printed circuit assembly from the source to the detector. These overlapping images make accurate solder joint measurement impossible.

Transmission x-ray imaging also cannot easily distinguish between the top, bottom, and barrel of PTH solder joints or the bottom of BGA solder joints. So transmission x-ray systems cannot be used for accurate measurement of and defect detection in solder joints on double-sided assemblies or for PTH and BGA solder joints.

### 53.10.3 Cross-Sectional X-Ray Systems

**53.10.3.1 Operating Principles.** Cross-sectional x-ray systems radiate x-rays at an acute angle from vertical through the printed circuit assembly being inspected. As Fig. 53.12 indicates, images from all around the particular view being inspected are added together or integrated essentially to create an x-ray focal plane in space. This focal plane creates a cross-sectional image, approximately 0.2 to 0.4 mm thick, right at the focal plane, by blurring everything above and below the focal plane into the background, or *noise*, of the image. By moving the top side of an assembly into the focal plane, cross-sectional images of only the solder joints on the top side are created. By moving the bottom side of an assembly into the focal plane, cross-sectional images of only the solder joints on the bottom side are created. Separate images of top and bottom sides are always created, preventing any image overlap from the two sides.

**53.10.3.2 Application.** Cross-sectional x-ray automated inspection systems work well for all types of printed circuit assemblies, including single-sided and double-sided, surface-mount, through-hole, and mixed-technology assemblies. These systems accurately detect the same solder joint and component defects as do transmission x-ray systems, but, in addition, the cross-sectional x-ray systems accurately detect insufficient solder conditions for BGA and pin-through-hole solder joints.

Some cross-sectional x-ray automated inspection systems go beyond just grayscale readings of specific solder joint features. By carefully calibrating grayscale readings to actual solder thickness, it is possible to generate real-world measurements, in physical units rather than grayscale numbers, of fillet heights, solder and void volume, and average solder thickness for

**FIGURE 53.12** Schematic of cross-sectional x-ray automated inspection system for solder joint measurement. Adding images around a circle from a rotating x-ray beam and detector creates a focal plane that captures just the solder joints of interest and nothing else below or above.

the entire joint. Figure 53.13 shows an example of these calibrated measurements. This figure includes the actual cross-sectional x-ray image of tape automated bonded (TAB) solder joints.

The profile shown at the top of the x-ray image is generated by the system in physical dimensional units by interpreting and calibrating the grayscale readings of pin 193 in the x-ray image.

The table below the x-ray image includes example measurements for both pin 193 and pin 194.

Analysis of these physical thickness measurements of solder joints provides the information required for process characterization and improvement. For instance, variations in average solder thickness or volume for the solder joints across a single assembly or from assembly to assembly provide insight into the quality level of the paste printing process as well as sources of defects.

The image-processing software then finds and measures solder joint features and flags defects accordingly.

#### 53.10.4 Advantages and Disadvantages of X-Ray Inspection

X-ray solder joint inspection systems can reach average inspection speeds of around 50 to 150 joints per second. X-ray solder joint inspection systems also have higher prices, typically about 50 to 100 percent more than the price of the optical solder joint systems with the fastest inspection speed capability.

Good board (pin 6)

Reference designator	Inspection point	Thickness (in 0.001")
U1 pin 193	Pad	0.59
	Heel	1.18
	Center	0.69
	Toe	1.34
U1 pin 194	Pad	0.58
	Heel	1.20
	Center	0.68
	Toe	1.30

**FIGURE 53.13** Cross-sectional x-ray image of TAB solder joints. Image-processing software converts the grayscale readings of the image for pin 193 into the side profile of solder thickness shown above the image. The actual calibrated measurements of average solder thickness across the pad, heel fillet height, center thickness, and toe fillet height processed from the images of pins 193 and 194 are shown in the table below the x-ray image. These measurements indicate that both of these solder joints are good.

Automated x-ray inspection of solder joints has the following major advantages:

- Its defect detection capability is extremely high.
- It eliminates visual inspection by automating solder joint defect detection, thereby also reducing unnecessary rework due to false reject calls.
- It reduces rework analysis time by pinpointing defects to the exact solder joint.

- It affords real-time process control of all three process steps—paste printing, component placement, and solder reflow—to lower defect rates and rework costs.
- It provides quantitative measurements to help permanently eliminate the causes of defects from all three process steps.
- It reduces failures at final assembly and in the field due to defective hidden solder joints and marginal solder joints due to insufficient solder or misalignment or excessive voids.
- During lead-free conversion, it can be used with minimal program tuning.

Automated inspection of solder joints has the following limitations:

- Test throughput is not always fast enough to inspect all solder joints within the manufacturing cycle time for the printed circuit assembly.
- A significant learning curve is required to become expert at developing solder joint tests with both low false accept and false reject rates.

### 53.11 IMPLEMENTATION OF INSPECTION SYSTEMS

---

Successful implementation of automated inspection systems into printed circuit assembly production lines requires a significant investment in training, process analysis, and system integration.

The implementation can be a lengthy process that requires concerted effort by engineers or skilled technicians. Listed here are highlights of what several manufacturers have learned are key aspects of successfully implementing automated inspection systems:

- **Assess requirements carefully** Start by carefully assessing the requirements for automated inspection in the particular production environment into which the system will be integrated. Determine exactly what kinds of defects are most important for the inspection system to detect, which measurements will most help with process improvement, and what benefits will generate the quickest financial return on investment.<sup>3</sup> This assessment must consider the testing and measurement capability that already has been implemented as well as new requirements arising from future printed circuit assembly designs.
- **Evaluate a select set of systems thoroughly** Select a small number of automated inspection systems to evaluate thoroughly and compare them against the system requirements. The evaluation should include a benchmark using printed circuit assemblies from production to determine the system's capabilities to detect accurately the important defect types within the required false reject rate, repeatedly make the required measurements, and not exceed the required test time. Elements of cost of ownership should be well understood, including test development time, maintenance skills and cost, expected system downtime, supplier support infrastructure, and supplier maintenance services and prices.
- **Plan for factory system interfaces** Consider and plan carefully for interfaces to other factory systems. These systems include board-handling equipment, bar code-reading systems, computer-aided design (CAD) systems for automatic download of board layout and component package information, and quality data management systems for SPC and historical quality tracking.
- **Focus on SPC measurements** Start with a focus on SPC measurements instead of defect detection. Until the process variation is reduced, most manufacturers will encounter either a false reject rate or a false accept rate that is higher than desired. Allowing one rate or the other to be too high while focusing on reducing the process variation first avoids time-consuming, unproductive tweaking of acceptance thresholds. Reducing process variation requires correlating measurements to the process parameters causing the variation and defects, and then properly adjusting these process parameters.<sup>4</sup>

- **Define defects carefully** With an understanding of the selected system's capability, carefully define the defects that must be detected for product quality and reliability. Many of the visual inspection criteria used in the past are not appropriate for automated inspection systems because the system takes objective and different measurements.
- **Invest enough resources** Do not underestimate the initial resource investment required to obtain optimum benefit from an automated inspection system. The implementation plan should include dedicated technical support for the first six months of operation and test development. Developing a thorough understanding of the measurement results and correlating the data to process parameters are key to successful use of the system. Implementation should also address the fact that production personnel will have to be convinced of the accuracy of the system's test results before full benefit can be obtained from the system.

## **53.12 DESIGN IMPLICATIONS OF INSPECTION SYSTEMS**

---

Automated inspection systems in general do not require many changes or limitations in the design of printed circuit assemblies. Because these systems use noncontact measurement techniques, fixturing requirements present very few design limitations, for instance. However, the following requirements will facilitate automated inspection if they are considered during printed circuit design.

### **53.12.1 Automated Board Handling Requirements**

- Parallel edges of the assembly or panel must have adequate clearance (typically at least 3 mm), to allow board-handling clamps or belts to grab the assembly.
- Three corners of the assembly or panel must include alignment fiducials (or solder joints in post-reflow configurations).
- Bar code identification of assembly number and serial number must be present at a predefined location on each printed circuit assembly.
- The board must be adequately rigid without a fixture to prevent excessive board vibration during movement.

Panels with prerouted breakaway boards or bare boards less than 30 mil thick present the biggest challenge: Component, heat sink, or daughter-board height above or below the bare board must not exceed the height clearance of the targeted automated inspection system.

### **53.12.2 Test Development Ease of Use Requirements**

- There should be as few suppliers as possible (ideally one) for each component type. Variation in lead and component package dimensions from supplier to supplier for the same component forces longer and more difficult development of inspection programs for each printed circuit assembly type.
- Pad shapes and sizes must be uniform, particularly for each component package type. Variation in pad size and shape within a component package type forces longer and more difficult development of inspection programs for each printed circuit assembly type.
- Solder joints for optical and structured light automated inspection systems must be clearly visible.

- For transmission x-ray automated inspection systems, no components should be opposite or under dense structures, such as transformers, large capacitors, or thick steel heat sinks.
- There should be no silk-screened outlines around components. Although such outlines may be useful for visual inspection, they just confuse automated optical inspection systems.

## DESIGN FOR TESTING

---

**Kenneth P. Parker**

*Agilent Technologies, Loveland, Colorado*

---

### 54.1 INTRODUCTION

---

In the latter part of the 1970s, it became clear that forces of technology were causing an evolution in board complexity that was quickly outstripping testing technology. It is quite possible to design boards that essentially cannot be tested in an economical sense. This will doom projects and products to failure.

The author has personal experience here, having consulted in the mid-1970s with a Silicon Valley start-up company that had created one of the first dedicated word processors. This product was based on a customized processor that had been designed and sent into production with absolutely no thought about how it was to be produced in volume. There was no test strategy. When it was determined that volume production was impossible, the design team was brought onto the production floor in a last-ditch effort to produce shippable units. High-priced design engineers could only produce one or two units a day, and they were no longer available for developing the next product. The company soon failed, a casualty of untestable design. The marketplace never got a chance to determine whether their product idea was a winner, because their design process was a loser!

In the 1970s and into the 1980s, it was very common for a design department to be physically and organizationally removed from the test department. The nature of product life cycles dictates that by the time a test department starts ramping up test program development for a board, the design team is off on the next project and finds it distracting to go back and help the test engineers with testing problems. Thus, in those years, the designers were unknowing contributors to difficult test problems. But what is different today, with the emphasis on outsourcing and contract manufacturing? Now, a design may be outsourced to one contractor, board layout to a second, test development to a third, and actual production to a fourth, all scattered about the globe.

Even if boards can be tested, the question bears asking, "Is there something a designer can do that will make testing easier, cheaper, more thorough, etc.?" The answer is that there is a great deal a designer can do (or fail to do) that will affect the testability of a board. The technology that addresses this problem is called design for testability (DFT).

By the middle of the 1980s, testing became a bottleneck in product development. The situation ultimately became severe enough that attention was paid to the effects that design has on testing. A landmark survey on DFT technology by Williams and Parker<sup>1</sup> brought DFT out of common lore and into the design lexicon of the electronics industry. That paper is still remarkably current\* nearly 20 years later. In it were coined the terms *ad hoc testability* and

---

\* This survey does not cover the topic of standards-based testing (Sec. 56.5), because the testability standardization work promulgated by the IEEE began in the later 1980s.

*structured testability.* Before jumping into the DFT discussion, however, some definitions are crucial.

## 54.2 DEFINITIONS

---

These definitions are fully discussed in Chap. 55 and are repeated here in an abbreviated form for reference.

1. A *defect* is an unacceptable deviation from a norm.
2. A *fault* is a physical manifestation of a defect.
3. A *fault syndrome* is a collection of measured deviations from an expected good outcome.
4. A fault is *detected* when an operation with an expected outcome is conducted and this outcome is not observed.
5. A fault is *isolated* when an operation with an expected good outcome and one or more failing syndromes is conducted and the outcome matches a member of the set of failing syndromes.
6. A *test* is one or more experiments that are specifically constructed to detect (and possibly isolate) failures.
  - A *detection test* has an expected good outcome.
  - An *isolation test* has an enumeration of possible fault syndromes indexed to specific failures.

The technology of testing, as covered in Chap. 55, is highly influenced either positively or negatively by the design of boards being tested. If the preceding definitions are not clear, then the discussion of loaded board testing should be digested first.

## 54.3 AD HOC DESIGN FOR TESTABILITY

---

Ad hoc design for testability consists of a set of simple design rules of the form “Do this, don’t do that,” where “this” and “that” are often not motivated with reasons. For example, when designing a board with ICs that have preset or clear pins, a rule might read as follows:

“Tie unused preset and clear pins off through a 100- $\Omega$  resistor to a power rail; do not tie them directly.”

The first-level reason for this is that a test engineer might want to access the preset/clear functions during testing, even though the designer did not use these functions. If these pins are tied through a resistor, a test engineer may still be able to manipulate them by applying a tester resource to them that can drive a signal in spite of the resistor. If these pins are tied directly to a power rail, the test engineer will never have that option. What might the difference be? Well, in a deeply sequential circuit, controlling the preset and clear functions might make the difference between a test that runs in milliseconds versus hours. Clearly, hours of testing (per board) are impractical, so the bottom line may be the difference between a thorough test and one that lacks significant fault coverage, affecting quality.

The real reason for the various ad hoc DFT rules is that, to effectively and economically test a circuit, one must be able to control and observe the circuit’s behavior. Most rules are related to controllability and/or observability of the circuit. The rule just cited is a controllability rule. Observability rules typically suggest ways one might be able to monitor signals that are deeply embedded in combinatorial circuitry, or that are activated only rarely by complex sequential events.

Ad hoc DFT is essentially the only way many products can have improved testability when those products are constructed with off-the-shelf merchant parts. Large, vertically integrated companies have the advantage of being able to customize testability into the heart of a design, including the very ICs themselves. Application-specific ICs (ASICs) allow more of this as well.

### 54.3.1 Physical Access

Testing is performed once the board to be tested is connected by some adaptor mechanism to the test system. This may be accomplished via the edge connector(s) of the board, where the tester is given the same access that the board gets in its end application. But far more common is “bed-of-nails” in-circuit test access, where the board to be tested is physically mounted on a platen and depressed into a field of precisely positioned spring-loaded probes (“nails”) that contact hundreds or perhaps thousands of internal board nodes. (See Sec. 55.4.2 in Chap. 55.) This can be a challenging mechanical proposition to implement, particularly when high-volume, reliable manufacturing is the goal.

Board designers must consider physical attributes of their boards early in the design process. They have a size target and then often find that there are density issues that may require fine-line geometries and two-sided component mounting to solve. The fact that in-circuit bed-of-nails access may be needed for testing should also be considered very early. See Ref. 2 for an excellent discussion of how test target pads need to be provided, and how artifacts of the board layout (particularly vias) may be used to satisfy some of these needs. However, due to the density revolution, full nodal access, which has been the holy grail of in-circuit testing, is often impractical. This leads to the question of what access is most important when full access is impossible. The answer to this question comes from the domain of circuit design.

### 54.3.2 Logical Access

Sometimes it is impractical to gain physical access to all nodes of a circuit. For example, Fig. 54.1(a) shows an IC containing a large amount of complex logic, much of it deeply buried and effectively inaccessible from the I/O pins. Figure 54.1(b) shows the same IC with two additional gates added. The first is an exclusive OR gate that collects three buried signals,

**FIGURE 54.1** (a) An integrated circuit with deeply buried logic. (b) Same IC with controllability and observability logic added.

adds them together,\* and brings the result to a spare I/O pin. This makes the states of those three signals much more observable. The second gate is an OR gate that allows us to insert a 1 from a spare input pin<sup>†</sup> into a deeply buried portion of the circuit. The assumption here is that the modified signal rarely reaches the 1 state in normal operation, so this extra controllability enhances our ability to manipulate the circuit for test purposes. Adding these extra gates can make it much easier to control and observe the performance of the IC. However, the downside is that we consumed a small amount of silicon area for the two gates, and, perhaps more importantly, we utilized two additional I/O pins. For many ICs, the extra cost of the pins could be a negative factor.

The choice of the optimal places to insert controllability and observability is not always clear, but rather is a trade-off of extra circuitry and pins vs. the difficulties that may be experienced in creating tests. There may be additional concerns as well with respect to circuit performance. For example, adding the controlling OR gate in Fig. 54.1 could add some signal propagation delay into the affected pathway, with detrimental results on system performance. When ad hoc circuit modifications are made for the sake of testability, it is likely that “seat-of-the-pants” decisions will be made rather than critical analysis. One person’s decisions might be remarkably different than another’s, with resulting great variability in testability improvements.

## 54.4 STRUCTURED DESIGN FOR TESTABILITY

---

Structured DFT was born inside companies that had vertical control over their designs, from custom ICs through systems. They also were well aware of their testing costs and realized that initial design decisions had a large impact on these downstream costs.

These companies studied the controllability and observability problems and instituted design rules into their design processes that, when followed, would guarantee that a circuit was testable. In the test department, where they also had complete control, they could utilize these added features with customized test development processes, gaining greatly enhanced levels of automation.

One of the earliest and most prominent structured DFT schemes was IBM’s Level Sensitive Scan Design (LSSD), which was developed in the 1970s.<sup>1</sup> It is the precursor to what is called full internal scan technology now. In (greatly simplified) summary, LSSD design discipline requires every memory element (flip-flop or latch) to be constructed such that it obeys a testability protocol. This protocol allows two modes of operation: first, the normal operation of being a memory element in a design; and second, an operation for testing purposes, in which all memory elements can be connected into a serial shift register that can be loaded and unloaded by serial shifting. This makes every memory element a control point and an observation point within a circuit. No other memory elements are allowed in the design, e.g., no asynchronous feedback is allowed. This guarantees that circuitry between any control/observation point is combinatorial, not sequential (Fig. 54.2).

As might be imagined, these rules were looked upon by designers as restrictions of their creativity. Ed Eichelberger of IBM, a major proponent of LSSD, happens to stand about 5.5 feet tall. When asked in 1977 how designers received the LSSD rules, he quipped that, at the start, he was over 6 feet tall. Structured testability is not easy to implement. It requires commitment from the whole organization, starting with management.

The next piece of the puzzle was IBM’s test generation software, which was able to automatically construct complete tests for combinatorial circuits (known as the D-algorithm and

---

\* The addition is modulo-2 yielding a single bit. Any single-bit error delivered to the three inputs of the exclusive OR will cause the output to change from its expected state.

<sup>†</sup> This spare input pin should be held to a 0 value when the IC is performing its normal function. A pull-down resistor to ground could assure this, whereas during test, a tester signal could assert a 1 value when needed for testing.

**FIGURE 54.2** Circuitry made up of gates and flip-flops, redrawn to show that it can be represented as a bank of memory elements and a combinatorial circuit.

its derivatives). These tests could be shifted into the circuit and applied, and the results shifted out. This takes a lot of bookkeeping, but computers are good at that.

By using the LSSD discipline, IBM could verify that its designs would be completely testable, and those tests could be created by a computer program. Other companies such as Sperry Univac, Amdahl, Hitachi, etc., had similar proprietary structured approaches. Most smaller, nonintegrated companies were not able to participate in structured DFT—that is, until nonproprietary industry standards came into play.

## 54.5 STANDARDS-BASED TESTING

In the closing years of the 1980s, it became apparent that some sort of structured testability technology had to become accessible to the electronics industry at large. A small group of

European companies led by Philips formed the Joint European Test Action Group (JETAG) and began work on a testability standard. The effort quickly attracted the notice of North American companies, giving rise to the JTAG standard. As the proposal took shape, it was turned over to the IEEE, which ultimately produced IEEE Standard 1149.1-1990, Standard Test Access Port and Boundary-Scan Architecture,<sup>3</sup> in 1990.\* Soon after 1149.1 came into being, a companion effort created IEEE Std 1149.4-1999, Standard for a Mixed-Signal Test Bus.<sup>4</sup> A complete coverage of these standards is beyond the scope of this chapter (see Ref. 5), so a brief summary is given here for an overview.

### 54.5.1 IEEE 1149.1, Boundary-Scan for Digital Circuits

The IEEE 1149.1 standard is a design discipline for digital ICs. It is a set of rules impressed primarily on the I/O structures of a device that allow two modes of operation, normal mode and test mode. In normal mode, the device performs its intended function. In test mode, the device obeys a protocol that has mandatory, optional, and customizable elements. The mandatory elements must exist, with the others being left as design options. The principle mandatory element of interest is a test mode dedicated to external test or EXTEST. When an 1149.1-compliant device is in EXTEST mode, its I/O pins are divorced from their normal operation and all internal functions of the device. Instead, the inputs become observation resources and the outputs become control resources<sup>†</sup> for test purposes. These resources are under control of the 1149.1 serial scan protocol. One can think of the I/O pins of the device being connected to shift register cells; states can be shifted in that will finally appear on all output pins (control) and the states of all input pins can be captured and shifted out (observe). This gives 1149.1-cognizant software a powerful tool for controlling and/or observing board-level node states. Figure 54.3 shows a simplified overview of the architecture.

Boundary register cells interposed between the IC pins and the internal logic surround the normal content of the IC called the mission logic. A small state machine called the test access port (TAP) is used to control the test functions. Four mandatory test pins (test clock [TCK], test mode select [TMS], test data in [TDI], and test data out [TDO])<sup>‡</sup> give standardized access to the test functions. All 1149.1 devices have a 1-bit BYPASS register used to bypass the (much longer) boundary register if it is not needed in a given testing activity. Figure 54.3 also shows an optional IDCODE register that can be shifted out to uniquely identify the IC, its manufacturer, and its revision.

It is intended that collections of ICs (called chains, as shown in Fig. 54.4) with 1149.1 be connected TDO-to-TDI so that they may form a long, shiftable register structure. The primary use for the 1149.1 EXTEST capability is to conduct board-level tests for shorts and opens. This is an example of how resources included in an IC design may be used to help with the testing problem at other levels in the manufacturing process.

Briefly, interconnections between ICs are tested as follows. Consider the circuitry in Fig. 54.5. Some circuit nodes (also known as *nets* or *traces*) are accessible with a bed of nails and some are not. (To avoid clutter, the TCK and TMS signals are not shown.) Boundary scan can be used to test all the nodes; those with nails can be tested by coordinating nails with boundary scan resources and those without nails are tested solely with boundary scan.

\* An IEEE standard has as a suffix the year of its creation or last update. A standard must be updated and/or reaffirmed every 5 years. Up to two supplements to a standard may be issued within the 5-year cycle. Users of a standard should keep up to date with it.

<sup>†</sup> Bidirectional signal pins can both observe and control the nodes to which they are connected.

<sup>‡</sup> An optional fifth pin called Test Reset (TRST\*) is an asynchronous active low reset for the 1149.1 circuitry. Because any TAP can be reset by five clock pulses to TCK while TMS is held high, TRST\* is not actually needed for resetting an 1149.1 device. It is often included as a fail-safe measure with a board-level pull-down resistor providing a constant reset to the TAP. Many 1149.1-compliant ICs do not include the TRST\* pin because the extra pin required may be too costly.

FIGURE 54.3 General architecture of an 1149.1-compliant integrated circuit.

As an example of this, boundary scan can be used to supply test patterns to nodes through a serialization process that a human would find laborious, but that is simple for a computer. When a set of patterns has been delivered (to control) and monitored (to observe) by the appropriate boundary register cells, we have uniquely identified each node with a “signature.” A defect such as a short will cause two nodes to have deviant signatures, as shown in Fig. 54.6. Software can correlate observed deviations with the known boundary scan structure of each IC and the board netlist to yield a diagnostic message.

**FIGURE 54.4** A collection (chain) of boundary scan devices can be used to test interconnections between ICs.

**FIGURE 54.5** A set of boundary scan ICs with interconnections. Note that four nodes do not have bed-of-nail access.

The EXTEST capability can also be used during system testing to see if there are any system integration problems such as bad connections in backplanes and cabling. An IC designer may not see much attraction in EXTEST, but the 1149.1 standard offers other test modes that will allow a designer to access internal scan paths or built-in self-test functions. The 1149.1 standard's name has two parts, *Standard Test Access Port* being the first and crucially

**FIGURE 54.6** Interconnect testing drives unique patterns assigned to each node from drivers to receivers. In this case, a short is shown that creates a wire OR result.

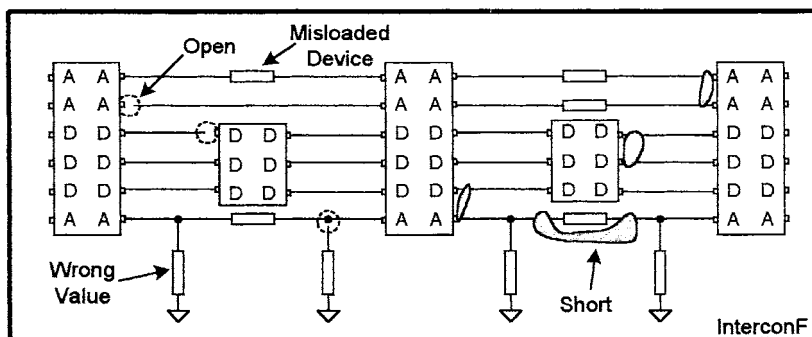

important one. It signifies that the standard anticipates being used as a standardized protocol for accessing any on-chip, board-level, or system-level testability scheme. In support of this, the standard is deliberately extensible, allowing clever designers to implement additional operational modes that can be used to solve unique testing problems.

The 1149.1 standard has proven itself to be quite useful and it has several contributions. First, it allows the creation of software that can automatically write tests for boards where in the past the same level of test effectiveness was nearly impossible to achieve, and then only with weeks or even months of skilled labor. It is not uncommon to see a boundary scan board test prepared in a single day that otherwise might have taken weeks. Second, 1149.1 ICs can “read” their input pins and scan out the result. This allows diagnostic software to pinpoint the location of open solder problems where in the past an IC might have been falsely indicted as faulty. Third, it allows tests to be performed on digital circuits without 100 percent accessibility to board nodes. With the trend toward miniaturization of components making it difficult to provide full nodal access, boundary scan is allowing the elimination of many access points. Of course, not all points may be eliminated, so one must understand which are still necessary. Finally, because many industry segments are affected by the test problem, a standard offers a way for everyone to benefit. One can find a large number of applications and tools available to solve testing problems that would not have been possible without a standard.

### 54.5.2 IEEE 1149.4, Boundary-Scan for Mixed-Signal Circuits

Boundary scan (1149.1) is a digital testability standard. However, there is also a trend in the superintegration of circuitry toward higher mixed-signal digital-analog content in our designs. The IEEE has developed a mixed-signal testability bus with a new standard 1149.4.<sup>4-6</sup>

This standard is constructed as a superset of 1149.1 boundary scan, adding two additional analog test pins to the definition. The goal of the standard is to support opens and shorts testing of mixed-signal boards and to provide the capability of making analog value measurements of discrete analog components such as resistors, inductors, and capacitors without direct nodal accessibility, that is, a full bed of nails. (See Fig. 54.7.) It has been likened to in-circuit testing without a bed of nails, which is again not without caveats. (The elimination of test access points will still have to be done with thoughtful deliberation.)

**FIGURE 54.7** A mixed-signal circuit with some possible defects. IC pins marked A and D are analog and digital, respectively.

A mixed-signal device constructed with 1149.4 has the general architecture shown in Fig. 54.8. It is in many ways identical to an 1149.1 IC, but it has an additional analog test access port (ATAP) that is used to facilitate the control and observability of analog signals at device pins. The ATAP brings into the IC two additional analog signals that are used during testing.

With 1149.4, digital device pins are treated exactly as done with an 1149.1 boundary register. Analog pins have an augmented structure called an analog boundary module (ABM) as part of the boundary register. The ABM allows an analog pin to be tested for simple shorts and opens (this is called 1149.1 interconnect test emulation) as well as allowing the injection and/or observation of analog signals via the ATAP.

An ATE system can utilize the test resources in an 1149.4 IC as shown in Fig. 54.9. This requires the coordination of a digital test sequencer with analog test resources—in this case, a current source and voltmeter. Pathways from these resources and through the 1149.4 IC can be used to make measurements on discrete analog components on a board, even with no bed-of-nails access to the components.

The pathways needed for a measurement are provided by silicon switches in the ABM. Because switches implemented this way have significant nonlinearity and nonnegligible impedances, these must be accounted for in the measurement processes. Figure 54.10 shows how an analog device can be tested with two measurements. First, the tester's current source is connected such that current can flow along AT1 into the IC. There it flows on the AB1 bus inside to the ABM connected to pin 1 of the IC. The current flows through Z and then into pin 2 of the IC. Pin 2's ABM directs the current to ground, completing the current path. In Fig. 54.10(a), the ATE system's voltmeter is connected via the path AT2-AB2 to the ABM on pin 1, where it can observe the voltage at the top of Z. In Fig. 54.10(b), the voltmeter is switched to measure the voltage at pin 2, the bottom of Z. Subtracting the two voltage measurements gives the voltage drop across Z for a known current. Ohm's law gives us the value of Z, which we can check for the right value. This process works even with suboptimal silicon switches

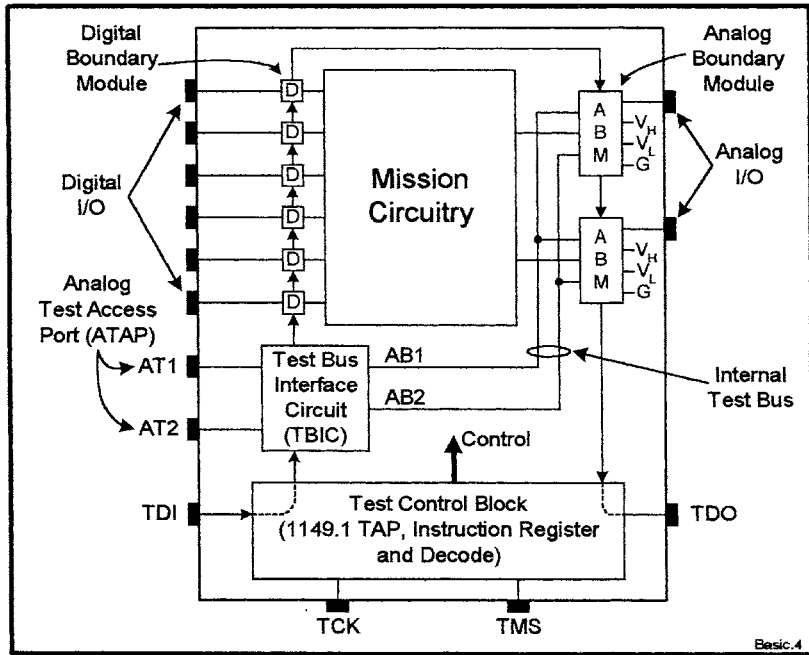

FIGURE 54.8 General architecture of an 1149.4-compliant IC.

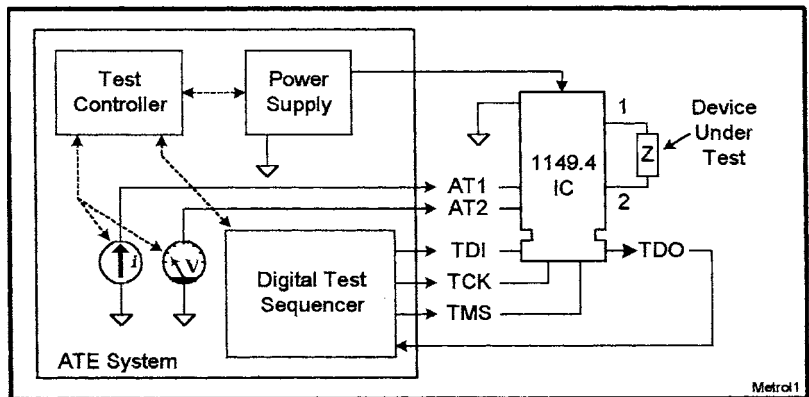

FIGURE 54.9 An ATE system can use 1149.4 resources to gain access to discrete analog components.

because we are using a current source to provide the known current and because the voltmeter pathway consumes a vanishingly small current and thus does not affect the accuracy of the measurement.

In the future, with these and other standards, test engineers may be able to do complex tests on superdense circuitry with far less nodal access than they were afforded in the past. This will be an enabling technology because without it the electronics industry may find it uneconomical to produce superdense designs except in very high-end applications.

**FIGURE 54.10** Two measurements (a) and (b) can be used to measure the voltage across Z for a known current.

# LOADED BOARD TESTING

---

**Kenneth P. Parker**

*Agilent Technologies, Loveland, Colorado*

---

## 55.1 INTRODUCTION

---

Printed circuit boards, like everything else in the electronics industry, have been undergoing rapid technological evolution. This is only natural because everything, from the boards themselves, to the CAD systems that create them, to the components that populate them, to the assembly methodologies used to fabricate them, has been undergoing similar changes. These changes have common themes: greater functional density, better performance, improved reliability, and lower cost.

In the early 1990s, the move toward surface-mount technology (SMT) accelerated to the point that SMT designs became the rule. SMT supplanted, in large part, the familiar 100 mil centered through-hole package technology. The change came slowly, embraced by leading-edge applications that needed the density improvements that came with SMT. Many held back because they did not have a need for higher densities and could not justify the risk of putting new processes in place to manufacture with SMT. The process of perfecting SMT brought to light a surprising fact—it was more efficient once the necessary automation was put in place and perfected. There are now applications that use SMT not because of the density improvements it affords, but rather because of the efficiency it provides. This is confirmed by the fact that many new devices can no longer be obtained in the old-style through-hole packages.

Along with SMT came increases in lead pitch density. First there was 50-mil pitch; soon came 25-mil pitch, then came 15-mil pitch, and so on. Other technologies such as tape automated bonding (TAB), chip-on-board (COB), multichip modules (MCM), and ball grid arrays (BGAs) are gaining acceptance. The industry has for some time been in the midst of a packaging revolution. This revolution has applied to boards as well. The average board, by virtue of high-density interconnect (HDI), now has more layers, finer lines and spaces, buried vias, devices mounted on both sides, and so forth. The net result is that loaded printed circuit boards are becoming incredibly densely packed with highly sophisticated components. We are in fact experiencing a density revolution. Figure 55.1 shows a range of common electronic devices superimposed on a penny to show scale.

Testing has been impacted by all these changes. If perfect components were fed through perfect processes utilizing perfect machines run by perfect employees—testing would not be needed! Unfortunately, nearly perfect components are fed through processes that are subject to drift in many of the hundreds of variables that govern them, using machines that require careful calibration and preventive maintenance, operated by people who tire and err. For these reasons, testing is still an important part of loaded board manufacturing. However, as a result of the miniaturization brought on by the density revolution, our ability to gain the physical and

**FIGURE 55.1** A US penny shows the size of some common PC board components, some older, some recent. The small black devices near Lincoln's bow tie are 04-02 (40 × 20 mils) surface-mount resistors. (Now 02-01 [20 × 10 mils] devices are being used.) Some 100-, 75-, and 50-mil test probes are shown for comparison. Note the lettering on the penny is done with 10-mil lines and the width of the circular part of the 9 is 35 mils, a common probe target size. (Photograph courtesy of Agilent Technologies.)

electrical access needed for testing purposes is increasingly hampered. Because access to a circuit is crucial for testing, accessibility difficulties make testing steadily more difficult to accomplish. On top of this, the electronics industry is expected to provide continued improvements in cost, reliability, and quality. Testing plays a crucial role in these improvements, as will be seen.

## 55.2 THE PROCESS OF TEST

In the earliest years of the electronics industry—indeed, before anyone may have called it an industry—there was no concept of test. A product was put together and shipped, because inherent in the putting together was a basic appreciation for how the product was supposed to look and behave. This crafting quickly gave way to mass production\* of somewhat more complicated items by workers who were not themselves experts in the craft. Of course, today, workers with little or no fathoming of what it is they are producing turn out items of unbelievable complexity. If they had to know everything about the process, it would undoubtedly be too expensive to make the product.

\* Perhaps the reader remembers the TV ads for Zenith televisions from about 25 years ago. They showed individual axial lead components being hand-wired onto lug strips and then soldered. The voice-over mentioned “hand-crafted” quality as if to imply that automated manufacturing (being used by Japanese manufacturers like Sony) was suspect.

It is also important to appreciate that boards are often themselves components of systems. Boards might have a respectable yield from a board test process of, say, 97 percent, which is to say, 3 of 100 still contain defects.\* However, if 20 such boards are used in a system, the probability that the system will turn on is only 54 percent.† Because debugging a system is usually far costlier and more difficult than testing a board, there is much interest in higher post-test yields. This is why yields are being pushed into the 99 percent and higher levels.‡

Test has gone through three stages of evolution during this time. It has been used as a sorting process, then as a repair driver, and finally as a process monitor.

### 55.2.1 Test as a Sorting Process

Test can be used to sort boards into two piles, good and bad. Essentially, such testing provides only one bit of information about a board. This one bit of information provides little clue as to what the problem is or how to repair it. If all we intend to do with a bad board is discard it, then one bit of information may be enough. In some applications, for example making \$2 digital watches by the million, it may be economically impossible to attempt to repair bad units. However, as will be seen soon, discarding bad boards may also lead to discarding of valuable information about the health of our manufacturing process.

### 55.2.2 Test as a Repair Driver

It is very often economically justifiable to repair a bad board, if it can be done quickly and with little skilled analysis needed. This is where modern test systems begin to come into their own. More bits of information are needed per bad board; a diagnostic test is needed that accurately resolves failures into defect reports that can be acted upon to effect repairs. Because a freshly repaired board will need retesting to ensure it is now defect free, one also would like to find as many defects as feasible in each pass across a tester to avoid a glut of work in progress.

### 55.2.3 Test as a Process Monitor

When repairing boards, valuable information about the health of our board manufacturing process is at our fingertips. Indeed, the repair process may have the ultimate defect resolution because faults detected by a tester may still not be perfectly correlated with defects (see Sec. 55.3). If one views test as a process monitor, one can gain valuable insight into what is happening upstream in many of the subprocesses that come together to produce boards. For example, one may see solder opens as a chronic problem. Further examination may show that they are happening in one area of a board more than in any other. That may lead to the examination of the solder application process, which shows that a solder screen squeegee has an uneven amount of solder paste on it. The root cause of this uneven distribution of paste can then be sought and corrected.

---

\* It is important to differentiate test yield from defect coverage of a test. The yield of the manufacturing process before test might be (say) 50 percent, and the yield after test may be 97 percent. This may be accomplished with a test that detects (covers) 90 percent of the important defects.

† From basic probability theory,  $(0.97)^{20} = 0.54$  is the chance that 20 independently manufactured boards with a probability of 0.97 of being fault free will all be fault free.

‡ Measuring yields in percentages is telling. In the IC industry, yields are measured in parts per million. One ppm corresponds to 99.9999 percent, and 250 ppm, a good IC yield, equals 99.975 percent yield. Will the board industry ever get into these ranges? Will it make sense to try?

It is quite important for the tester to do a good job of resolving faults into defects. Using an example of solder opens on digital devices, digital in-circuit test (detailed in Sec. 55.5.2) alone may indict devices as failing when it is really more of an open solder problem. The repair technician may notice this. However, it may well be overlooked because replacing the device “fixes” the problem. This pollutes the information about our process, causing one to call the IC vendor with complaints when one should be examining the solder process. If tests are focused more closely on defects than on faults, then one may be able to better trust tester-derived process information. This requires test engineers to be students of their manufacturing process and available test technologies so that test techniques are kept in balance with the defects that are most important.

## 55.3 DEFINITIONS

---

*Testing* is a word often used in a vacuum. What are tests actually looking for? The answer to this question has a huge impact on how to go about testing effectively. It makes little sense to test meticulously for problems with low likelihood of occurring, just as it makes little sense to inadequately test for likely problems. However, many of the terms used in the testing industry are overloaded such that surprisingly little agreement on their definitions may be found. Worse, this confusion is often not realized, which complicates communications between process people, test people, and equipment vendors.

### 55.3.1 Defects, Faults, and Tests

**55.3.1.1 Defects.** A *defect* is an unacceptable deviation from a norm. As an example, a bond wire could be missing in an IC. This defect may in turn be due to a problem (the “root cause”) in a wire-bonding machine, such as it misfeeding wire. Other deviations may not be considered defects, but rather acceptable variations. For example, the plastic used to encapsulate a component may have significant variations in color that are still considered acceptable.

Defects require remedial action of some sort. Most often, defects lead to a repair operation that removes the defect and restores the product to acceptable status. In some cases, a defect may not be economically repairable and thus causes scrap. It is also possible that a defect will be overlooked and thus be delivered within a product to an end customer. In some cases, such as the manufacture of \$2 wristwatches, some amount of defective product may be deemed acceptable. However, for many products, defects perceived by end customers can have grave economic consequences and are strenuously avoided.

**55.3.1.2 Faults.** A *fault* is a physical manifestation of a defect. (The word *fault* is often used synonymously with *failure*.) Thus a fault reveals the presence of a defect. A single defect may cause several faults (i.e., have several different manifestations), and a single fault could be the manifestation of several different defects.

A defect shows up as a fault. For example, the aforementioned missing bond wire on an input to a logic gate may cause it to see a permanent logic 1 rather than a time-varying signal. Several other defects can produce this same fault behavior. For example, missing solder between the input pin and the board, an electrostatically damaged input buffer within the IC, or a broken printed circuit trace between the upstream driver and the input will all exhibit the same faulty behavior. Similarly, one defect may cause several fault manifestations. For example, an open solder joint on an input pin (particularly a reset input) may cause an IC to show incorrect results, and these incorrect results vary in time.

An observed fault is not always a reliable pointer to a defect. For example, if an IC loaded onto a board has defective solder on one input pin causing an open circuit, this may appear to the IC to be a permanent, stuck-at-1 fault on that input. This faulty behavior may not be readily

apparent because the effect of the erroneous logic 1 must propagate through the internal workings of the IC before its effects (improper output behavior) are seen.\* When this faulty output behavior is finally observed, it can be a highly challenging task to relate this observed behavior to the input stuck-at fault caused by the defective solder. This is illustrated in Fig. 55.2.

**FIGURE 55.2** A defective solder joint on an input pin to IC1 causes a fault on an output of IC2. Note that IC1, R3, and IC2 are suspect, as well as six solder joints, two IC input buffers, two IC output buffers, and four IC bond wires.

**55.3.1.3 Fault Syndromes.** A *fault syndrome* is a collection of measured deviations from an expected good outcome. For example, a digital device may produce an incorrect response on several of its outputs when its inputs are stimulated in a certain sequence. The incorrect pins, their states at the point where they were incorrect, and the point in time where each failure was noted form a fault syndrome.

**55.3.1.4 Fault Detection.** A fault is *detected* when an operation with an expected outcome is conducted and this outcome is not observed. For example, when you turn on the power to a personal computer, you expect to see it boot up. If it doesn't, then you have detected a failure of some kind. There could be a plethora of reasons for this result, but you have little information to act upon. In other words, the underlying defect may not be easily resolvable.

**55.3.1.5 Fault Isolation.** A fault is *isolated* when an operation with an expected good outcome and one or more failing syndromes is conducted and the outcome belongs to the set of failing syndromes. For example, as your personal computer boots up, it may do a series of self-test operations. If any of these fail, a diagnostic message may appear on the screen that specifically identifies a failure. Again, the underlying defect may not be easily resolvable, but there is more information to act upon than you had when the fault was simply detected.

**55.3.1.6 Tests.** A *test* is one or more experiments that are specifically constructed to detect (and possibly isolate) failures. A *detection test* has an expected good outcome. An *isolation test* has an enumeration of possible fault syndromes indexed to specific failures. Thus, when a test fails, it provides us with information: a single bit of detection information, or a fault syndrome that may match an enumerated outcome, pointing to a fault.

A well-constructed detection test will detect a large number of potential failures. A well-constructed isolation test will accurately resolve a failure from a large list of potential failures. Note that an isolation test may encounter a failure that it was not constructed to isolate. If it fails (that is, if it detects the fault), it may not produce a syndrome that matches one from its

\* See Sec. 55.6 for a discussion of how a new testing methodology may pinpoint a defect that conventional methodologies have difficulty isolating.

list, or it may produce a match that is erroneous. In either case, it has been reduced to a detection test.

Remember that an isolation test may point to a fault, but the fault may not be a good indicator of the actual defect that is present. For this reason, it is important to construct tests that target expected faults and that accurately resolve underlying defects. When defects are resolved correctly, it is then much easier to find and correct the causal problems.

There are, in general, three categories of faults being tested: performance faults, manufacturing defects, and specification failures.

### 55.3.2 Performance Faults

A *performance fault* is a fault in the performance of a system that occurs due to a mismatch of important parameters among the system's components. This mismatch is the defect. As a common example, the path delay seen by a digital signal as it passes through several components may exceed the intended design value, causing a malfunction. No single component in the path is defective, but the cumulative contributions of several components cause the performance fault. The repair for this defect is to replace one or more components in the path with new components specifically selected to give the proper delay.

There are several problems with testing for performance faults. First, the test developer must know about the circuit design in great detail. Second, it is difficult to set up a test that can resolve faults into specific defects (for example, the mismatch of parameters in several components). Third, it is difficult to avoid being confused by unanticipated defects that produce behaviors similar to the defects of interest.

Solving these problems implies great knowledge and understanding of a board design. Indeed, in some instances in a carefully designed board, the designer may have specific knowledge of some critical parameter that has to be precisely managed and can alert those responsible for test. However, much of the testing for performance faults carried out in the past was not done with this knowledge, but rather because of a lack of this knowledge. In the past, tools that could help control the key parameters of a design were unavailable, or designers were using components that were incompletely specified, or perhaps they were too trusting of their "seat-of-the-pants" instincts. It was expected that performance testing would give adequate coverage of any problems that might occur. In effect, performance testing was used to validate a design after the fact.

The expectation that performance testing will somehow protect products from the effects of poor design is now obsolete. It amounts to wildly shooting in the dark against a well-hidden, stealthy enemy force of unknown size and distribution. Given the ever increasing complexities of boards, it is simply not reasonable to expect that test engineers could stumble at random across effective tests for all possible design problems, and certainly not within the lifetime of the design. With the increase in effectiveness of design tools, designers should no longer be relying on test for design validation. Testing for performance faults will still be important, but it must be used in its proper role—to verify that critical parameters identified in the design process are properly controlled.

### 55.3.3 Manufacturing Defects

A *manufacturing defect* is a defect resulting from a problem in the manufacturing process. Manufacturing defects tend to be fairly gross in nature. Table 55.1 gives a list of potential manufacturing defects.

Manufacturing defects are the result of the havoc inherent in manufacturing processes. These defects result in faults that may be very easy to detect and to correlate with their root cause(s), but this is a function of the test approach. Some manufacturing defects can still be difficult to detect and resolve, as the example given of a solder open on a device input pin shows (Fig. 55.2).

**TABLE 55.1** Examples of Manufacturing Defects Seen at the Board Level, Sources of the Problems and Causes

Defect	Source(s)	Cause(s)
Shorts between solder pins	Wave/reflow soldering	Too much solder, solder screen defect, pin misregistration, bent pins
Solder open	Solder application, wave/reflow soldering	Too little solder, solder screen defects, tombstoning, bent pins
Missing component	Placement, soldering	Shock, abrasion, too little glue
Wrong component	Placement setup, inventory, handling	Handling error, mismarked packages, operator error, wrong specifications
Misoriented component	Placement setup	Handling error, operator error
Dead component	Placement, soldering	Dead on arrival, handling damage, electrostatic damage

#### 55.3.4 Specification Failures

Specification failures are similar to performance faults. Performance specifications are checked against requirements for the full range of operating conditions expected, such as temperature, humidity, vibration, electronic noise, etc. Specification test is often a regulatory or contractual requirement. One may argue that these specifications are largely unnecessary because, if a circuit design is robust, makes use quality components, is accurately assembled, and is thoroughly tested for manufacturing defects, one does not have to make it perform all of its functions to know that it works. This is the “proof by construction” argument, used by successful manufacturers of kitchen matches and bomb detonators. Full specification test may also be impossible in practical terms because there may be too many combinations of circuit functions versus operating ranges. If only a subset of combinations is to be checked, this begs the question of which subset.

If specification test is required nonetheless, such testing is usually carried out with custom-tailored test equipment that can simulate the range of operational environments of interest. Such testing may be quite time consuming, and the cost of the supporting test equipment may range from trivial to hyperexpensive. At one extreme, a manufacturer of I/O cards for personal computers may simply plug each one into a computer and see if it performs a simple loopback test. At the other extreme, a manufacturer of guidance computers for missiles may require a missile shot on a test range, full telemetry, and support from the Air Force and Navy. The bottom line is that you should seriously question the motivations for and expectations of testing for specification faults.

### 55.4 TESTING APPROACHES

We have seen a spectrum of faults, performance faults, manufacturing defects, and specification faults. Each has evolved a test technology.

#### 55.4.1 Testing Boards for Performance Faults

Performance testers are often known as edge connector functional testers. They connect to the edge connectors of the board under test with mating connectors that are then adapted to the tester resources by a customized fixture called an adapter. In most cases, no other connections are made by the test fixturing to any internal nodes of the circuit. In essence, the board is tested in an environment that resembles its application environment to some degree.

Some performance testers have guided probe capability.<sup>1,2</sup> A guided probe is a manually positioned test probe with a measurement (and sometimes stimulus) capability and supporting software. It is used to temporarily gain access to internal nodes of a circuit, one at a time, where observations of internal circuit behavior during a test can be made and processed by software to provide enhanced fault resolution.

How does this software know what the nodes of a circuit are supposed to be doing during a test? One could enter all these data by hand if one knew the design of a circuit well, but this is impossible for any circuit that consists of more than a handful of gates. The most popular way to get these data is by logic simulation of the circuit.<sup>\*2</sup> Good circuit simulation is often used by designers to prove the circuit behaves the way they expect it to under various input conditions (input vectors) they are interested in. Fault simulation is used to study how a circuit behaves when that circuit is perturbed by a modeled fault. An example of a modeled fault is a stuck-at-0 on a gate output, meaning no matter what the gate's inputs are, the output is 0. The single stuck-at model is the most prevalent fault model in existence. It assumes that only one stuck-at (either 0 or 1) may exist in a circuit at any one time. A fault simulator can be used to predict, for a given modeled fault, how the circuit will behave when stimulated with input (test) vectors. If the modeled fault causes one or more observation points (like circuit output pins) to deviate from normal behavior, we can declare the fault detected by that vector. In the common case of sequential circuits, it is more accurate to say all vectors detected the fault up to and including the one that caused the observable deviation.

Another technology used by some performance testers is the fault dictionary.<sup>2</sup> Fault dictionaries are prepared with fault simulators. A fault dictionary is a three-dimensional data structure of Boolean true/false bits (see Fig. 55.3). The first dimension is an enumeration of all test vectors. The second dimension is a list of modeled faults that are to be simulated. The third dimension is an enumeration of the circuit's output pins. A given bit in the fault dictionary is true if the corresponding output pin fails on the corresponding vector for a given fault.

\* Logic simulation implies the treatment of the digital nature of the circuit, typically omitting any interaction with any analog portions of the circuit. Analog simulators do exist, but are implemented in a very different technology from digital simulators. Mixed-signal simulation is not anywhere near as viable as digital simulation, which presents a problem for test engineers.

**FIGURE 55.3** A fault dictionary. For each “page” corresponding to a modeled fault, bits set to 1 indicate that a given output pin fails for a given vector number. When testing is performed, the failing output(s) and failing vector number are noted and then each page is searched at those coordinates to look up a matching fault. (Note that more than one fault may produce a match.)

For a given vector and fault, the output pins that are expected to fail can be looked up in this dictionary. In a testing scenario, we take a failing test vector and list of failed output pins, and attempt to look up a fault (or faults) that match the failed pin behavior for that vector. Fault dictionaries work well when actual defects that cause a circuit to fail closely match the fault model. When defects occur that vary from the modeled faults, then a dictionary lookup may come up empty (no matching fault), or matches may be found but point to the wrong faults, or so many matches may be found that it is impractical to examine them all to see which (if any) are the actual problem. Dictionary generation is computationally intensive, dictionaries may consume huge amounts of storage space,\* and dictionary lookups may not work. This technology was invented along with small-scale integrated bipolar technologies such as early TTL or ECL. The advent of large-scale integration and CMOS technology<sup>†</sup> has made fault dictionary technology nearly useless in board testing practice.

Performance testers are intended to emulate the environment the board would encounter in its native application. This means the tester itself needs to be carefully customized to supply this environment, or it must be a general-purpose tester with a great degree of flexibility. Flexibility brings cost, so commercial functional testers tend to be among the most expensive. Programming such machines is a complex task, due both to the flexibility of the tester and to the nature of the test requirements. It is difficult at best to get automated support for functional test programming. Typically, such programming takes extreme patience and a high level of skill—again, two more costs. To compound this, any last-minute design changes to the board may cause expensive and time-consuming test modifications or invalidate the tests altogether.

#### 55.4.2 Testing Boards for Manufacturing Defects

Manufacturing defects can be detected by a functional test, but because functional testers are expensive and difficult to program, other techniques have arisen to test for them. These testers have one or more of the following advantages:

1. They are much easier to program, often requiring less than 10 percent of the time of functional test development.
2. Automatic test program generators that analyze the circuit design database do most of the work and relieve the skill required of the programmer.
3. Their programs are much less sensitive to design changes because they take a divide-and-conquer approach; the effects of design changes are localized, requiring that only a portion of the test be reprogrammed.
4. They offer much better defect resolution for many defects because localized portions of the circuit are being analyzed, reducing diagnostic complexity.

The principal technology is the in-circuit tester. This tester utilizes a high degree of nodal access—that is, connection to printed circuit traces—to perform its work. Nodal access is provided by a unique fixture called the bed of nails. (See Fig. 55.4.) This fixture is made up of a platen that supports the board under test. The platen is drilled with holes below each target point for nodal access. In the holes are spring-loaded “nails” that contact the target points on

---

\* For example, say a circuit has 100,000 gates. The number of stuck-at faults to be simulated may easily be 200,000. A set of test vectors for these may easily exceed 500,000. If the circuit has a fairly normal complement of 250 outputs, then a fault dictionary for this example would consume the product of faults times vectors times outputs ( $2.5 \times 10^{13}$  bits, or about 3.125 terabytes, give or take a gigabyte). Fault simulation times lasting months, even on very fast computers, have been reported. Of course, larger circuits will need more!

<sup>†</sup> CMOS VLSI circuits have several defect modes that are inconvenient to model in popular fault simulators, and thus fault models are more likely not to match defects. Two of the offending defect modes are bridging faults (intermetal shorts) and metallization opens that may actually introduce capacitive memory into a circuit. These are difficult to represent with traditional fault-modeling techniques.

**FIGURE 55.4** Cutaway drawing of a board resting on top of an in-circuit vacuum-actuated fixture, the bed of nails. The interface pins (the mechanical interface to the ATE pin electronics) are placed very close to reduce path lengths.

the board. (Special clamshell fixtures allow nail access to both sides of a board.) The platen with board forms the movable top layer of a vacuum chamber. When vacuum is actuated, the platen with board moves down, depressing the nail springs and causing nail contact with board nodes. (Sometimes mechanical actuation is used in place of or to assist vacuum.) The nails are wired (typically with wire-wrap technology) to the stimulus/measurement resources of the tester. These resources contain mechanical relays that allow connection of various tester functions to a given nail.

Once a tester has access to the nodes of a board, it can perform in-circuit (also called in situ) tests. The idea is to test components as if they are standing alone, while they in fact are part of a board circuit. The actual electrical processes used in in-circuit testing are explained in Sec. 55.5.

### 55.4.3 Testing Boards for Specification Faults

There is not much to add here because often, testing for specification defects is very similar to testing for performance faults. However, if for (say) contractual reasons, you are required to show your boards working as specified, you may be required to construct “live” situations where they are performing in a realistic system setting. Again, the extreme case of a missile shot on a test range could be involved. The question must be, is there an easier way?

## 55.5 IN-CIRCUIT TEST TECHNIQUES

---

The problem of in-circuit testing can be subdivided into two main categories, analog in-circuit testing and digital in-circuit testing.

### 55.5.1 Analog In-Circuit Test

Analog in-circuit test addresses testing for shorts in the printed wire circuitry; analog components, passive devices such as resistors, inductors, and capacitors; and simple semiconductor components such as diodes and transistors.\* Analog in-circuit testing is conducted without applying power to a board; that is, it is an unpowered test methodology.

Shorts (unwanted connections between nodes) are tested for first because subsequent testing will profit from the assumption that shorts are not a factor, and subsequent testing may need to apply power to the board. Unpowered shorts testing may be accomplished by applying a small DC voltage<sup>†</sup> to a node while all others are connected to ground. If current flow is observed that is below a computed threshold, then the node cannot be shorted to any of the grounded nodes. If the current flow is above the programmed threshold, there may be an unexpected path to at least one of the grounded nodes. The destination node(s) can be determined by linearly searching the grounded nodes for the current flow (this is slow) or by using half-splitting techniques (which are fast<sup>‡</sup>) to determine the other node(s) the current is flowing to. When the algorithm has finished stimulating all nodes sequentially, it can declare which nodes are shorted and use  $x$ - $y$  position data to show where to look for the problems. Typically, shorts are repaired before continuing with other tests because they may confuse the resolution of defects and may cause physical damage when the power is later turned on.

Unpowered tests on analog components such as resistors, capacitors, inductors, etc., are performed next. Again, low stimulus voltages keep semiconductor junctions turned off. AC voltages are applied and phase-shifted currents are measured in order to deduce the values of reactive components (capacitors, inductors). For a simple measurement of a lone<sup>§</sup> impedance  $R$ , apply a voltage to one terminal of the component (through the bed of nails) and connect a

---

\* Complex analog devices such as analog or mixed-signal ICs are not very amenable to analog in-circuit testing because they require power to be applied to the board. Simple diodes and single transistors can be tested by in-circuit stimulus that essentially examines the characteristics of their semiconductor junctions.

<sup>†</sup> The reason for using a small stimulus voltage (typically less than 0.2 V) is to prevent current flow through semiconductor junctions that may exist between nodes. This voltage will not turn on a junction. These junctions may exist in parasitic form within ICs and are not always documented.

<sup>‡</sup> A half-splitting technique (also called a binary chop) is a fundamental algorithm of computer science. It works by successively considering half of a set of items (grounded nodes that are receiving current in this case) while removing the other half from consideration. It recursively divides sets repeatedly until only one item is left to consider. It has a complexity related to the logarithm (base 2) of the size of the original set of items. By comparison, a linear process has a complexity linearly related to the size of the original set.

<sup>§</sup> This component may not be alone in a physical sense, but because low stimulus voltages are used, other connected devices such as ICs may be electrically quiescent so that the component is electrically alone.

current-measuring device (conceptually, an ammeter with zero impedance to ground) to the other component terminal. The current flow observed due to the known stimulus voltage is related to  $R$  by Ohm's law ( $R = V * I$ ). See Fig. 55.5(b).

**FIGURE 55.5** An analog component on a loaded board can be accessed by two in-circuit probes that connect its terminals with tester resources. There are two approaches: force a known current and measure a voltage (a) and force a known voltage and measure a current (b).

However, some discrete analog components may be connected to one another in ways that prevent simple measurement of the current flowing through the component due to parallel pathways that sidetrack some of the current. In Fig. 55.6, when applying a voltage to one terminal of  $R$ , a current also flows in a parallel path through  $R_a$  and  $R_b$ . The ammeter does not measure the true current through  $R$  because current from the parallel path also gets to the ammeter.

**FIGURE 55.6** Three analog devices interconnected with an integrated circuit (U1).

The parallel path problem can be solved with a process called guarding. Guarding is accomplished by using a third nail to connect ground to the node marked  $C$  as shown in Fig. 55.7. When  $C$  is grounded, all the sidetracked current goes to ground because there is no voltage drop across  $R_b$  to attract current to or from the ammeter. All the current seen by the ammeter comes through  $R$ , so again Ohm's law gives the value of  $R$ . This is a classic three-wire measurement. It turns out that, for general component topologies, multiple guards (ground connections) may be required, but these are still considered three-wire measurements. In some cases where enhanced accuracies are needed or where there are extreme ratios of component

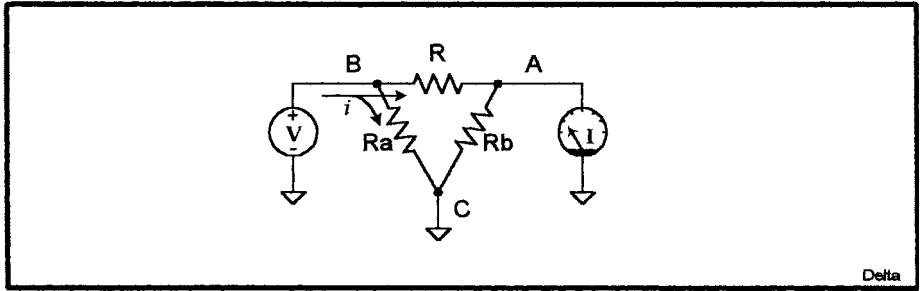

FIGURE 55.7 Equivalent circuit for Fig. 55.6 when making a guarded measurement.

values in a network, additional sense wires are used to eliminate errors that are due to small voltage drops in fixture nail, wire, relay, and trace contributions. (See Fig. 55.8.) See Ref. 3 for a discussion of enhanced measurement accuracies.

FIGURE 55.8 Routing of tester resources to the circuit to be tested.

### 55.5.2 Digital In-Circuit Test

Digital in-circuit test focuses on the digital components residing on a board, and requires that power be applied to activate the digital logic contained within the ICs. Just as analog components

can be tested without removing them from a board, digital components can be tested the same way. The key technology is backdriving. When applying digital stimuli to a digital device's inputs (via the bed of nails), a tester's driver must overcome the voltage levels that connected upstream devices are producing. This is done by equipping the digital in-circuit tester with powerful, low-impedance drivers that can backdrive upstream drivers with enough current to create the desired signal voltage in spite of their state. With tester receivers connected by nails to the device's outputs, the tester can monitor these outputs for expected responses to the stimuli. (See Fig. 55.9.)

**FIGURE 55.9** In-circuit digital test setup with full nodal access. The device under test is most often connected to other devices.

A problem with backdriving is that the tester drivers are abusing the upstream drivers in other devices\* while testing the device of interest. Studies<sup>4</sup> have shown that this is a legitimate concern and that damage to upstream devices may occur. For example, overdriven silicon junctions or device bond wires may heat up enough to be damaged. Sometimes this damage may occur surprisingly fast (within milliseconds). This problem can be solved by careful application of tests with an eye toward their duration. If backdrive testing can be done quickly, and/or with appropriate cooling intervals, then damage can be successfully avoided.<sup>5</sup> This has allowed digital in-circuit testing to become the dominant testing technology.

A great advantage of digital in-circuit testing is that it is performed directly on the inputs and outputs of a targeted device. If the device should fail testing, this is seen directly, rather

\* This abuse can be mitigated by "conditioning" upstream drivers. One method is to disable the upstream drivers by devoting additional tester drivers to driving states on disabling inputs (when they exist) such as output enable pins. Of course, the problem may simply be moved upstream, because the disabling inputs may also be connected to upstream drivers that are now being overdriven in place of the original drivers. This conditioning process may be carried out to several levels, if desired.

than having its identity masked by interactions with other devices. This is a major differentiation from functional testing. Faults typically can be resolved to two categories of defects: failed ICs or solder opens on I/O/power pins.

Another major differentiator is the ease—indeed, automation—of test programming that is possible with digital in-circuit testing. Tests for ICs can be prepared as if the ICs were standing alone,\* stored in a library, and recalled from the library when needed. Modern digital in-circuit testers may have library tests for tens of thousands of devices. For custom, one-of-a-kind ICs for which a library test may not exist (e.g., ASICs), it is still substantially easier to create a test for just the one device than it is for a collection of ICs.

### 55.5.3 Manufacturing Defect Analyzer (MDA)

A manufacturing defect analyzer (MDA) is essentially a very low-end analog in-circuit tester. One way it maintains low equipment cost is by not having power supplies to power up a board. Another cost savings comes by having only rudimentary programming and operating software. Some amount of test accuracy and yield must be traded for these savings.

### 55.5.4 General-Purpose In-Circuit Tester

The workhorse of the electronics industry is the general-purpose in-circuit tester that merges support for analog and digital in-circuit tests. An example of a widely used system is shown in Fig. 55.10. It contains power supplies for powering boards and often contains sophisticated

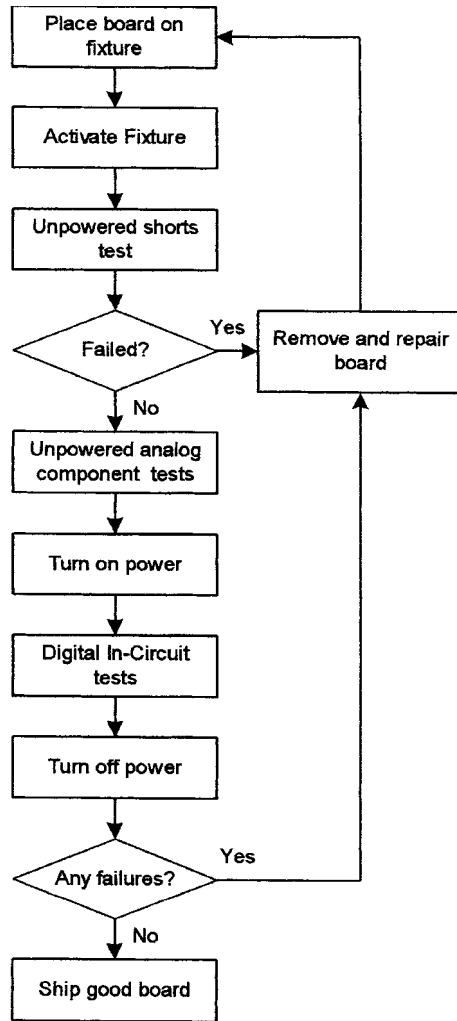

---

\* This assumes that the IC does not have any topological constraints on its I/O pins, such as having an input pin connected directly to ground or an output pin fed back to an input pin. In such cases, the prepared test may be incompatible with these constraints and may only be used after incompatible segments of the test are deleted, reducing fault coverage.

**FIGURE 55.10** Example of a commercial in-circuit test head and operator terminal, with a printed circuit board mounted in the testing position on top of the bed-of-nails fixture.

analog in-circuit programming tools and extensive libraries of digital tests. The typical test and repair flow for this tester is shown in Fig. 55.11. Note the early exit to repair for boards that fail shorts testing. This avoids applying power to boards that contain shorts because these may present hazards to the board and human operator, plus they also confuse the diagnosis of faults later in testing.

**FIGURE 55.11** Typical test and repair flow for an in-circuit tester.

### 55.5.5 Combinational Tester

In situations where a manufacturing line has a variety of technologies in production, a need may exist for both functional and in-circuit testing. Thus, hybrid functional/in-circuit testers (commonly called combinational testers) exist. These machines give test engineers a full

complement of tools to address testing problems. They also allow “one-stop” testing, where manufacturing defects and functional performance faults can be detected at one site in the production flow.

A combinational tester utilizes a bed of nails to perform in-circuit analog and digital tests. It may also utilize edge connector access to perform functional tests. In some cases these approaches are hybridized by constructing a two-stage bed-of-nails fixture that has two lengths of nails used in the bed, and a platen that has two stations of depression during operation. The first station is full depression, which brings all nails into contact with the circuit board for standard in-circuit access. The second station is partial depression, where only the longer nails still contact the board, perhaps at the board edge, for functional testing. The removal of the shorter nails removes the electrical loading they present to internal circuit nodes and allows the board to operate in a more natural environment.

## 55.6 ALTERNATIVES TO CONVENTIONAL ELECTRICAL TESTS

---

Alternative tests use radically different approaches to specifically address the resolution of defects. These may be needed to address blind spots in traditional electrical test methodologies. Two specific examples of defects that are difficult to resolve by conventional tests are given here.

First, consider a board with a large number of bypass capacitors. All of these capacitors are connected between power and ground so their parallel capacitances are summed. Using an analog in-circuit test, it is possible to test for this summed capacitance. However, if one capacitor is missing or tombstoned, the tester most likely will not notice because the resulting decrement in capacitance will likely fall well within the summed tolerances of the summed capacitances. The performance of the board at higher operating frequencies may be adversely affected, however, due to a loss of noise immunity. This could be detected (possibly) by a performance test. However, if this performance test failed, it could be very difficult to resolve which capacitor was missing. One non-traditional way to test for this problem is to use human visual inspection to look for missing capacitors. This may not find solder opens, however. Another approach would be to use an automated x-ray laminographic tester to check for the existence and solder integrity of each capacitor. Even the orientation of polarized capacitors can be verified. (See Chap. 53 for a discussion of x-ray inspection.)

Second, consider again the open solder problem on a digital device input. This defect may manifest itself as improper device behavior, but it would be wrong to replace the device (which would also fix the solder open) because the device is not at fault. Digital in-circuit testing has trouble resolving solder opens on input pins from bad devices.\* Final resolution can be obtained either by visual inspection or by using a handheld probe to see if board signals reach IC legs, but this is becoming increasingly difficult as packaging dimensions continue to shrink (e.g., TAB) and newer attachment technologies (e.g., ball grid arrays) are used that prohibit visual inspection or probing altogether.

An alternative approach to the open solder problem uses a capacitive coupling technique to look for opens. The technique exploits the fact that many ICs have a leadframe that forms the conductive path from the legs of the device to the die bond wire pads. Using the bed of nails, all but one node attached to the IC can be grounded (this is an unpowered technique) and a small AC signal can be applied to the node that remains. An insulated metal plate pressed against the top of the IC forms the top plate of a capacitor and the stimulated IC leg and lead frame conductor form the bottom plate.

---

\* Ignore for the moment the possibility of using boundary scan to solve this problem, which is discussed in Chap. 54.

FIGURE 55.12 Capacitive leadframe testing used to find open solder joints.

Figure 55.13 shows an equivalent circuit for capacitive opens test for a properly soldered IC lead and for an open solder condition. The capacitance  $C_1$  may be on the order of 100 fF ( $100 \times 10^{-15}$  F), which is small enough to require sophisticated detection electronics to measure in the face of environmental noise. Now, if the IC leg is soldered to the stimulated board node, the correct capacitance will be measured. If the solder joint is open, then a second small capacitance  $C_2$  now exists in series with the first. This reduces the measured capacitance by a factor of 2 to 10. Capacitive leadframe test allows testing of complex ICs for solder opens without knowing what the ICs actually do and without applying power. The technique requires no complicated programming, and gives accurate resolution of solder defects. The technique has been extended to allow testing of solder integrity for connectors and switches. A fixture for capacitive leadframe testing is shown Fig. 55.14.

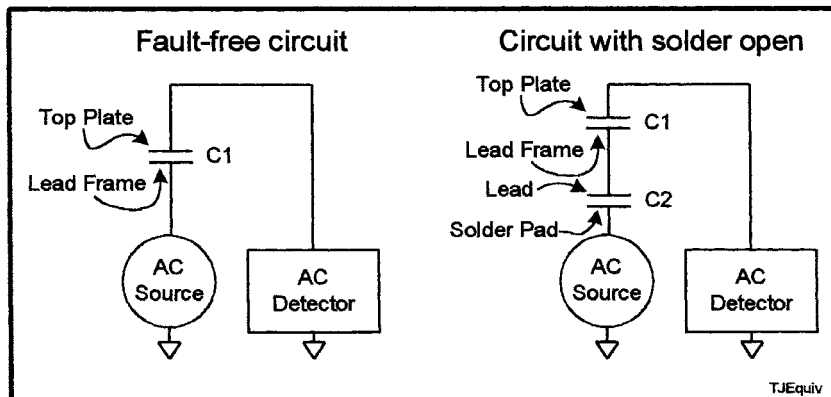

FIGURE 55.13 Equivalent circuits for fault-free and open solder conditions.

**FIGURE 55.14** A test fixture with board on a bed of nails, with clamshell top fixture containing capacitive sensor plates. Notice eight closely spaced sensor plates (right) that test for opens in eight (white) connectors on the board.

**55.7 TESTER COMPARISON**

Table 55.2 summarizes the types of tester for comparative costs and capabilities. A majority of manufacturers value good diagnostic resolution and fault coverage, so it is not surprising that in-circuit and combinational testers are in widespread use. Next in prevalence are the MDA testers, which are typically used where coverage and diagnostic resolution may be sacrificed

**TABLE 55.2** Costs and Capabilities of Various Testers

Tester type	Typical cost (\$)	Programming time	Diagnostic resolution	Fault cover	Comments
MDA	10 <sup>4</sup> –10 <sup>5</sup>	1–2 days	Fair	Poor	No digital coverage; requires known good board for programming.
In-Circuit	10 <sup>5</sup> –10 <sup>6</sup>	5–10 days	Best	Good	Fixturing is a major portion of preparation time.
Combo	10 <sup>5</sup> –10 <sup>6</sup>	10–30 days	Best	Best	Functional test programming is a major portion of preparation time.
Functional	10 <sup>5</sup> –10 <sup>6</sup>	1–4 months	Fair	Fair	Very high skill required for test preparation and interpreting results.
Specification	10 <sup>3</sup> –10 <sup>8</sup>	Weeks to years	Poor	?	Very high skill required for test preparation and interpreting results.

for ease and speed of programming, usually in low-cost, high-volume products. Functional and specification testers are becoming rare, and are often only justified by the existence of contractual or regulatory requirements.

## CHAPTER 56

---

# CONDUCTIVE ANODIC FILAMENT FORMATION

---

**Dr. Laura J. Turbini**

*University of Toronto, Ontario, Canada*

---

### 56.1 INTRODUCTION

---

The failure mode, conductive anodic filament (CAF) formation was first observed in the mid-1970s by two different research groups, Bell Laboratories and Raytheon. Since then, further studies have led to an understanding of the factors that affect CAF formation. These include substrate choice, conductor configuration, voltage and spacing, processing, humidity and the storage, and use environment. CAF has been identified as a copper hydroxy chloride salt that causes catastrophic failure when it bridges because it has semiconductor properties. A CAF test method for multilayer boards has been developed by Sun Microsystems, and then introduced as an IPC test method. This chapter will explore these topics in more detail. It then identifies the printed wiring board (PWB) manufacturing tolerance limitations and makes recommendations for the design of CAF test coupons.

---

### 56.2 UNDERSTANDING CAF FORMATION

---

In the mid-1970s, Bell Labs' researchers were concerned about potential failures of printed wiring boards intended for high-voltage switching applications. They reported<sup>1,2</sup> on accelerated life testing of flexible PWBs coated with ultraviolet (UV)-cured resin, and identified two new failure modes: conductive bridges between conductors on the surface, and conductive shorts through the substrate.

AT&T Bell Labs' test vehicle (see Fig. 56.1) was a flexible epoxy-glass PWB, 0.005 to 0.007 in. thick with comb patterns of 0.008 in. lines and 0.009 in. spaces. Some combs were biased on the surface and some were biased through the substrate. Processed boards, coated with conformal coating, were tested from 35 to 95°C, 25 to 95 percent relative humidity (RH), and direct current (DC) voltages up to 400 V. For accelerated testing at 85°C, 80 percent RH, and 78 V bias, failures occurred within two to five days.

Bell Labs' technicians identified two major failure modes that they described as causing "catastrophic loss of insulation resistance due to the formation of conductive bridges between conductors." The first failure mode—*through-substrate shorts*—only occurred above 75°C and 85 percent RH and thus was not considered to be a problem at use conditions (see Fig. 56.2).

**FIGURE 56.1** AT&T test vehicle compared: (a) double-layer glass reinforcement; (b) single-layer glass reinforcement; (c) single-layer glass reinforcement with extra "buttercoat." © 1976 IEEE

The second mode involved shorts between conductors on the same side of the board in which conductive material accumulates between the glass bundles and the epoxy (see Fig. 56.3). R. H. Delaney and J. N. Lahti<sup>2</sup> noted that the thicker the buttercoat, the less this failure was observed. They also detected a failure, which they termed *anodic eruption failure mode*, in which corrosion

**FIGURE 56.2** Through-substrate short.<sup>2</sup> © 1976 IEEE

**FIGURE 56.3** Subsurface substrate failure.<sup>2</sup> © 1976 IEEE

products emerged from the anode to the covercoat surface, charring the surface, and then growing back through the covercoat to the cathode, where it shorted (see Fig. 56.4).

In 1976, Aaron Der Marderosian at Raytheon, while studying measling, crazing, and delamination, examined the reliability of multilayer PWBs by applying a DC voltage between ground planes and conductor traces (see Fig. 56.5).<sup>3</sup> Test coupons were biased at 100 V and aged at 65°C and 95 percent RH for 10 days. Based on the results, Der Marderosian reported a failure that he termed the “punch thru” phenomenon. This is similar to the “thru substrate shorts” reported by Delaney.<sup>2</sup> To study this failure further, Der Marderosian obtained test coupons from three different vendors biasing some at 100 V DC, others at 100 V AC, and a third group was unbiased. Since “punch thru” was observed only when DC bias was applied, Der Marderosian concluded that this failure was due to electrochemically initiated metal migration. He reported that the number of incidents of “punch thru” decreased as aging voltage was decreased. The addition of a urethane conformal coating appeared to accelerate, not suppress, the problem.

“Punch-thru” is an electrical failure that eventually manifests itself in a rupture of the insulation between two layers of copper metallization. In the early stages, Der Marderosian observed conductive copper-containing deposits that he assumed were CuO along the glass fibers. Eventually these deposits shorted to the cathode, carbonizing the epoxy, which caused

FIGURE 56.4 Anodic eruption failure mode.<sup>2</sup> © 1976 IEEE

FIGURE 56.5 Raytheon test coupon with “punch thru” from anode trace to copper ground plane.<sup>3</sup>

the epoxy to be more conductive. Epoxy blowout then ruptured the glass fibers. In the later stages, Der Marderosian observed melting of the metal traces.

Equation 56.1 represents Der Marderosian's concept of the production of CuO and Cu(OH)<sub>2</sub> at the anode. At the cathode, reduction takes place yielding copper and hydrogen gas. He noted that copper hydroxide decomposes to copper oxide above 60°C.

D. J. Lando et al.<sup>4</sup> first used the term conductive anodic filament (CAF) to describe this failure in 1979. They defined the mechanism of CAF formation as a two-step process: degradation of the epoxy/glass interface, followed by the electrochemical reaction (see Eq. 56.2).

In 1980, T. L. Welsher et al.<sup>5</sup> reported that CAF was potentially a serious reliability problem for closely spaced conductors and proposed a mean time to failure (MTTF) based on Eq. 56.3:

$$\text{MTTF} = a(H)^b \exp\left(\frac{E_a}{RT}\right) + d \frac{L^2}{V} \quad (56.3)$$

where

- $H$  = humidity
- $E_a$  = activation energy
- $R$  = gas constant
- $T$  = temperature in Kelvin
- $L$  = conductor spacing
- $V$  = voltage
- $a, b, E_a, d$  = material-dependent

Welsher et al. noted that additional work was needed to determine the exact dependence of CAF on conductor spacing and humidity. They also reported that glass-reinforced triazine is CAF-resistant.

In 1981, they expanded their view of the MTTF and reported it as shown in Eq. 56.4:

$$\alpha \left(1 + \beta \frac{L^n}{V}\right) \cdot H^\gamma \exp \frac{E_a}{kT} \quad (56.4)$$

where

- $\alpha, \beta$  = material-dependent constants
- $\gamma$  = humidity-dependent constant
- $n$  = related to the orientation of the conductors
- $L$  = spacing
- $V$  = voltage
- $H$  = humidity
- $E_a$  = activation energy
- $k$  = Boltzman's constant
- $T$  = temperature in Kelvin

W. J. Ready and L. J. Turbini<sup>6</sup> studied the effect of voltage and spacing on CAF failures for a hole-to-hole test pattern (see Fig. 56.6). Using two different spacings (0.50 mm and 0.75 mm)

**FIGURE 56.6** Hole-to-hole test vehicle used by Ready and Turbini.<sup>6</sup>

and two different bias voltages (150 V and 200 V), they were able to show the relation is  $L^4/V^2$  (see Eq. 56.5):

$$\text{MTTF} = c \cdot \exp\left(\frac{E_a}{kT}\right) + d \left(\frac{L^4}{V^2}\right) \quad (56.5)$$

In addition, they provided evidence for different CAF morphologies when different flux constituents were used. Coupons that were aged without flux exhibited only a copper salt at the fiber and epoxy interface, whereas those processed with water-soluble flux showed the presence of a copper-containing material within the polymer matrix. Ready and Turbini also identified the chemical nature of CAF as atacamite:  $\text{Cu}_2\text{Cl}(\text{OH})_3$ . An examination of the Pourbaix diagram (see Fig. 56.7) for the copper-chlorine-water system reveals that copper hydroxy chloride is insoluble below pH4 and thus this salt will grow from the anode, which is acidic. They also explained that the high conductivity of this salt, which causes catastrophic failure when it bridges to the cathode, suggests that it conducts through electrons and holes, that is, it has semiconductor properties.

CAF filaments are typically no larger than 50  $\mu\text{m}$  in diameter and 0.2 mm in length.

### 56.3 ELECTROCHEMICAL MIGRATION AND FORMATION OF CAF

CAF is a conductive copper-containing salt created by electrochemical migration. Thus, it is important to review the electrochemical migration process in more detail. It begins with a substrate material, which serves as an insulator, preventing current flow between adjacent traces. This resistance to current flow is termed *insulation resistance*.

FIGURE 56.7 Pourbaix diagram of the copper-chlorine-water system.

Ohm's law (Eq. 56.6) describes the linear relationship between voltage, current, and resistance:

$$V = IR \tag{56.6}$$

where  $V$  = voltage drop  
 $I$  = current in amps  
 $R$  = resistance in ohms

Resistance is not an intrinsic property of a material. Rather, it depends on some geometric factors as well as the intrinsic resistivity of the substrate. For surface resistance, use Eq. 56.7:

$$R = \rho \left( \frac{d}{A} \right) \tag{56.7}$$

where  $\rho$  = resistivity of the material  
 $d$  = the separation between the conductors traces  
 $A$  = the cross-sectional area

Conductivity ( $\sigma$ ) is the inverse of resistivity:

$$\sigma = \frac{1}{\rho}$$

**FIGURE 56.8** Electrochemical migration showing the movement of positive ions toward the cathode and negative ions toward the anode.

Both resistivity and conductivity can be affected by processing chemicals.

Electrochemical migration (see Fig. 56.8) is the movement of an ionic species under the influence of a DC voltage. Electrochemical corrosion increases as circuit spacing decreases. This is due to the increase in the electric field, which is inversely proportional to the spacing between the conductors (see Eq. 56.8).

$$E = \frac{V}{d} \quad (56.8)$$

where  $E$  = the electric field  
 $V$  = the voltage  
 $d$  = the spacing between the conductors

Moisture is essential to electrochemical migration. In the presence of moisture, metal ions form at the anode and migrate toward the cathode, where they plate out to form dendrites. When a dendrite bridges the gap, a short occurs that may burn out quickly due to the high current within the fragile dendrite.

In the case of CAF formation, copper ions are created electrochemically at the anode. Residual chloride ions from the reaction of epichlorhydrin with Bisphenol A (forming a precursor to the epoxy) exist at low levels in the FR-4 substrate. These react with the copper ions and water to produce the CAF— $Cu_2Cl(OH)_3$ —which grows from the anode since it is insoluble in acid. The favored path for this is at the epoxy-glass interface.

Ionic contaminants, which dissolve in the moisture on the surface, increase the conductance (lower the resistance) of the insulating layer between the anode and cathode. Their presence enhances electrochemical migration. How much the migration is enhanced depends on several factors: the solubility of the ion, the mobility of the ion, the effect of pH on solubility, the reactivity of the ion, temperature, and relative humidity.

The solubility of the ion and its mobility in water are important because conductivity depends on both of these factors (see Eq. 56.9).

$$\sigma = \sum N_i q_i \mu_i \quad (56.9)$$

where  $N_i$  = the number of charge carriers of a particular type (e.g.,  $\text{Na}^+$  cations, or  $\text{Cl}^-$  anions)  
 $q_i$  = the charge of the carrier  
 $\mu_i$  = the mobility of the charge carrier

The mobility of a given ion is dependent on temperature and its diffusion coefficient per Eq. 56.10:

$$\mu_{\text{ion}} = \left( \frac{q}{kT} \right) D_{\text{ion}} \quad (56.10)$$

where  $k$  = Boltzmann's constant  
 $T$  = degrees Kelvin  
 $D_{\text{ion}}$  = Diffusion constant for a particular ion.

Tables of ionic conductance in aqueous solution as well as diffusion constants can be found in the *Handbook of Chemistry and Physics*.<sup>7</sup>

Most contaminants from processing do not exist in isolation from one another. Rather, there may be several ionic species present, some of which will interact to create new ionic species.

Solubility of the contaminant salts also depends on the pH. Water ionizes under a bias voltage, creating an acidic medium at the anode and a basic medium at the cathode, as shown in the following reactions:

Temperature is another important factor to consider. An increase in temperature increases ion solubility, mobility, and reactivity.

In summary, several factors affect electrochemical migration. These include the nature of substrate and metallization, the presence of contaminants, the voltage gradient, and the presence of sufficient moisture. This last element is critical, for without sufficient monolayers of water on the surface, ion mobility is impossible.

#### 56.4 FACTORS THAT AFFECT CAF FORMATION

A number of factors affect CAF formation. These include substrate material, conductor configuration, processing, voltage and spacing, soldering flux, and humidity in the storage and use environment.

### 56.4.1 Substrate Material

Lando et al.<sup>4</sup> compared FR-4 with several substrates: G-10 (a non-fire-retardant epoxy/woven glass material), polyimide/woven glass (PI), triazine/woven glass, epoxy/woven kevlar, and finally polyester/woven and chopped glass. Similarly, B. Rudra et al.<sup>8</sup> performed an extensive experimental comparison among the substrates: bismaleimide triazine (BT), cyanate esters (CE), and FR-4. In addition, Ready<sup>9</sup> compared the CAF susceptibilities of FR-4 with CEM-3 (a substrate similar to G-10 except with chopped glass) and MC-2 (a blended polyester and epoxy matrix with woven glass face sheets and a chopped glass core). Of all materials tested by these investigators, the BT material proved to be most resistant to CAF formation (due to its low moisture absorption characteristics). Conversely, the MC-2 substrate proved to have the least resistance to CAF formation. The susceptibility of the materials follows the trend below:

$$\text{MC-2} > \text{Epoxy/Kevlar} > \text{FR-4} \sim \text{PI} > \text{G-10} > \text{CEM-3} > \text{CE} > \text{BT}$$

To ensure immunity to CAF, the laminate of preference is BT. In recent years, laminate suppliers have developed other CAF-resistant substrate materials. However, there is a cost penalty to consider.

**56.4.1.1 Conductor Configuration.** Lando et al.<sup>4</sup> evaluated several different conductor configurations:

- Line-to-line (L-L)
- Hole-to-line (H-L)
- Hole-to-hole (H-H)

This evaluation showed that susceptibility to CAF is H-H > H-L > L-L. Lahti et al.<sup>10</sup> demonstrated that the smaller the spacing between conductors and the greater the proximity of the glass fibers to the copper conductors, the faster the growth of CAF. They noted that for a multilayer board, failure initiated in the most deeply buried layers.

### 56.4.2 Processing

The epoxy-glass bond can be weakened by the drilling or depaneling processes in PWB manufacture. It will also be weakened during the soldering process due to the difference in coefficient of thermal expansion (CTE) of the epoxy and glass. Data from Turbini et al.<sup>11</sup> demonstrated that the increased soldering temperature associated with lead-free alloys significantly increases the incidence of CAF.

Another processing factor is the diffusion of polyglycols from water-soluble flux into the PWB substrate that occurs during soldering. Since the diffusion rate is temperature-dependent, the length of time that the board is above the glass transition temperature will affect the amount of polyglycol absorbed into the epoxy, and that will in turn affect its electrical properties. J. A. Jachim et al.<sup>15</sup> reported on water-soluble flux-treated test coupons that were prepared using two different thermal profiles. Those which experienced the higher thermal profile exhibited a Surface Insulation Resistance (SIR) level that was an order of magnitude lower than those processed under less aggressive thermal conditions.

### 56.4.3 Voltage and Spacing

Two other critical factors used in determining CAF susceptibility are voltage and spacing. The CAF growth is fueled by the electric field ( $V/d$ ), and failure occurs more quickly with smaller spacing between conductors.

#### 56.4.4 Effect of Soldering Flux

It has been shown that polyglycols<sup>12</sup> (which are found in water-soluble fluxes) diffuse into the epoxy during soldering.<sup>13</sup> This absorption has been shown to reduce electrical performance by increasing moisture uptake by the substrate.<sup>14</sup> Jachim et al.<sup>15</sup> were the first to link the use of polyglycols in soldering fluxes and fusing fluids to increased susceptibility to CAF formation.

Ready et al.<sup>16</sup> showed that the use of certain water-soluble fluxes or fusing (hot air solder level [HASL]) fluids could increase CAF formation. In examining a catastrophic field failure (see Fig. 56.9), Ready et al.<sup>16</sup> demonstrated the presence of a copper-bromide containing salt between an innerlayer power plane and ground pin, separated by 0.005 in. Using a test coupon manufactured in the same lot as the failed product, they extracted the flux residues from an innerlayer of the multilayer board and used ion chromatography to match the residues from the board's innerlayer with the constituents of the flux.

**FIGURE 56.9** Catastrophic field failure of military hardware. The conductive filament grew from the +20 V ground plane to the -20 V ground pin. Flux residues enhanced this failure rate.<sup>16</sup>

The morphology of CAF is different when certain fluxes are used.<sup>6</sup> In Fig. 56.10(a), when no flux is used, CAF forms only as a crystalline filament at the epoxy-glass interface; in Fig. 56.10(b), the flux contained polyethylene propylene glycol (1800) and there appears to be copper-containing compounds in stratified layers within the matrix in addition to the filament at the epoxy-glass interface; and in Fig. 56.10(c), the flux contained a linear aliphatic polyether and one sees a copper-containing compound appearing in a striated morphology as well as in the filament at the interface.

#### 56.4.5 Humidity in the PWB Storage and Use Environment

J. A. Augis et al.<sup>17</sup> determined that there is a humidity threshold below which CAF formation will not occur. They found that this relative humidity threshold depends on operating voltage and temperature. It is important to remember that this relative humidity need not be present in the operating environment. Moisture absorption can occur during any part of the assembly's lifetime.

**FIGURE 56.10** Morphology of CAF differs when different flux constituents are used: (a) CAF only at the glass-epoxy interface; (b), (c) an additional copper-containing compound within the polymer matrix.

This is particularly critical during transportation or storage, when the assembly may experience harsh environmental conditions.

## 56.5 TEST METHOD FOR CAF-RESISTANT MATERIALS

---

In the late 1990s, laminate suppliers began to develop new materials that they marketed as CAF-resistant. To evaluate these materials, K. Sauter<sup>18</sup> developed a CAF test vehicle, which consisted of a multilayer board with daisy-chained hole-to-hole spacing of 0.25 mm, 0.375 mm, 0.50 mm, and 0.625 mm. The holes were either inline with the glass fiber direction or staggered. Accelerated aging was done at 65 °C and 85 percent RH for 500 hours. Sauter's results show variations based on laminate material, manufacturer, and diagonal versus inline holes, with the former being more CAF-resistant. He also defined a "readily conductive region" around the plated-through holes, which must be considered in establishing design rules. This test vehicle and procedure has been developed as an IPC Test Method (IPC-TM-2.6.25), "Conductive Anodic Filament (CAF) Resistance."<sup>19</sup>

## 56.6 MANUFACTURING TOLERANCE CONSIDERATIONS

---

Test board designs for performing statistical studies of CAF-resistant materials must take into account the limitations of the PWB manufacturing process.<sup>20</sup> As hole-to-hole spacing becomes closer, the limits of the drilling process must be considered. Drill wander can be caused by splay when the drill enters the board at an angle. These two factors are exacerbated with smaller drill size. Typical manufacturing tolerances for hole-drilling equipment are specified at  $\pm 0.075$  mm. Based on this, test board design for statistical CAF studies should have the minimum edge-to-edge spacing of 0.375 mm, since the manufacturing tolerance should be no more than 20 percent of the hole-to-hole distance.

CAF-resistant substrates are frequently more expensive than traditional FR-4, and therefore they are reserved for products that require high reliability, optimizing both cost and performance. Designs are multilayer rather than double-sided rigid boards. An important difference between a multilayer board and a double-sided rigid board is the glass-to-resin ratio. In drilling the holes, more damage will occur at the epoxy-glass interface for boards with higher glass content.

Typical double-sided PWBs use eight sheets of 7628-glass cloth with a thickness of 0.175 mm (0.007 in.) to create a 1.5 mm (0.062 in.) thick board. The portion of resin in this board would be 30 to 40 percent. For a multilayer board, the glass cloth thickness may range from 0.035 mm to 0.10 mm (0.001 in. to 0.004 in.) per layer. In this case, the amount of resin ranges from 45 to 50 percent in the case of the 0.10 mm glass cloth thickness, it ranges from 55 to 65 percent in the case of the 0.035 mm thickness. In the drilling process, the board with a higher resin content creates less hole damage than one with a lower resin content.

Microvias that are created by laser drilling can be located at a reduced pitch for CAF studies because one does not expect drill damage from a laser-ablated hole and it will not be subjected to the drill wander of a mechanically drilled hole. Thus, laser drill tolerances are below 0.025 mm (0.001 in.).

The catastrophic failure presented earlier in this chap. (see Fig. 56.9) was caused by a power plane (anode), which created a CAF that shorted to the hole (cathode). In designing a test board, the power plane must always be the anode in order to reduce the current density for corrosion. A large cathode in contact with a small anode creates a high-current density at the anode and increases the corrosion rate. Present BGA board designs have microvias of 1 mm (0.040 in.) or even 0.8 mm (0.032 in.). These become problematic when the plane-to-hole separation is below 0.2 mm (0.008 in.).

# CHAPTER 57

---

# RELIABILITY OF PRINTED CIRCUIT ASSEMBLIES

---

**Judith Glazer\***

*Hewlett-Packard Company, Electronic Assembly  
Development Center, Palo Alto, California*

This chapter describes the response of functional printed circuit board assemblies (PCAs) to environmental stresses—that is, their reliability in service—and the influence of design, materials, and manufacturing decisions on this behavior. A variety of stresses may be present in the service environment of the assembly. *Thermal* stresses come from fluctuations in the ambient temperature in the service environment of the assembly or from power dissipation of high-power devices mounted on the printed circuit board (PCB). There are also thermal stresses associated with assembly and rework. *Mechanical* stresses may be due to bending and flexing of the assembly during later assembly steps or in service, mechanical shock during transportation or use, or mechanical vibration, for example, from cooling fans. *Chemical* sources of environmental stresses include atmospheric moisture, corrosive gases (for example, smog or industrial process gases), and residual chemically active contaminants from the assembly processes (for example, from flux). These environmental stresses may act singly or in concert with one another and the electrical potential differences that exist when the assembly is functioning to cause electrical failures in the printed circuit assembly (PCA). This chapter will focus on the reliability of the PCB and the interconnects to it. Reliability of the electrical components themselves is beyond the scope of this chapter (see Fig. 57.1).

By defining reliability as the response of functioning assemblies to environmental stresses, we have excluded the large class of production defects that are detected in the testing processes immediately after manufacturing or that will cause the assembly to be nonfunctioning from the outset. This chapter will focus on the delayed effects of manufacturing defects and the wear-out mechanisms of properly manufactured product.

The remainder of this chapter is organized into six major sections:

- 57.1 Fundamentals of Reliability
- 57.2 Failure Mechanisms of PCBs and Their Interconnects
- 57.3 Influence of Design on Reliability
- 57.4 Impact of PCB Fabrication and Assembly on Reliability

---

\* Significant portions of this chapter are drawn from T. A. Yager, “Reliability,” chap. 30, *Printed Circuits Handbook*, 3d ed. (Coombs, ed.), 1988.

**FIGURE 57.1** Schematic drawing of a printed circuit board assembly. This chapter focuses on the reliability of the printed circuit board and the interconnect between the printed circuit board and the components (shaded area in the drawing).

### 57.5 Influence of Materials Selection on Reliability

### 57.6 Burn-in, Acceptance Testing, and Accelerated Reliability Testing

Where applicable, each section covers printed circuit boards, printed circuit board assemblies, and components and their packages, in turn. Section 57.2 is the core of the chapter; it covers the fundamental of the failure mechanisms and is the assumed underlying basis of the subsequent sections. The breadth of this chapter, the complexity of the failure mechanisms involved, and the rapid evolution of the field mean that this chapter can provide only a brief overview of important topics in PCB and PCA reliability, many of which are the subject of books in their own right. The reader is encouraged to refer to the references and suggestions for further reading given at the end of the chapter before attempting quantitative reliability predictions.

## 57.1 FUNDAMENTALS OF RELIABILITY

### 57.1.1 Definitions

The reliability of a component or system can be defined as the *probability* that a functioning product at time zero will function *in the desired service environment* for a *specified amount of time*. Without these three parameters, the question “Is  $x$  reliable?” cannot be answered yes or no. Since reliability describes the probability that the product is still functioning, it is related to the cumulative number of failures. Mathematically, the reliability of an object at time  $t$  can be stated as

$$R(t) = 1 - F(t)$$

where  $R(t)$  is the reliability at time  $t$  (i.e., the proportion of parts still functioning) and  $F(t)$  is the fraction of the parts or systems that have failed at time  $t$ . Time may be measured in calendar units or some other measure of service time such as on/off cycles or thermal or mechanical vibration cycles. The unit of time that makes sense depends on the failure mechanism. When several failure modes are present, it is often helpful to think in terms of several time scales.

A plot of the failure rate of a product as a function of time typically takes the shape of a “bathtub” curve (see Fig. 57.2). This curve illustrates the three phases that occur during the lifespan of a product from a reliability perspective. In the first, infant mortality phase, there is an initially high but rapidly declining failure rate caused by infant mortality. Infant mortality is typically caused by manufacturing defects that went undetected during inspection and testing and lead to rapid failure in service. Burn-in can be used to remove these units before shipment. The second phase, the normal operating life of the product, is characterized by a period of stable, relatively low failure rates.

**FIGURE 57.2** Classic bathtub reliability curve showing the three stages during the life of a product from a reliability perspective: infant mortality, steady-state, and wear-out.

During the operating life, failures occur apparently randomly and the failure rate  $r$  is roughly constant with time. An exponential life distribution is often assumed to describe the behavior in this region. In that case,

$$r = \left( \frac{N_t}{N_o} \right) \left( \frac{1}{\Delta t} \right)$$

and

$$R(t) = e^{-rt} = e^{-\frac{t}{\text{MTBF}}}$$

where  $N_t$  = number of failures in time interval  $\Delta t$   
 $N_o$  = number of samples at the beginning of the interval  
 MTBF = mean time between failures

During the third phase, the wear-out period, the failure rate increases gradually due to wear-out phenomena until 100 percent of the units have failed. For some systems, the second steady-state region may not exist; for solder joints, the wear-out region may extend over most of the life of the assembly. Understanding wear-out phenomena, which manifest themselves in properly manufactured parts after a period of service, and predicting when they will significantly affect the failure rate, are the primary focuses of this chapter.

Most wear-out phenomena can be characterized by cumulative failure distributions governed by either the Weibull or the log-normal distribution. Weibull distributions have been successfully used to describe solder joint and plated-through-hole fatigue distributions, while log-normal distributions are generally associated with electrochemical failure mechanisms. While these distributions may be quite narrow in some cases, their use should serve as a reminder that even with nominally identical samples, failures will be statistically distributed over time.

A practical use of fitting a distribution to reliability data is to extrapolate to smaller failure rates or other environmental conditions. To simplify the equations, the expressions in the text refer to the mean life of the relevant portion of the assembly. If the constants that define the failure distribution are known, the time to reach a smaller proportion of failures may be readily calculated. For example, for failure modes that are described by a Weibull distribution, the time  $t$  to reach  $x\%$  failures is given by:

$$t(x\%) = t(50\%) \left[ \frac{\ln(1 - 0.01x)}{\ln(0.5)} \right]^{1/\beta}$$

where  $\beta$  is the Weibull shape parameter, usually between 2 and 4 for solder joint failures.

### 57.1.2 Reliability Testing

Almost every reliability test program must solve the problem of determining whether an object is reliable in a calendar time period that is much shorter than the expected use period. Obviously, one cannot spend 3 to 5 years testing a personal computer that will be marketed for an even shorter time span or 20 years testing a military system. Depending on the failure mechanism, there are two approaches, which may be combined: (1) accelerate the frequency of the occurrence that causes failure and test the ability of the object to survive the expected number of events, or (2) increase the severity so that fewer occurrences are needed. Drop tests that simulate shock during transportation are an example of the first approach. Since the time between drops does not affect the amount of damage caused, a lifetime of drops can be conducted in rapid succession. However, the effect of temperature and humidity on corrosion over the lifetime of the product can be tested only by increasing the temperature, the humidity, or the concentration of contaminants, or some combination of these. The difficulty is ensuring that the test reproduces and/or correlates to the failure mechanism in service.

To use this data for making true reliability predictions—that is, *the probability of failures at a given time under given conditions*—testing must be continued until enough parts fail that a life distribution can be estimated. Unfortunately, this process can be time consuming and qualification tests are often substituted. Qualification test protocols specify a *maximum number of failures that may be observed in a specified period* in a sample of specified size. If few or no failures occur, a qualification test provides almost no information about the failure distribution; for example, the probability of failure during the next time interval is unknown. This limitation of qualification testing is minimized when the life distribution for properly manufactured samples is already known or can be estimated based on experience with similar designs. Many of the “reliability” tests described in Sec. 57.6 are actually qualification tests.

Many reliability or qualification testing schedules follow neither of these schemes. Instead, they test the ability of the product to survive a sequence of tests under extremely severe conditions for a short time or small number of exposures. Again, this type of testing may be adequate when it is supported by long experience with both the product type and its use environment; however, it is risky because it is not based on ensuring that probable failure modes will not occur in the life of the product. When new technologies or geometries are introduced, the old tests may not always be conservative. By the same token, irrelevant failure modes that would not occur in service may be introduced by the harsh test conditions.

## 57.2 FAILURE MECHANISMS OF PCBs AND THEIR INTERCONNECTS

---

This section will discuss the most important failure mechanisms of PCBs and the interconnects between PCBs and the components mounted on them. The discussion of PCB failure mechanisms will be more detailed since interconnect failures have been described far more extensively elsewhere. Whatever the environmental stress or the material response, these failures ultimately manifest themselves in terms of the functionality of the assembly, first as a change in electrical resistance between two points and then as electrical shorts or opens.

### 57.2.1 PCB Failure Mechanisms

PCB failure mechanisms fall into three groups: thermally induced failures, of which plated-through-holes are the most important example; mechanical failures; and chemical failure mechanisms, of which dendritic growth is the most important example.

**57.2.1.1 Thermally Driven Failure Mechanisms.** PCBs are exposed to thermal stresses in a variety of situations. These may be either prolonged exposure to an elevated temperature or isolated or repeated temperature cycles. These temperature cycles can cause various PCB failures. The most important sources of thermal stress are:

- *Thermal shocks and thermal cycles during PCB manufacturing.* Thermal shocks are usually defined as temperature ramps faster than  $\sim 30^\circ\text{C/s}$ , but include any ramp fast enough that temperature differentials play an important role. Examples include solder mask cure and hot-air solder leveling.
- *Thermal shocks and cycles during printed circuit assembly.* Examples are glue cure, solder reflow, wave soldering, and rework using a soldering iron, hot air, or molten solder pot.
- *Ambient thermal cycles in service.* Examples are going from inside to outside temperatures or ground to upper atmospheric temperatures, and elevation in box temperature due to heat dissipation from functioning electronic components.

The primary PCB failure mechanisms accelerated by these thermal stresses are plated-through-hole cracking and delamination of the laminate.

*Plated-Through-Hole Failures Due to Thermal Shocks or Cycling.* Plated-through-holes (PTHs) are the most vulnerable features on PCBs to damage from thermal cycling and the most frequent cause of printed circuit board failures in service. PTHs include holes for through-hole (TH) components and vias that make electrical connections between layers. Figure 57.3 shows the common failure locations. Most organic resin-matrix substrate materials are highly anisotropic, with a much higher CTE above the glass transition temperature  $T_g$  in the through-thickness ( $z$ ) direction than in the plane of the woven matrix cloth (the  $x$ - $y$  plane of the board). Since above  $T_g$  the CTE climbs sharply, aggressive thermal cycles can result in large strains in the  $z$  direction and, consequently, on the PTHs (see Fig. 57.4<sup>1</sup>). The PTH acts like a rivet, which resists this expansion, but the Cu barrel is stressed and may crack, causing electrical failure. Figure 57.4 also illustrates the increasing strain on the barrel associated with a high temperature excursion. Failure may occur in a single cycle or may take place by initiation and growth of a fatigue crack over the course of a number of cycles. For high-aspect-ratio through-holes subject to repeated thermal shocks from room temperature to solder reflow temperatures ( $220$  to  $250^\circ\text{C}$ ) during board fabrication

**FIGURE 57.3** Schematic diagram of a plated-through-hole in a cross section of a four-layer printed circuit board showing common failure locations under thermal stress.

(e.g., hot-air solder leveling) and assembly (reflow, wave soldering, rework), it is not unheard of to encounter failures after 10 or fewer of these thermal cycles.

On a physical level, the number of thermal cycles to failure is affected by the strain imposed on the Cu in each cycle and the fatigue resistance of the copper. These factors are in turn controlled by a number of environmental, material, and manufacturing parameters. Low-cycle metal fatigue, in which most of the strain is plastic strain, can be treated approximately with the Coffin-Manson relation:

$$N_f \propto \frac{1}{2} \left( \frac{\epsilon_f}{\Delta \epsilon} \right)^m$$

where  $N_f$  = number of cycles to failure

$\Delta \epsilon$  = strain

$\epsilon_f$  = strain ductility factor, which correlates closely with tensile ductility

$m$  = constant near 2.

**FIGURE 57.4** Strain vs. temperature for FR-4 (epoxy-glass), copper, and a PTH barrel in an FR-4 board during a single thermal cycle from 25 to 250 to 25°C. While the thermal expansion of the individual materials is fully reversible, much of the strain in the Cu PTH barrel is plastic, so most of the strain is not reversed during cooling. Note that the rate of thermal expansion of the FR-4 increases sharply at  $T_g$ . Results from Ref. 1.

This relation will significantly underestimate life for high cycle fatigue which can occur after repeated thermal cycling in service. The strain  $\Delta\epsilon$  can be estimated by finite element modeling or analytically. If no other data are available,  $\epsilon_f$  for electroplated Cu can be approximated as 0.3.

The number of cycles to failure can be increased by increasing  $\epsilon_f/\Delta\epsilon$ , primarily by decreasing  $\Delta\epsilon$  by:

- Decreasing or eliminating thermal shocks by preheating the board before hot-air leveling, wave soldering, rework with a solder pot, etc.
- Decreasing the size of the thermal cycle (see Fig. 57.5<sup>2</sup>). Decreasing the size of the thermal cycle is the single most effective measure for increasing the life of the PTH, especially if the thermal cycle exceeds  $T_g$ .
- Decreasing the free thermal expansion of the laminate over the thermal cycle. The free thermal expansion can be reduced primarily by choosing a laminate material with a higher  $T_g$ , but also by choosing a laminate material (e.g., with Aramid fibers) with a low CTE below  $T_g$  (see Fig. 57.6).
- Decreasing the PTH aspect ratio (usually quoted as board thickness divided by finished hole size) by decreasing the board thickness or increasing the hole diameter (see Fig. 57.7). Aspect ratios tend to be higher in boards with eight or more layers because of their thickness and via density; aspect ratios greater than 3:1 require good-quality plating and aspect ratios higher than 5:1 are not recommended, in part because of the difficulty of achieving adequate plating thickness in the center of the barrel.
- Increasing the Cu plating thickness (see Fig. 57.8<sup>2</sup>). Increasing the plating thickness also increases the distance a fatigue crack must propagate to cause an electrical failure.
- Using Ni plating over the Cu (see Sec. 57.5.1.3 for more discussion).

The ratio  $\epsilon_f/\Delta\epsilon$  can be increased by:

- Increasing the Cu ductility (increases  $\epsilon_f$ ) and yield strength (decreases  $\epsilon$ ). Cu strength and ductility are often inversely related, so these two factors must be balanced against one

**FIGURE 57.5** Peak temperature vs. number of cycles to failure by PTH barrel (solid bars) or corner (dashed bars) cracking in three different tests. Calculated lines are shown for comparison. Results are for pyrophosphate copper and FR-4. Other parameters are total strain energy required to cause fracture,  $50 \text{ J/cm}^3$ ; hole radius, 0.45 mm; distance from hole center to free end, 0.8 mm; plating thickness, 0.02 mm; distance from hole center to pad edge, 0.8 mm; board thickness, 2 mm. Results from Ref. 2.

another. However, the strength-ductility relationship can be altered by the choice of plating bath and plating conditions.

The number of cycles to failure can be dramatically decreased by defects in the hole wall or Cu plating in the hole or PTH knee that act as stress concentrations (increasing the local stresses and strains) and/or facilitate crack initiation. Because of the importance of this failure mode, it has been extensively studied experimentally and with analytical modeling techniques and more quantitative models are available.<sup>3,4,5</sup>

*Laminate and Cu/Laminate Adhesion Degradation.* When a PCB is exposed to elevated temperatures for long periods of time, the adhesion between the Cu and the laminate and the flexural strength of the laminate itself will gradually degrade. Discoloration is usually an early symptom.

Several standards tests are used to compare the thermal resistance of different laminate materials. Cu adhesion is measured using a peel test.<sup>6</sup> Adhesion at elevated temperatures or after elevated temperature exposure gives some insight into the ability of the material to withstand rework and other high-temperature processes. Flexural strength stability is compared by measuring the times at 200°C before the flexural strength decreases to 50 percent of

**FIGURE 57.6** Effects of substrate  $T_g$  and PTH diameter on mean number of cycles to failure. The thermal cycle was 2-h cycle with extremes at  $-62$  and  $+125^\circ\text{C}$ . Multilayer printed circuit board thickness 0.10 in (2.5 mm); Cu in unfilled PTH is 1.2 mil ( $30\ \mu\text{m}$ ) thick. Results from Ref. 33.

**FIGURE 57.7** Cycles to failure vs. PTH aspect ratio for  $-65$  to  $+125^\circ\text{C}$  thermal shock cycles. Various hole diameters, board thicknesses, and board constructions. (After Ref. 3.)

**FIGURE 57.8** Effect of PTH plating thickness on number of thermal cycles to failure for thermal cycles with the indicated peak temperatures. For acid sulfate copper and FR-4 boards. Other hole parameters are the same as Fig. 57.5. (After Ref. 2.)

its original value. The quality of the bond between the resin and reinforcement is compared by measuring the time it takes for copper-clad laminate to blister during a solder float test at 290°C.<sup>7</sup>

**57.2.1.2 Mechanically Induced Failures.** PCBs may be mechanically loaded by test fixtures or processing equipment, when PCAs are loaded into card cages or fixtured into place with brackets, or when the assembly experiences mechanical shock or vibration in use. In general, once the PCA has been assembled, the interconnects to the components are the weak links in mechanical loading situations, not the boards themselves.

**57.2.1.3 Electrochemical Failure Modes.** The primary function of a printed circuit board is to provide electrical connections with the desired, stable, low-impedance and high-impedance insulation between them. A high surface insulation resistance (SIR) value is usually assumed by the circuit designer. Exposure to humidity, especially when ionic contaminants are present, is a common cause of insulation resistance failures that is accelerated by elevated temperatures and electrical bias. The impedance often decreases slowly over a long period of time. If the SIR value falls below the designed level, there will be cross talk between circuit elements that should be isolated, and the circuit may not function properly. Insulation

resistance deterioration is particularly harmful for analog measurement circuits. If these circuits are used to measure low-voltage, high-impedance sources, changes in circuit impedance can result in the deterioration of instrument performance. Medical products that use sensors attached to a patient also pose special concerns, because deterioration of insulation resistance has the potential to cause electrical shock. For general applications, the surface resistivity is usually specified to exceed  $10^8 \Omega/\square$ , but for these specialized applications higher values may be required. Electrochemical failures are usually accelerated by temperature, humidity, and applied bias.

High humidity is a significant cause of reliability problems because many corrosion mechanisms require water to operate. A humid environment is an excellent source of water, even when it is not condensing. Polymers commonly used in PCBs are hygroscopic; that is, they absorb moisture readily from the environment. This phenomenon is reversible; the moisture can be driven out of the PCB by baking it. The amount of moisture absorbed and the time to reach equilibrium with a humid environment depend on the laminate material, its thickness, the type of solder mask or other surface coating, and the conductor pattern.

The moisture absorbed by the PCB and ionic contaminants on or in the PCB play a role in a number of failure modes. Because the permittivity of water is much higher than that of most laminate materials, the increased water content can significantly affect the dielectric constant of the laminate, and thus may affect the electrical functionality of the board by increasing the capacitive coupling between traces. Absorbed and adsorbed water can lower SIR values, especially in the presence of ionizable contaminants (often from flux residues) and DC bias. The introduction of no-clean assembly processes has significantly increased the importance of measuring SIR values because contaminants left on the PCB remain there after assembly. Industrial pollutants can also be a source of ions that accelerate corrosion. In addition, typical industrial pollutants such as  $\text{NO}_2$  and  $\text{SO}_2$  can damage many materials used in PCAs, particularly elastomers and polymers. Some important mechanisms that cause failures due to low insulation resistance include dendritic growth and metal migration, galvanic corrosion, and conductive anodic filament growth. Whiskering can also cause electrical shorts, but neither electrical bias nor moisture is required.

*Conductive Contaminant Bridging.* Bridging of circuits by conductive salts may occur if plating, etching, or flux residues remain on the board. These ionic residues are good conductors of electricity in a moist environment. They tend to migrate across both metallic and insulating surfaces to form shorts. Corrosive byproducts, such as chlorides and sulfides formed in industrial environments, are chemically similar and can also cause shorting. An example of this type of failure is shown in Fig. 57.9.<sup>8</sup>

*Dendritic Growth.* Dendritic growth occurs by the electrolytic transfer of metal from one conductor to another; consequently, it is also termed *electrolytic metal migration*. It is also referred to as *electromigration*, although it should not be confused with the process that occurs in aluminum conductors in integrated circuits, which has a different mechanism. An example of a dendritic growth failure is shown in Fig. 57.10. Dendrites form on surfaces (including the interior surfaces of cavities) when the following conditions are met:

- Continuous liquid water film, a few molecules or more in thickness
- Exposed metals, especially Sn, Pb, Ag or Cu, that can be oxidized at the anode
- Low-current dc electrical bias

It is significantly accelerated by the presence of hydrolyzable ionic contaminants (for example, halides and acids from flux residues or extracted from polymers). Delaminations or voids that promote the accumulation of moisture or contaminants can promote dendritic growth. Conductive anodic filament growth (discussed later) is a special case of dendritic growth. Time to failure is inversely proportional to spacing squared and voltage. The failure mechanisms in accelerated tests have been reviewed.<sup>9</sup>

Dendritic growths usually form from cathode to anode. Metallic ions formed by dissolution at the anode are transported along a conductive path and reduced and deposited at the

**FIGURE 57.9** Migration of corrosion products across the surface of FR-4 bridging two conductors. From Ref. 11. (From IPC-TR-476. Courtesy of Department of Defense.)

**FIGURE 57.10** Transmitted light micrograph through a PCB that failed in the field. Dendritic growth has formed at the interface of a UV-cured screened solder mask and the FR-4 surface.

cathode. The dendrite resembles a tree, since it consists of a stalk with branches. When the growth touches the other conductor there is an abrupt rise in current, which sometimes destroys the dendrite but may also cause an electrical circuit to temporarily malfunction or damage a device.

It has been proposed that the absorption of moisture produces an electrochemical cell. The following electrode reactions for Cu are an example:

where the majority of the leakage is due to the electrolysis of water. Copper metal is dissolved at the anode and migrates to the cathode, where it is no longer soluble. The dendrite that forms follows the resulting pH gradient.<sup>10</sup> The voltage difference between the cathode and anode also affects the rate of dendrite growth. When the cathode and anode are the same metal (e.g., Cu), the voltage difference is determined primarily by the applied bias, although the access of moisture and air also has an effect. Corrosion can be accelerated in a crevice because an oxygen concentration differential between the anode and the cathode develops. When the metals are dissimilar, galvanic corrosion may occur without a bias voltage.

If there is an applied bias, dendritic growth will occur almost instantly if the cathode and anode are under water. A simple laboratory experiment can prove the point. A 6-V bias across two conductors is sufficient to induce rapid growth (readily observable with a low-power microscope) even when distilled or deionized water bridges the conductors, although growth will occur faster with tap water.<sup>11</sup>

*Galvanic Corrosion.* Galvanic corrosion occurs between dissimilar metals because they have differing affinities for electrons (i.e., they are more or less electronegative). Galvanic series have been compiled for many common metals and alloys (see Table 57.1). Metals near the top of the series (noble metals) do not corrode; those near the bottom corrode easily. When these metals are near each other, the more noble metal becomes the cathode, the less noble the anode. Moisture is required to couple the two metals electrically. Applied bias is generally not required, but may accelerate the reaction if the polarity is correct. When the anode is very small compared to the cathode, its corrosion can be very rapid. Conversely, if the anode is much larger than the cathode, corrosion is unlikely to be serious, particularly if the difference in electronegativity is small.

*Conductive Anodic Filament Growth.* Conductive anodic filament growth (CAF) causes electrical shorts when a metal that dissolves anodically is redeposited at the interface between the glass (or other) fibers and the resin matrix of a printed circuit board. Conductive anodic filament growth is promoted by delamination at the glass-polymer interface, which may in turn be promoted by various environmental stresses including high temperatures (greater than about 260°C for FR-4) and thermal cycling. Shorts seem to occur most rapidly when a single fiber bundle connects two pads. Once delamination has occurred, the metal migration that causes shorts to occur is promoted by increasing temperature, relative humidity, and applied voltage. Small conductor spacings also significantly decrease times to failure.<sup>12</sup> In multilayer boards, failures occur faster on outerlayers than innerlayers because the surface layer absorbs moisture more readily. By the same reasoning, solder mask and conformal coating both increase the time-to-failure because they slow the absorption of moisture from the atmosphere into the board.

*Whiskers.* Whiskers are faceted filament-like structures that grow spontaneously on the surface of a plated metal and can cause shorts between closely spaced conductors (see Fig. 57.11). Whiskering can be differentiated from other causes of shorts such as dendritic growth, because neither an electrical field nor moisture is required for whiskers to form. Whiskering is a particular problem with pure tin. The whiskers grow in response to internal stresses in the plating or external loads. Sn whiskers are commonly 50  $\mu\text{m}$  long and 1 to 2  $\mu\text{m}$  in diameter.

Once started, they may grow as fast as 1 mm per month. The tendency toward whisker growth is influenced by a variety of factors including plating conditions and the characteristics of the substrate. Growth may be inhibited by a Cu or Ni barrier layer beneath the tin coating. Pb seems to suppress whisker growth; eutectic Sn-Pb solder is considered almost immune. Whiskers do not cause the corrosion resistance or solderability of the tin coating to deteriorate, so tin may be used as a temporary finish. To avoid whiskering, plated pure Sn should not be used on closely spaced conductors that could short during service, such as connector terminations or component leads.<sup>13,14</sup>

## 57.2.2 Interconnect Failure Mechanisms

### 57.2.2.1 Thermally Driven Failure Mechanisms.

*Thermal Fatigue of Solder Joints.* Thermal fatigue of solder joints has been extensively researched in the last decade. The mechanism of fatigue, accelerated testing methods, and methods for predicting life have all been described at length, although there is still much controversy about many of the details.<sup>15-17</sup> These references also illustrate how modern finite element methods can be used to model the strains in the solder under both operating and accelerated test conditions. This section briefly reviews some of the important principles underlying solder joint thermal fatigue.

The focus of the discussion is on surface-mount solder joints, which have been extensively researched; however, many of the same principles also apply to through-hole solder joints. Through-hole joints are generally less prone to solder joint fatigue failures, so long as the through-hole barrel is full of solder. Ideally, complete fillets should be observed on both surfaces of the board. Reviews of this topic can be found in Refs. 18 and 19.

Thermal fatigue in solder joints occurs because of the thermal expansion (CTE) mismatch between the PCB and the component interconnected by the solder joint (see Fig. 57.12).

**FIGURE 57.11** Tin whisker growth on a tin-plated surface. From Ref. 11. (From IPC-TR-476. Courtesy of Burndy Corporation.)

The imposed thermal cycle  $\Delta T$  results in an imposed cyclic strain  $\Delta \epsilon$  of the solder joint, which is generally the weakest part of the system. The relationship is simple under the assumptions that the part and substrate are rigid, the solder joints are relatively small, and that homogeneous shear deformation caused by the global CTE mismatch predominates:

$$\Delta \epsilon = \frac{(\Delta T)(\Delta \alpha)l}{h} \tag{57.1}$$

**FIGURE 57.12** Schematic illustration of strains imposed on solder joints to leadless and leaded surface-mount components during a thermal cycle. Although the relative displacement of the substrate and component body is the same, the strain on the joint is reduced in the leaded case by the deflection of the lead.

where  $\Delta\alpha$  = difference in thermal expansion coefficients of component and substrate  
 $l$  = distance between center of component and joint  
 $h$  = height of solder joint

If the component has leads or if the substrate is flexible, there will be some compliance in the system that will reduce the strain imposed on the solder joints. The local mismatch between the solder and the component lead or the pad or via metallization on the substrate can also contribute to the strains imposed on the solder.

Like plated-through-holes (PTHs), solder joints fail by a low-cycle-fatigue mechanism which can be crudely approximated by the Coffin-Manson relation

$$N_f = \frac{1}{2} \left( \frac{\epsilon_f}{\Delta\epsilon} \right)^m \quad (57.2)$$

where, again,  $N_f$  is the number of cycles to failure,  $\epsilon_f$  is the fatigue ductility, and  $m$  is an empirical constant near 2. However, unlike the PTH case, the number of cycles to failure also depends on the frequency at which the cycles are imposed and the hold time at each temperature extreme. The reason for this dependence is that, for solders, the primary deformation mechanism causing thermal fatigue failures is creep.

The phenomenon of creep and its connection to fatigue are fundamental to understanding thermal fatigue of solder. Creep is time-dependent deformation that occurs gradually in response to a fixed imposed stress or displacement (see Fig. 57.13). Creep occurs by a variety of thermally activated processes. These processes play an important role only when the temperature exceeds half the melting temperature (in degrees Kelvin) of the material and, even then, the rate of deformation increases strongly with increasing temperature. For electronic solders, even room temperature is well above half the melting temperature; consequently, creep is the most important deformation mechanism of solder. When a displacement is first imposed, the strain is a combination of elastic and plastic strain. The elastic deformation is reversible and damages the microstructure relatively little, while the plastic deformation is permanent and contributes more significantly to the initiation and propagation of fatigue cracks in the solder (see Fig. 57.14). Given time, the creep process relieves some or all of the elastic stress through further permanent deformation. This additional deformation does further microstructural damage and increases the amount of plastic strain imposed when the thermal cycle is reversed. Because there is less time for creep to occur, rapid thermal cycles are less damaging than slow cycles or cycles with long hold times at the temperature extremes, a fact which is important in designing accelerated reliability tests as well as in service. The importance of creep makes the fatigue behavior of solder different from structural metals, such as copper, aluminum, or steel.

In summary, the effects of the thermal cycling profile on solder joint thermal fatigue life are as follows:

• *Temperature extremes:* Decreasing the size of the thermal excursion is the single most effective way to increase the life of the solder joints. Since creep occurs more rapidly at higher temperatures, decreasing the peak temperature of the thermal cycle further decreases the amount of creep deformation that occurs during the hold at high temperature.

• *Frequency:* The thermal fatigue damage per cycle is greater at lower cycling frequencies because there is more time for creep to occur, increasing the amount of permanent deformation. (Recall that most of the damage is

**FIGURE 57.13** Typical behavior of solder in response to a constant applied displacement (for example, due to thermal expansion). The initial stress is relaxed over time as the solder elongates.

**FIGURE 57.14** Thermal fatigue failure in eutectic Sn-Pb solder for a TSOP component. (Photo courtesy K. Gratalo.)

caused by the plastic deformation that occurs during each cycle, not by the cyclic stressing of the joint.)

- *Hold time:* As long as the stress on the solder joint remains nonzero, the thermal fatigue damage per cycle is increased if the hold time is lengthened, again because there is more time for creep to occur. Once the stress relaxation process has gone to completion, no further damage occurs and increasing the hold time further has no effect.
- *Thermal shock:* If the thermal cycle is extremely rapid, the components of the PCA may not be at the same temperature; consequently, the imposed strains may be larger or smaller than at slower rates.

Although the designer may be able to influence the peak temperature through cooling schemes, the thermal cycling profile and the frequency of thermal cycles in service are largely fixed by the application.

Solder joint fatigue life may be increased by decreasing the strain  $\Delta\varepsilon$  imposed on the solder joint by:

- Choosing a package with a compliant attachment scheme. In this case, part of the strain is taken up by deflection of the lead, reducing the amount of strain in the solder. For these packages, the joint life can be further extended by decreasing the lead stiffness and increasing the joint area.
- Decreasing  $\Delta\alpha$ , the difference in the package and substrate thermal expansion coefficients, by carefully selecting the CTE of the package and substrate (see Secs. 57.5.3.1 and 57.5.1.1, respectively).
- Decreasing the size of the package, decreasing  $\Delta l$ .
- Increasing the height  $h$  of the solder joint.

Solder joint fatigue life may also be increased by:

- Decreasing the local CTE mismatch that occurs at the interfaces between the solder and the component lead and substrate metallization. While the substrate metallization is usually

Cu, which is moderately well matched to solder (17 vs. 25 ppm/°C), the leads may be made of a low-expansion metal such as Alloy 42 (−5 ppm/°C) or Kovar, as well as of Cu.

- Decreasing the mean stress imposed on the solder joint (for example, due to residual stress after assembly).
- Increasing  $\varepsilon_f$  or decreasing the creep rate of the solder by controlling the solder joint microstructure or by selecting an alternative solder. (Finer microstructures, which may be achieved by faster reflow cooling rates, have significantly greater fatigue lives because they are resistant to fatigue crack initiation and propagation. Unfortunately, solder microstructures coarsen over time, even at room temperature. Some solders, such as Sn-4Ag and 50In-50Pb, seem to have significantly improved fatigue lives over eutectic Sn-Pb; however, their higher reflow temperatures are not necessarily compatible with FR-4. See Sec. 57.5.2.2.)

*Thermal Shock.* Thermal shocks (>30°C/s) cause failures because differential heating or cooling rates introduce large additional stresses into the assembly versus thermal cycling. Under thermal cycling conditions, it is a good assumption that all components of the assembly are at approximately the same temperature. (High-power components may be an exception.) Under thermal shock conditions, different portions of the assembly are temporarily at different temperatures because their heating or cooling rates are not the same. These temperature transients are caused by differences in thermal mass and thermal conductivity across the assembly; they are caused by component selection and placement decisions and by differences in the physical properties of the materials used in the assembly. The temperature differences across the assembly and any resulting warpage can enhance the stresses normally imposed during temperature changes due to differences in CTE. Thermal shocks can cause reliability problems, such as solder joint failures in overload and crazing in conformal coatings leading to corrosion failures, as well as a range of component failures. Because of the differential thermal stresses that may be induced, thermal shock can cause failures that do not occur during slower thermal cycling between the same temperature extremes. On the other hand, rapid thermal shock cycles actually cause less solder joint fatigue than slower thermal cycles; because little creep occurs, more cycles are needed to cause solder fatigue failure.

**57.2.2.2 Mechanically Induced Failures.** PCAs can also fail in response to externally imposed mechanical stresses, for example, due to mechanical shock or vibration in shipping or in use. These failures can be divided into two categories: overload failures and mechanical fatigue failures, which are caused by mechanical shocks and vibration, respectively. Susceptibility to mechanical failures is closely linked to design of the PCA and the housing in which it is installed. The design determines the resonant frequency of the board, which in turn determines its response to external mechanical stresses. Cantilevers with low natural frequencies, such as an edge-mounted PCB with an unanchored large mass in the center, are particularly prone to failure. Depending on connector design and mounting scheme, solder joints to surface-mount connectors can also be vulnerable, particularly if there are many connector insertion cycles. See Ref. 20 for a more detailed discussion of design methodologies for mechanical durability.

*Overload and Shock Failures of Solder Joints.* When a printed circuit assembly is flexed, jolted, or otherwise stressed, solder joint failures may occur. In general, solder is the weakest material in the assembly; however, when it connects a compliant structure such as a leaded component to the board, the lead flexes and the solder joint is not placed under much stress. Solder joints to leadless components will see large stresses since the board can bend and the components themselves are usually rigid. These stresses can occur if the assembly is mechanically shocked, for example, if the unit is dropped, or during further assembly processes if the PCB is bent through a significant radius. The primary method of eliminating this failure mode is through package selection; however, other factors also play a role, including PCB design, process control during printed circuit board fabrication and assembly, and the shear strength, tensile strength, and ductility of the solder. Solder joints are particularly prone to failure in

tension because the brittle intermetallics at the interface between the solder and the substrate are stressed. Joints with thick intermetallic layers are more susceptible.

**Mechanical (Vibration) Fatigue.** Vibration (a common source is an improperly mounted fan) can cause solder joint fatigue by repeatedly stressing the interconnects. Metal fatigue can occur even when this stress is well below the level that causes permanent deformation (that is, the yield stress). As for thermal fatigue of solder joints, the number of cycles to failure in mechanical vibration fatigue can be described by the Coffin-Manson relation. However, in contrast to thermal fatigue, failures usually occur after very large numbers of small, high-frequency cycles in which most of the strain in the solder is elastic ( $\epsilon = \sigma/E$ , where  $\sigma$  is the stress and  $E$  is the elastic modulus of the solder). Consequently, creep does not play an important role in vibration fatigue. Although the damage per cycle is minimal, the number of cycles can be extremely high; they are often imposed at 50 or 60 Hz. Over time, a crack can nucleate, and subsequent cycles serve to propagate this crack. Again, the risk is much higher for joints to large leadless parts, since there is no compliant structure to take up part of the stress. The amount of damage to the solder joint depends on the imposed strain in each cycle, which depends largely on whether the excitation frequency is close to the natural frequency of the board. The mass of the component (including any heat sink) also plays an important role.

**57.2.2.3 Electrochemically Induced Failures.** The electrochemical failure mechanisms accelerated by temperature, humidity, and electrical bias that were described in Sec. 57.2.1.3 for printed circuit boards also apply to the remainder of the PCA. The solder used for the interconnects and the metal component terminations and lead frame finishes can also be involved in the reactions. The large number of dissimilar metals increases the complexity of the situation and the possibility of galvanic corrosion in a humid environment. In addition, contaminants introduced during printed circuit assembly such as flux residues can contribute to the failures.

## 57.2.3 Components

Although the failure mechanisms of electronic components in general have been described in detail elsewhere<sup>21-24</sup> and are beyond the scope of this chapter, there are a few failure mechanisms that are specifically associated with electronic assembly. In addition, component de-rating for high-temperature service should be evaluated if the unit will be exposed to a severe service environment. Component failures due to thermal shock, exceeding the maximum allowable component temperatures, and plastic package cracking can occur during reflow or wave soldering. These assembly-related failure mechanisms are described briefly as follows.

**57.2.3.1 Thermal Shock.** Multilayer ceramic capacitors may crack if exposed to thermal transients exceeding 4°C/s. These cracks are usually invisible, but may be the sites for dendritic growth in service, when the assembly is exposed to moisture under applied bias. Capacitors with high values and larger thicknesses are most susceptible. These failures can be avoided by following the manufacturer's requirements for maximum temperature excursion and rate of temperature change.

**57.2.3.2 Overtemperatures.** Many components, including connectors, inductors, electrolytic capacitors, and crystals, cannot survive the SMT reflow process, although most will survive wave soldering. Problems can include melting of internal soldered connections, melting or softening of polymeric capacitor dielectrics, and expansion of elastomeric materials. These failures can be prevented by carefully following the manufacturer's recommendations for maximum processing temperature.<sup>25</sup>

**57.2.3.3 Molding Compound Delamination in Plastic SMT Packages.** Plastic-packaged integrated circuits are generally transfer molded using a filled epoxy-based compound.

The plastic can absorb moisture, which tends to accumulate at interfaces within the package, such as the die attach paddle. Subsequent heating can cause the moisture to vaporize, causing delamination at the interface, eventually leading to package failure. This delamination phenomenon is also termed package cracking or “popcorning.” The newer thin SMT components (e.g., TSOPs and TQFPs) are more susceptible because the distance the moisture must diffuse through the plastic to reach internal interfaces is shorter. Delamination when these components are exposed to high temperature may be prevented by ensuring that the components are dry through dry storage and/or baking.<sup>23</sup>

### 57.3 INFLUENCE OF DESIGN ON RELIABILITY

---

Design has a major influence on the reliability of any product. The implications of the demands of the application and expected service environment on product design should be considered as early as possible, since they can influence a wide range of decisions, including integrated circuit partitioning, package and substrate selection (which will impose specific design rules and electrical performance characteristics), component layout and box design, and heat sinking and cooling. IPC Standard D-279, Design Guidelines for Reliable Surface Mount Technology Printed Board Guidelines, is a good place to start in considering these issues. Section 57.2 has already described how design can promote or hinder certain failure mechanisms. Section 57.4 discusses the influence of materials, which are selected during the design process, on PCB and interconnect failures. This section highlights the importance of good thermal and mechanical design.

The size of the thermal cycles imposed on the PCA during power on/off cycles can have an overwhelming influence on the reliability of integrated circuits, solder joints, and plated-through-holes, especially if the external service environment is not particularly severe; consequently, good thermal design is critical to reliability. The thermal cycles imposed on the assembly can come from joule heating from high-power components and from ambient heating. Integrated circuit reliability depends on maintaining low enough junction temperatures, usually below 85 to 110°C, depending on the IC technology. During continuous operation, solder joint temperatures should be kept below about 90°C to avoid the extensive intermetallic growth and grain coarsening that occur during long-term exposure to higher temperatures. As described under Sec. 57.2.1.1 and 57.2.2.1, the size and number of thermal excursions directly affect the fatigue life of both solder joints and plated-through-holes. Component spacings, orientations, air velocities, and enhancements such as thermally enhanced packages, heat sinks, and fans can all have major effects on the thermal cycle experienced by the assembly. PCBs can also be enhanced with metal cores to improve heat dissipation.

As mentioned in the earlier descriptions of specific failure modes, package selection and via and PTH specification can have a major effect on reliability. Although small holes can be desirable from a design density perspective, use of the smallest holes (aspect ratios of 5:1 or greater) should be minimized to minimize the risk of PTH failures. This is especially true if the design includes large through-hole parts which are likely to be reworked frequently (for example, due to test escapes). Similarly, some package styles are more susceptible to solder joint fatigue than others. The effect of integration on reliability can depend on the difference in package styles for the options under consideration. Integration can have a positive effect by reducing the total number of connections that could fail. On the other hand, if it requires a large package with a large CTE mismatch to the substrate, integration may reduce the reliability of the assembly.

The effect of externally imposed mechanical shock and vibration on PCA reliability is largely determined by design factors, although substrate and package selection also play a role. Component placement and PCA mounting in the box determine the natural frequency of the board and, consequently, the extent to which the board deflects. High-mass packages, often due to large heat sinks, are particularly susceptible, especially if there is a large lever arm.

## 57.4 IMPACT OF PCB FABRICATION AND ASSEMBLY ON RELIABILITY

### 57.4.1 Effect of PCB Fabrication Processes

**57.4.1.1 Laminate and Lamination.** Delamination in PCBs may occur between the laminate materials or between the laminate material and the Cu foil. One cause of delamination is defective laminate material. Defects such as incomplete bonding at the resin/fiber interface can result in delamination due to formation of voids at these interfaces. Other common causes of delamination are excessive lamination pressure and/or temperature, contamination at interfaces, heavily oxidized copper foil surfaces, and lack of oxide treatment to enhance adhesion between copper innerlayers and prepreg. Debonding increases the risk of conductive anodic filament growth because it provides a place for moisture to accumulate. It can also result in increased stresses on the plated-through-holes (PTHs) during thermal cycling.

Laminate voids and resin recessions are separations of the laminate material from the copper conductor that may occur during multilayer PCB lamination. Most acceptability specifications prohibit voids larger than 0.076 mm (0.003 in); however, smaller voids are not generally considered to be detrimental to reliability. Some of the causes of laminate voids are entrapped air during lamination, improper flow of resin, and improper epoxy cure, perhaps due to improper lamination pressure and/or temperature, inappropriate heating rate, or too little prepreg.

**FIGURE 57.15** Ladwig panel ductility test. (After Ref. 26.)

**57.4.1.2 Cu Foil.** The major cause of innerlayer foil cracks seems to be poor ductility of the Cu. Poor foil ductility can have a more significant effect on PTH reliability than such well-known culprits as insufficient plating thickness and excessive etchback. A minimum of 8 percent elongation is required for 1-oz foil to eliminate this problem. Foils plated in a Hull cell can be easily evaluated for room-temperature ductility using a 180° bend test. This technique is illustrated in Fig. 57.15, in which the sample panel is bent flat parallel to the axis along which current is varied.<sup>26</sup> Fractures occur at current densities producing low-ductility copper. This test can also be used to evaluate the influence of bath chemistry on ductility or as a bath monitor. Poor copper ductility can be correlated to the microstructure observed in metallographic cross sections.<sup>27</sup>

**57.4.1.3 Drilling and Desmear.** Poor drilling and desmear (etchback) can cause PTH failures by providing stress concentrations that cause fatigue cracks to initiate. They can also cause voids and cracks at the interface to the copper plating, which can trap chemicals during plating and then contribute to conductive anodic filament growth. The following paragraphs describe the effects of poor desmear and

some drilling defects which can cause poor plating, such as resin smear, rough walls, loose fibers, and burrs.

Resin smear can cause weak connections between plated-through-holes and innerlayer copper that fail under environmental stress. There is always some resin smear, which is removed by the desmear (etchback) process. If the desmear process is not effective, or if the resin smear is excessive, poor interconnection to the innerlayers can result. Possible causes of excessive smear are a dull drill or the wrong feed rate or drill speed, all of which can cause increased drill heating, resulting in more smear.

Similar errors in drilling setup can cause rough hole walls, loose fibers, or burrs. These defects are not serious in and of themselves, but can lead to rough plating or copper nodules, which introduce stress concentrations. Rough walls are typically associated with an incorrect feed rate or drill speed, or insufficiently cured material. Loose fibers may be caused by incorrect drilling parameters or improper cleaning. Burrs are usually associated with too fast a drill feed or a dull drill.

Poor drill registration can also decrease reliability of innerlayer via connections or the soldered connection to through-hole components. Poor registration can cause breakout on innerlayers; i.e., the drill hole may fall outside the pad on the innerlayer it is intended to connect to. Breakout increases the probability of PTH barrel failures. Breakout on outerlayers means that the solder fillet for a through-hole component will be partially missing, resulting in decreased reliability for some critical components.

Whether caused by excessive resin smear or not, poor etchback can result in a weak connection between the plating in the hole and the innerlayer copper. Etchback (see Fig. 57.16) removes laminate resin and woven glass in the hole so that the internal copper projects slightly into the hole, permitting the plating to make contact with the innerlayer foil on three sides. This strength is important to prevent cracking at the interface under thermal shock conditions. A review of innerlayer cracking in or around the electroless copper at the junction between the innerlayer foil and the electroplated Cu in the hole suggests that *negative* etchback, in which the electroplated Cu projects into the laminate may also give good results. Zero etchback, when innerlayer foil is flush with the hole wall, is the most dangerous case because the bond line between the foil and the plated copper is located at the point of maximum stress.<sup>28</sup> Causes of insufficient etchback include improper lamination and curing, hardened epoxy smear, a depleted smear removal bath, or a host of process control issues, including improper bath temperature, agitation, or time exposure.

FIGURE 57.16 Schematic illustrations of positive, flush, and negative etchback. (After M. W. Gray.<sup>28</sup>)

**57.4.1.4 Plating.** Defects from the plating process can be responsible for a variety of PTH reliability problems; in addition, as previously described, problems in earlier process steps such as drilling and desmear often show up as plating defects.

Uniform coverage of the hole with electroless Cu is critical to the strength of the through-hole and the adhesion of the metallization to the laminate. Oxidation of the innerlayer copper prior to electroless Cu plating is one source of poor plating adhesion. Poor control of bath composition can have the same effect.

The adhesion of the electroplated Cu to the electroless Cu and the ductility of the electroplated Cu also strongly affect PTH reliability. If the adhesion between the layers is poor, this interface may be the weak point where failure initiates when the PTH is subjected to thermal stresses. Causes can include tarnished electroless copper that is insufficiently microetched, burning the electroless copper with too much current in electrolytic plating, and film contamination

in the electrolytic copper.<sup>28</sup> Susceptibility to innerlayer cracks may be identified by looking for cracks in microsections after a solder float test. The fatigue life of the copper is directly related to its ductility. Plating process parameters and plating additives can strongly affect the plating ductility. For example, Mayer and Barbieri<sup>29</sup> found that good thermal shock resistance of electrodeposits of acid copper depended on proper concentrations of three additives:

1. A leveling agent, to smooth over surface imperfections. (Without the leveling agent imperfections are reproduced in the deposit.)
2. A ductility-promoting agent, which functions to produce the equiaxed grain structure.
3. A carrying agent, to guide the other two components to create the equiaxed structure. (Striations occurred with insufficient carrying agent.)

Additive levels below a certain threshold make the bath more susceptible to impurity effects. For example, iron contamination of 100 mg/L without the recommended concentration of ductility-promoting agents was found to produce a columnar grain structure at the hole corners. Similarly, organic contaminants such as photoresist can produce laminar deposits.

Insufficient plating thickness in the barrel also directly reduces PTH reliability because the stress and, consequently, the strain in the Cu are increased. Overall insufficient plating thickness can be caused by a depleted bath or insufficient plating time, among other things. Insufficient plating thickness in individual holes can also occur as a result of nonuniformities in plating current caused by nonuniform copper feature density. It is particularly difficult to obtain adequate plating thickness in the center of high-aspect-ratio PTHs; good process control is important for aspect ratios greater than 3:1. Good coverage is difficult to obtain for aspect ratios greater than 5:1 by electroplating.

What constitutes “sufficient” plating thickness in PTHs is a subject of some controversy. Specifications range from 0.5 to 1 mil (12 to 25  $\mu\text{m}$ ) Cu thickness in the barrel. There are at least two reasons why there is no one right specification. First, different applications provide different levels of thermal stress and demand different levels of reliability. Second, design factors such as the aspect ratio of the plated holes determine the susceptibility of the PTHs to thermal fatigue. The IPC recommends an average minimum copper-plating thickness of 0.5 mil for consumer products (Class 1) and 1.0 mil for general industrial and high-reliability applications (Classes 2 and 3).

Poor coverage at the PTH knee can significantly accelerate PTH failures because it means the plating is thin at a point of high stress. It can be caused by excessive concentration of the organic leveling agents added to an electroplating bath.

**57.4.1.5 Solder Mask Application.** If it is properly applied, solder mask plays an important role in reducing the possibility of insulation resistance failures on PCBs. The solder mask protects the substrate from moisture and contaminants, which would otherwise promote shorting under electrical bias. The ability of the solder mask to perform this function depends on good conformity and adhesion of the solder mask to a clean, dry substrate. If solder mask conformity or adhesion is poor, moisture and other contaminants may accumulate at crevices or delaminations between the solder mask and the substrate. Substrate cleanliness is particularly critical, because in addition to causing poor solder mask adhesion, it can also provide the ionic species needed for rapid electromigration. When the laminate material absorbs moisture readily (e.g., polyimide, aramids), baking before reflow may be required to prevent solder mask delamination (as well as reinforcement/resin delamination). Other causes of poor adhesion or conformity include moisture on the board when the solder mask is applied, improper solder mask lamination or coating parameters, and improper solder mask cure parameters. Incomplete solder mask cure can create local soft pockets, which are common sites for delamination or contaminant entrapment. Solder mask over solder should also be avoided because delamination caused by reflow of the solder may allow contaminants to be entrapped.

## 57.4.2 Effects of Printed Circuit Assembly Processes

**57.4.2.1 Stencil Printing and Component Placement.** Stencil printing and component placement generally do not cause reliability problems; however, poor stencil design or stencil printing or placement process control can create issues with solder volume and component cracking. Very low solder volume can result in weak solder joints that fail rapidly in thermal fatigue or by overload. In some cases, excessive solder volume can also accelerate solder joint fatigue failures because the compliance of the lead is reduced. Assuming that the stencil was designed and manufactured correctly, low solder volumes are usually due to small or missing paste bricks caused by a clogged stencil aperture, a stencil that needs cleaning, or improper stencil-printing parameters. Paste bridging can cause low solder volumes on some joints and high volumes on others because one joint may rob solder from another. Paste bridging may be caused by improper stencil design or stencil-printing parameters or by excessive force when placing chip carriers (e.g., PLCCs) and quad flat packs (e.g., PQFPs). Excessive placement force can also cause component cracking, particularly for small leadless ceramic components.

**57.4.2.2 Reflow.** The reflow process attaches SMT and some TH components to the PCB by melting solder paste to form solder joints using an oven with a controlled thermal profile (see Fig. 57.17) and, in some cases, a controlled atmosphere (often  $N_2$ ). Reliability problems that can arise due to improper reflow parameters can be grouped into three categories: damaged components, poor solder joints, and, for no-clean assemblies, cleanliness issues.

**FIGURE 57.17** Schematic reflow profile for eutectic Sn-Pb solder paste, FR-4 substrate and typical surface-mount components illustrating key features from a reliability perspective.

**Component Damage.** The reflow process is responsible for most of the assembly-process-related component failures described in Sec. 57.2.3. These failures include molding compound delamination in plastic packages that have absorbed moisture (popcorning) and component failures due to overheating or thermal shock caused by excessive heating or cooling rates. All of these problems are preventable with good procedures and process controls.

Package cracking can be prevented by storing components in the unopened dry bags in which they are shipped and by baking the moisture out of components that have been exposed to ambient conditions for too long. The manufacturer's recommendations regarding bake-out conditions and maximum exposure times before reflow should be followed, but a good general guideline is that packages that have been exposed to the atmosphere for more than 8 h should be baked to a moisture content below 0.1 percent by weight immediately prior to use; a bake of  $125^{\circ}\text{C}$  for 24 h is usually safe, although shorter times may be acceptable. Note that the same concerns apply for rework and second-side reflow of double-sided boards; for example, if the boards are stored for several days between reflow steps, bake-out before the second reflow step may be required.

Component failures due to overheating or thermal shock can be prevented by monitoring the reflow temperature profile in several locations on the PCB to ensure that it meets the manufacturer's specifications for temperature-sensitive components. Measuring the board profile is important because temperatures on the board can differ significantly from oven panel temperatures and from the ambient temperature in each oven zone. Temperatures may also vary significantly across the board if there are large differences in the thermal mass of the components or in component density. Areas of the assembly that are devoid of components are particularly sensitive to overheating, which can damage the laminate as well as any small components in the area. Temperature variations across the assembly tend to be much smaller for ovens with predominantly convection heating than for ovens with predominantly infrared heating. A poor reflow profile can also cause a variety of other problems; some of the others that also affect reliability will be mentioned here.

*Poor Solder Joints.* A sound solder joint wets both the component termination and the substrate well, does not contain large or numerous voids, and does not have excessively thick intermetallic layers at the interfaces. When using solder paste, the reflow profile is the dominant factor in achieving these goals. Good wetting requires solderable incoming materials, but it also requires a reflow profile that gives the flux sufficient time to act in the right temperature range. In addition, the profile should ensure that all parts of the board are at least 15°C over the melting temperature of the solder for at least several seconds. "Cold," improperly formed solder joints can occur if the solder does not fully melt or if oxidation prevents the solder balls in the paste from melting together. The latter problem can be caused by an improper reflow profile or the wrong reflow atmosphere. Voiding is generally caused by a reflow profile that does not permit enough time for the solvents in the paste to boil off before the solder melts. All of these problems can be avoided by ensuring that the reflow profile of the board and reflow atmosphere (e.g., O<sub>2</sub> level) correspond to the manufacturer's recommendations for the solder paste.

Excessively long reflow times (time above the solder liquidus) can cause thick intermetallic layers to form at the interface between the solder and the component termination or substrate. Formation of an intermetallic layer at the solder interface indicates good metallurgical bonding, but thick intermetallic layers are undesirable because intermetallics are brittle and prone to fracture, especially if the joint is stressed in tension rather than shear. Because solder joint fatigue takes place in the solder rather than in the intermetallics or at the solder/intermetallic interface, the basic mechanism is unaffected. Nonetheless long reflow times and the accompanying thick intermetallic layers should be avoided. Cross-sectioning can be used to judge the extent of intermetallic growth; as long as the intermetallic layer thickness is relatively small compared to the joint thickness, reliability should not be adversely affected.<sup>30</sup> (Note however that minimizing reflow time is still a good thing; the reliability of all the components on the board is adversely affected by time at elevated temperature, both during processing and in service. Unfortunately, in developing a reflow profile, there is often a tradeoff between reflow time and peak temperature.)

*Cleanliness Issues.* An improper reflow profile can also cause solder balling and increase the amount of flux residue remaining on the board after reflow. The reliability concerns associated with these process issues are discussed in Sec. 57.4.2.4. Solder balls can be caused by a combination of improper paste storage or handling, incompatibility between the flux and reflow atmosphere, and a reflow profile that does not conform to the manufacturer's specification.

**57.4.2.3 Wave-Soldering Process.** Improper wave-soldering practice can cause reliability problems. The root cause is generally thermal shock, overheating of the top side of the board, or contamination of the solder bath.

*Component Cracking.* Ceramic components such as resistors and capacitors will crack under thermal shock conditions. When they are located on the bottom of the board they can be heated rapidly by the solder wave. Prevention is relatively simple; the assembly must be preheated before it hits the solder wave. A temperature difference between the component and the solder wave of less than 100°C is recommended; a typical preheat temperature is 150°C.

*Hot Cracking.* Hot cracking, also known as partial melting, can cause previously sound solder joints to fail during the wave-soldering process. A typical mixed TH/SMT assembly is manufactured by assembling the surface-mount components to the top side, inserting the through-hole components, and wave soldering these components to the board from the bottom side. The first step of the wave-soldering process usually involves preheating the entire board. During the wave-soldering process, the SMT joints on the top side will be further heated due to conduction of heat through the board, particularly if there are many vias. If these solder joints reach the melting temperature of the solder (usually 183°C), the joints will begin to melt. If the joints melt completely, the assembly may be intact after reflow; however, if they only begin to melt, the surface tension of the solder is insufficient to prevent cracks from forming between the portions that are still solid. This type of failure is often detected as an intermittent in the field, since in-circuit test fixtures may bring the two halves of the joint into mechanical contact, causing the joint to appear electrically good.

*Solder Bath Contamination.* Solder bath contaminant levels should be regularly monitored and limited to levels found in IPC-S-815. Many metals found on component terminations will dissolve into molten eutectic Sn-Pb solder. High Cu concentration is a relatively common occurrence that is associated with a rough solder surface and causes poor solderability. High Au concentrations can embrittle solder joints (see Sec. 57.5.1.3 for a discussion of this phenomenon).

**57.4.2.4 Cleaning and Cleanliness.** Improper handling procedures and improper selection and application of solder paste and wave-solder fluxes and their associated cleaning processes can cause ionic residues to be left on the board that result in low surface insulation resistance. Low SIR values can cause failures in and of themselves for some sensitive circuits and in other cases set up the conditions for further corrosion that eventually result in short circuits. Sodium and potassium ions and halide ions are the most commonly quoted culprits for these failures. The major source of sodium and potassium ions is handling, i.e., fingerprints. The primary sources of halide ions are soldering fluxes.

The elimination of chlorofluorocarbons (CFCs) mandated by the Montreal Protocol has caused most SMT manufacturers to switch to water cleaning or a no-clean process. Water cleaning has been used by most printed circuit board manufacturers for some time, but outgoing cleanliness was not carefully monitored since the boards were cleaned again after assembly. Both the no-clean and water-clean assembly approaches must meet certain criteria to provide reliable assemblies.

In a no-clean assembly process, there is no cleaning step after SMT or TH assembly. The finished assembly has whatever contaminants were present on the incoming board and components, plus any additional contaminants added during the assembly process. These contaminants are generally flux residues, both from the solder paste and the flux applied for wave soldering, although adhesives and fingerprints are other potential sources. A no-clean flux should have a low solids content so that it leaves little residue and be free of ionic contaminants such as halides that promote corrosion. Use of a flux that contains halides will result in low SIR readings and may result in shorting due to corrosion, particularly if the assembly is exposed to a humid environment. However, the incoming components and boards are cleaned, it is important that they are also free of halides when they arrive for assembly. Although SIR testing provides the best correlation with reliability, an ionic contamination test may be used for statistical process control. The measurement method may be found in MIL-P-28809.

Solder balls may also be a problem on no-clean assemblies. Solder balls are formed during reflow of solder paste when some solder is left behind when the solder melts and beads up and by spattering during wave soldering. These solder balls are usually washed off by solvent or water cleaning; however, in a no-clean process they remain on the board. Solder balls can cause shorts by bridging the pads of small capacitors or resistors or the leads of fine-pitch quad flat packs.

In a water-clean assembly process, the assemblies are cleaned with jets of deionized or saponified water after SMT and TH assembly. This process will work only if the flux residues

and other contaminants are sufficiently soluble in either water or saponified water. It also depends on good access to the residues; consequently, a minimum component standoff that permits cleaning is required if it is possible for flux to get underneath the component body during assembly. It is almost as important that the board be thoroughly dried because water is an excellent medium for galvanic corrosion. Proper drying can be quite difficult even with substantial air flow since water has a much lower vapor pressure than CFCs do. If the component standoff is low, capillary action holds water in the small gap. If water cleaning is done in midprocess (e.g., before a reflow or wave-soldering step), plastic components may absorb moisture; in this case, the board must be baked out to prevent package cracking in subsequent high-temperature processes (see Secs. 57.2.3 and 57.4.2.2).

The rework process should not be overlooked in planning a flux and cleaning strategy. Compared to the automated processes that proceed it, it is typical to use a more aggressive flux and more of it to do rework. Use of a halide-free flux or proper cleaning after rework is essential to prevent cleanliness-related reliability problems.

Finally, the cleaning process itself can damage the PCA. Ultrasonic cleaning can damage components with internal wire bonds or die attach. It has also been observed to cause fatigue cracking of solder joints to LEDs and SOT-23s when the energy density was high because these components have terminations that are mechanically resonant near the generator frequencies. Solvent cleaning can attack the polymers used in solder masks, PCBs, conformal coatings, and components. D-limonene (terpene)-based solvents should be tested carefully for compatibility with exposed plastics and metals.

**57.4.2.5 Electrical Test and Depanel.** The electrical testing and depanel processes can impose large mechanical stresses on the PCB and its components. In-circuit electrical test utilizes a bed of nails or two beds in a clamshell arrangement to contact each electrical node on the board. The probes must contact the board with sufficient force to make good electrical contact. If the board is not properly fixtured or if the loading in a clamshell fixture is unbalanced, the resulting deflections can cause solder joint or component cracking. These cracks may cause electrical failures immediately or after some period of service. Depaneling, the process of separating individual images from a larger panel, is done by a variety of methods. The associated mechanical deflections or vibration can cause component cracking or solder joint fatigue.

**57.4.2.6 Rework.** Rework, whether repair of open or shorted solder joints or replacement of defective components, has a significant negative effect on component reliability. If there were not enough other incentives for low process defect rates, the effect on product reliability would be enough. Reworking the quality in does not bring the board to the quality level that would have been reached if the boards were built right the first time. Some of the ways rework processes can adversely affect reliability are described here.

*Thermal Shock During Rework.* Thermal shock to components is a concern during rework as it is during reflow. The maximum heating or cooling rate is driven by the requirements for ceramic capacitors and should not exceed  $4^{\circ}\text{C/s}$ .<sup>31</sup>

Rework of large through-hole components, such as pin grid arrays (PGAs) and large connectors, poses special problems. If it is improperly done it can result in PTH failures. Because the damage during these large thermal cycles is cumulative, the number of rework operations at a given site should be monitored and limited to a safe number. The number of cycles that will cause a fatigue crack to initiate in the copper in the barrel and propagate to failure depends on the aspect ratio of the PTH, the type and thickness of plating in the hole, the substrate material, etc.

Due to the large number of joints that must be melted at once and the large thermal mass of the components, rework of large TH components is often done with a solder pot. The thermal shock caused when the molten solder hits the board can cause PTH cracking due to z-axis expansion. A preheat step (to about  $100^{\circ}\text{C}$  for FR-4) helps to reduce the damage. The time the board is in contact with the solder fountain should also be minimized since dissolution of the copper plating inside the PTH occurs during this time. Thinning the plating in the PTH tends

to increase the strain in the Cu during thermal cycling, further accelerating failure. If the total time for part removal and replacement is kept under 25 s, little dissolution is measured.<sup>32</sup> Weakening of the PTH by copper dissolution during PGA rework can be essentially eliminated by using NiAu plating. Although the thin Au coating that protects the Ni dissolves almost instantly during soldering, Ni dissolves quite slowly and effectively prevents thinning of the PTH metallization.

*Damage to Adjacent Components.* Rework can also damage components adjacent to the one being repaired or replaced. The hot cracking phenomenon during wave soldering can also occur in solder joints near the rework site if they reach the melting temperature of the solder. At slightly lower temperatures, rapid intermetallic growth can occur. Temperature-sensitive components can also be damaged. To prevent these problems, localized heating and shielding should be used and the temperature of adjacent components monitored. The generally recommended maximum temperature is 150°C. There are wide variations in the amount of heating of adjacent components among different types of rework equipment and between process protocols.<sup>33</sup>

*Other Rework Concerns.* Rework can cause a host of moisture-related problems including measling and package cracking. Both of these problems can be prevented by baking the PCA beforehand to drive out moisture and by minimizing the peak temperature and time at elevated temperature during rework. Rework temperatures also weaken the adhesive bond between the copper conductors on the PCB and the laminate material; use of force to remove components when the solder is not completely molten can cause the pad to lift off the board. The latter can be a particular problem when using a soldering iron.<sup>21,31</sup>

## 57.5 INFLUENCE OF MATERIALS SELECTION ON RELIABILITY

### 57.5.1 PCB

**57.5.1.1 Substrate.** Difunctional FR-4 is the workhorse material for high-reliability PCBs because its moderate  $z$ -axis expansion and moisture uptake characteristics are available at relatively low cost. Alternative substrate materials (see Table 57.2) are generally selected for more favorable properties in one or more of the following three areas: thermal performance, including maximum operating temperature and glass transition temperature; thermal expansion coefficient; and electrical properties, such as dielectric constant. Thermal performance characteristics and thermal expansion coefficient can have a significant effect on PCB and solder joint reliability. Other characteristics of these materials, such as moisture absorption, can also affect reliability.

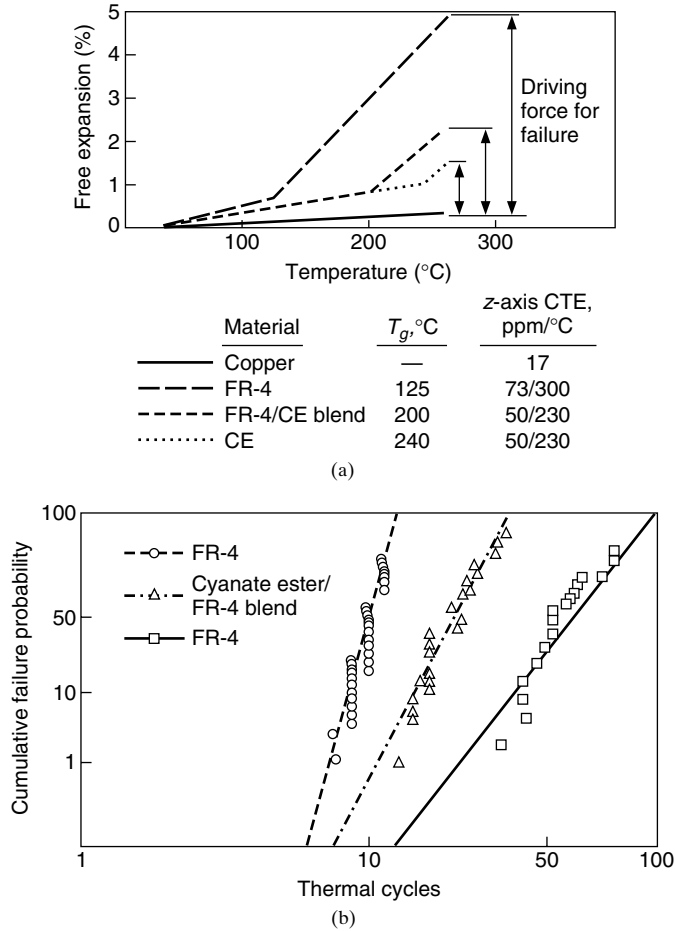

PTH reliability can be improved by selecting a laminate with a lower  $z$ -axis CTE or a higher  $T_g$ . The damage caused to the PTH during a thermal cycle depends on the total  $z$ -axis expansion during the temperature change. Since the CTE is much lower below  $T_g$  than above,

**TABLE 57.2** Physical Properties of Some Printed Circuit Board Laminate Materials

Material	CTE, $x,y$ ppm/°C	CTE, $z$ ppm/°C	$T_g$ , °C
Epoxy glass (FR-4, G-10)	14–18	180	125–135
Modified epoxy glass (polyfunctional FR-4)	14–16	170	140–150
Epoxy aramid	6–8	66	125
Polyimide quartz	6–12	35	188–250

Source: After IPC-D-279.

the PTH strain can be reduced by increasing the  $T_g$  so that more or all of the cycle is below  $T_g$  (see Fig. 57.18a). Figure 57.18b shows that the increase in life can be quite significant. The strain imposed on the PTH can also be reduced by decreasing the CTE at temperatures below  $T_g$ , but the effect on total z-axis expansion is much smaller.

**FIGURE 57.18** (a) Effect of differences in CTE below  $T_g$  and  $T_g$  on the free z-axis expansion of FR-4 (epoxy-glass), cyanate ester (cyanate ester-glass) and a cyanate ester/epoxy blend.  $T_g$  and CTE for each material below/above  $T_g$  are indicated. Cyanate ester is abbreviated CE in the figure. Cu is shown for comparison. (b) Weibull plot of PTH failures for these substrates during thermal shock cycling between 25 and 260°C. PTHs are 0.029-in diameter on 0.100-in grid on 0.125-in-thick laminate. (After Fehrer and Haddick.<sup>4</sup>)

A variety of specialty resins with increased  $T_g$  is available, albeit at higher prices. Modified FR-4 materials with higher functionality offer the best combination of improved  $T_g$  at a reasonable price. Further improvements in  $T_g$  and other characteristics can be obtained with bis-maleimide triazine (BT), GETEK, cyanate ester, and polyimide, but at greater price penalties.

Interconnect failures due to thermal fatigue of solder joints can be reduced by closely matching the  $x$ - $y$  plane thermal expansion properties of the substrate to at-risk components. Large leadless ceramic components that are used because of their hermeticity pose a particular risk. Possible approaches include altering the laminate reinforcement material, adding constraining metal cores or planes, and switching to a ceramic substrate. The first two approaches are discussed here. A more extensive discussion of these options can be found in Ref. 33.

A lower  $x$ - $y$  plane thermal expansion coefficient laminate can be obtained by replacing the continuous-filament E-glass used in most FR-4 PCBs with an alternative material. The CTE decreases as the fraction of silica dioxide ( $\text{SiO}_2$ ) decreases and the level of quartz (as well as the cost) increases in the progression E-glass, S-glass, D-glass, and finally quartz, which has a CTE about one-tenth of E-glass. Aramid (Kevlar) actually has a negative CTE, but it is available in only a few glass styles. Some of the disadvantages of aramid fibers are higher  $z$ -axis expansion and higher moisture absorption relative to glass fibers that can result in decreased susceptibility to PTH failures and corrosion-related insulation resistance failures, respectively. Aramid fiber is also used to make nonwoven paper fabric which has a lower modulus, but also a much smoother surface because there is no weave pattern. This form has better dimensional stability and reduced microcracking during thermal cycling.

Low-thermal-expansion metal cores or planes can also lower the overall substrate CTE because they constrain the expansion of the polymer material they are laminated to (see Fig. 57.19). Copper-Invar-copper (CIC) is the most widely used material for constraining metal cores (also termed polymer-on-metal or POM construction), followed by copper-molybdenum-copper (CMC). The PCB and core are bonded with a rigid adhesive, usually in a balanced construction to minimize warping. Other special processing is also required. The CTE of the assembly can be estimated using a simple model for composite structures most often written as

$$\text{CTE(overall)} = \frac{\sum E\alpha t}{\sum Et}$$

where  $E$ ,  $\alpha$ , and  $t$  are the elastic modulus, CTE, and thickness, respectively, of the various layers. A more sophisticated model can be found in Ref. 34.

An example of the low overall CTE that can be obtained using a CIC core is shown in Fig. 57.20. Unfortunately, the constrained  $x$ - $y$  axis expansion results in increased  $z$ -axis expansion that can reduce PTH reliability to dangerously low levels, especially in an environment in which the full mil-spec thermal cycle of  $-55$  to  $+125^\circ\text{C}$  is imposed. Consequently, use of polyimide is recommended with CIC cores. Because of its high  $T_g$  and low CTE below  $T_g$ , polyimide imposes much lower strains on the PTH for a given thermal cycle than other dielectrics.

Constructions utilizing constraining low-CTE metal planes usually use CIC layers in place of ground and power planes in a standard multilayer board. The same PTH reliability concerns that hold for CIC core boards apply to these PCBs as well. PTH reliability can be improved by using polyimide resin and by using CuNiAu or CuNiSn metallization in the PTHs. These substrates are easier to manufacture than metal core boards because standard PCB fabrication techniques can be used for the most part.

Resin material can affect fiber/resin delamination, one of the prerequisites for conductive anodic filament growth. Measling occurs at about  $260^\circ\text{C}$  for FR-4, but may occur at lower temperatures for boards with more hygroscopic resins.

**57.5.1.2 Solder Mask.** The three major types of solder mask—liquid screen-printed, dry film, and liquid photoimageable (LPI)—come with different benefits and concerns from a reliability perspective. The solder mask material should be selected for its compatibility with the heat and solvent characteristics of the assembly process, its capability to provide good conformity over surface features on the PCB, and its ability to tent vias if required. Since many of these characteristics are product-specific, only a few general guidelines can be provided here. Where tenting of vias is required to keep solder, moisture, or flux from wicking up

**FIGURE 57.19** Examples of alternative construction using Cu-Invar-Cu to achieve low- $x$ - $y$  CTE: (a) metal core (sides A and B may be multilayer boards) and (b) metal plane constructions. (After F. Gray.<sup>34</sup>)

under components, dry film solder mask should be used. However, excessively thick solder mask, particularly dry film over closely spaced traces, can result in crevices. If the solder mask cannot flow enough to adhere closely to the board, the resulting crevices can entrap contaminants such as flux that can accelerate corrosion later. LPI solder mask provides excellent coverage, resolution, and alignment to other features, but it generally cannot be used to tent vias. IPC-SM-840 defines the performance and qualification requirements for solder mask.

**57.5.1.3 Metal Finish.** The metal finish on the SMT and TH pads can have an impact on PTH reliability and on the reliability of the solder joints made to these pads. Common metal finishes for solder-mask-over-bare-copper (SMOBC) boards include hot-air solder leveling (HASL or HAL), organic-coated copper (OCC), and electroless NiAu. Galvanically plated CuNiAu and CuNiSn made by another processing route are also available. These finishes provide a solderable finish for later printed circuit assembly. The pros and cons of the various finishes are discussed in turn.

Of the common metal finishes, HASL is the only one which can directly reduce reliability of the board. In a typical HASL process, the board receives a severe thermal shock when it is dunked into a bath of molten eutectic Sn-Pb solder. The PTHs can survive only a certain number of solder shocks without failure; this process uses up one of these thermal cycles before the board leaves the fabricator.

**FIGURE 57.20** Example of the low overall CTE that can be achieved for a metal core construction similar to Fig. 57.19a. Two 0.055-in (1.4-mm)-thick multilayer FR-4 boards were bonded to a 0.085-in (2.2-mm)-thick copper-Invar-copper core. Data shown are for the third thermal cycle. (After F. Gray.)

Organic-coated copper provides a consistent, flat, solderable metal finish. Exposed copper after printed circuit assembly has been a persistent reliability concern, because it is generally not permitted on HASL boards. While exposed Cu on HASL boards is associated with poor solderability, which may be due to contaminants that were not removed before the HASL process, there is little evidence that exposed Cu on a properly processed OCC board causes reliability problems. Surface insulation resistance (SIR) testing shows that OCC boards have comparable or better performance than HASL boards in high-temperature, high-humidity storage tests.

CuNiAu boards fabricated either with the NiAu as the Cu etch resist or by the SMOBC process followed by electrolessly plating Ni and Au can confer improved PTH reliability. There are two mechanisms for the observed improvement: the enhanced rivet effect provided by the Ni and the elimination of Cu dissolution during solder shocks such as wave soldering or PGA rework. For high-aspect-ratio holes, electroless Ni confers an additional benefit because the plating thickness in the barrel is more consistent than for conventional electroplating.

In the simple picture of PTH failure shown in Fig. 57.3, the comparatively low CTE metal-plated PTH acts as a rivet that resists the  $z$ -axis expansion of the PCB. Because Ni has a higher elastic modulus than Cu, it strains less under the stress imposed by the expanding PCB. Consequently, adding Ni plating lowers the strain imposed on the Cu and lessens the amount of fatigue damage. In this model, the Ni protects the Cu, increasing PTH life.

The ability of the Cu to withstand the forces imposed on it by thermal expansion of the PCB is also dependent on the thickness of the Cu in the PTH. Unfortunately, in the SMOBC process all subsequent steps after pattern or panel plating reduce the Cu thickness from the plated amount. Nickel plating is resistant to the etches and developers used in later processing steps, so it protects the underlying copper from thinning due to dissolution. The HASL process and rework of large through-hole connectors or pin grid arrays (PGAs) can have particularly negative effects. Cu dissolves rapidly into molten eutectic Sn-Pb solder. During the HASL process or component removal and replacement with a solder fountain, large amounts

of Cu can dissolve from the knee of the PTH. Nickel barrier plating minimizes this effect because Ni dissolves far more slowly in eutectic Sn-Pb solder than Cu does.

Use of Au plating can embrittle the eutectic Sn-Pb solder most commonly used in electronic assembly. Gold plating of various thicknesses is used for a variety of reasons, including as a solderability preservative over nickel plating, for connector contacts, and to provide wire-bondable pads. Reliability problems can arise because Au has a high solubility in eutectic Sn-Pb solders at reflow temperatures and dissolves extremely rapidly. In most cases, the Au finish on a PCB or component termination will be completely dissolved into the solder. In a wave-soldering process, the Au will be washed into the bath, requiring monitoring and bath changes to maintain the Au concentration at a low level that does not affect the process. However, in a reflow process, this Au remains in the finished solder joint. To avoid embrittlement of the solder by the  $\text{AuSn}_4$  and  $\text{AuSn}_2$  intermetallics that can form, the Au concentration should be kept below a critical level that most authors set at 3 to 5 percent by weight.<sup>35,36</sup>

For most components used today, a nominal 5- $\mu\text{m}$  (0.1- $\mu\text{m}$ ) thickness Au flash to preserve solderability is harmless. However, if thicker Au plating (e.g., for connector contacts or wire bonding) is used, if the component lead pitch is less than 0.5 mm, or if the component lead terminations are also Au-plated, care should be taken to ensure that the Au concentration remains below the 3 to 5 percent by weight limit. For some applications in which use of thick Au is unavoidable, 50In-50Pb solder, in which Au dissolves very slowly, has been used to get around this problem.<sup>37</sup> Selective thick Au plating is another option.

The Au concentration in the finished reflowed solder joint can be estimated using the following equation:

$$\text{Wt. \% Au} = \frac{(\text{Au volume})}{[(\text{Au volume}) + (\text{solder volume})(\rho_{\text{solder/Au}})]}$$

where  $\rho_{\text{solder/Au}}$  is the ratio of the density of the solder to the density of Au (0.4552 for 63Sn-37Pb solder). If the Au is less than 1  $\mu\text{m}$  thick, it is usually valid to assume that all of the Au on the joined surfaces has dissolved into the joint. The solder volume should include any solder plated on either the component or board termination as well as that applied by stencil printing. It is common to specify only a minimum Au plating thickness; it is important to use a representative value to calculate the expected Au content in the solder joint.

## 57.5.2 Interconnect Material

**57.5.2.1 Eutectic Sn-Pb Solder.** Eutectic Sn-Pb solder, 63Sn-37Pb, and near-eutectic Sn-Pb solders, including 60Sn-40Pb and 62Sn-36Pb-2Ag, are used in the overwhelming majority of soldered electronic assemblies. From a reliability perspective, the most important characteristics of these solders are their susceptibility to creep and fatigue because ambient temperatures are so close to the metal temperature of the solder, their ability to dissolve common termination metals rapidly and in large amounts, and their tendency to form thick intermetallic layers with termination metals.

Although solder joint thermal fatigue is a major source of PCA field failures, the industry has used the same solder alloy for several decades. At present, there is no generally agreed-on alternative to eutectic Sn-Pb solder that has improved fatigue resistance as well as the favorable processing characteristics of eutectic Sn-Pb solder. However, there has been a tremendous surge in research into alternative solders, especially Pb-free solders, in the last decade and one can expect improved alloys in the future. There is some evidence that solders containing 2 percent Ag have improved properties in thermal cycling to high temperatures.

Many common termination metals dissolve rapidly in eutectic Sn-Pb solder, including Ag, Au, and Cu.<sup>36</sup> The dissolved metals can alter the properties of the solder. Reliability can also be impacted if the termination metal is dissolved entirely, the most notable case being Ag (or AgPd with less than 33 percent Pd) terminations on ceramic resistors and capacitors. If the entire

termination thickness is dissolved, the solder will dewet from the ceramic part, leaving an open joint if the entire termination is dissolved, or a substantially weakened one if it is dissolved only in some areas. Use of 63Sn-36Pb-2Ag substantially reduces this problem, since the presence of Ag in the solder reduces the dissolution rate of the Ag forming the termination.

Finally, eutectic and near-eutectic Sn-Pb solders form intermetallics with the termination metals that influence the properties of the finished joints. On the most common termination metals, Cu and Ni, continuous intermetallic layers form:  $\text{Cu}_3\text{Sn}$  and  $\text{Cu}_6\text{Sn}_5$  on copper, and  $\text{Ni}_3\text{Sn}_4$ ,  $\text{Ni}_3\text{Sn}_2$ , and  $\text{Ni}_3\text{Sn}$  on nickel. These intermetallic layers are composed of compounds that are hard and brittle in comparison to both the solder and the termination metals. Although there have been few systematic comparisons made, it is general wisdom that when the intermetallic layers are very thick, solder joint reliability is reduced. While solder joint thermal fatigue mostly involves cracking in the solder, the intermetallics can affect their ability to withstand mechanical stresses, particularly in tension. The Ni-Sn intermetallics are particularly brittle. In every case, an effort should be made to minimize the total time the solder is molten during processing and to minimize the time above about  $150^\circ\text{C}$  once the solder joint is formed.

**57.5.2.2 Other Solders.** A number of other solders are used in specialized applications, including 80Sn-20Pb for lead finishes, 50In-50Pb for solder on thick Au, high-Pb solders such as 95Pb-5Sn and 97Pb-3Sn for flip-chip assemblies (usually on ceramic substrates), and low-temperature solders such as 58Bi-42Sn and 52In-48In, where hierarchical soldering is desirable. Further information can be found in Refs. 23, 24, and 38.

**57.5.2.3 Conductive Adhesives.** Electrically conductive adhesives are used today for specialized applications such as connections to LCD displays and attachment of small resistors and capacitors. These materials consist of conductive particles, usually silver flakes or carbon, suspended in a polymer matrix, most commonly epoxy. The electrical resistance of the contact to the PCB tends to be unstable over time, so these materials are not suitable for applications requiring a constant, low-resistance contact. The primary failure mechanism is moisture migration through the epoxy to the interface, resulting in oxidation of the contact metal. Adhesion strength is also a reliability concern. New materials suitable for a broader range of applications are under development. Further information can be found in Ref. 39.

### 57.5.3 Components

Components and their packages influence many of the field failures of electronic assemblies. Packages are primarily designed and selected for their ability to protect the electronic components inside; for example, ceramic packages may be selected over plastic ones for their greater hermeticity. This section will discuss the ways in which package selection can influence solder joint and cleanliness-related failures.

**57.5.3.1 Package Selection to Minimize Solder Joint Thermal and Mechanical Failures.** Minimizing solder joint thermal and mechanical fatigue failures means minimizing the global and local mismatches in the system and introducing compliance that minimizes the stresses and strains transmitted to the solder joints. Figure 57.21 illustrates the important features of these systems. The following describes how component parameters can influence the incidence of solder joint failures.

*Surface-Mount Technology vs. Through-Hole Components.* Although there is little compliance in the system, the reliability of through-hole solder joints generally exceeds that of surface-mount joints in thermal fatigue (assuming good solder fillets are present in both cases), because the loading geometry makes it difficult for a crack to propagate far enough to cause an electrical failure. However, the PTHs themselves may be susceptible to failure if they are exposed to even a few thermal cycles well above  $T_g$ .

**Plastic vs. Ceramic Package.** The global mismatch between the component body and substrate is minimized for most printed circuit boards if the package is plastic rather than ceramic. Most electronic ceramics have CTEs in the neighborhood of 4 to 10 ppm. Since the printed circuit board CTE is 14 to 18 ppm in-plane below  $T_g$ , the match to plastic packages which usually have average CTEs of 20 to 25 is better. The overall CTE of a plastic package can be significantly below that of the plastic if the die is large compared to the total package body. For example, TSOP components can have overall CTEs as low as 5.5 ppm. It is also worth recalling that component-level reliability must be considered; plastic packages suffer from other disadvantages versus ceramic packages, such as moisture absorption.

**Leaded vs. Leadless Surface-Mount Components.** Leadless surface-mount components with peripheral solder joints (e.g., leadless ceramic chip carriers, LCCCs) are more susceptible to solder joint failures due to thermal and mechanical stresses than leaded components because there is no compliance in the system (see Fig. 57.21). A compliant lead can take up relative displacement between the component body and the substrate during mechanical or thermal stressing. In doing so, it minimizes the stress and strain imposed on the solder joint, thus reducing the likelihood of failures. Large leadless components should be avoided whenever possible. If they must be used, the substrate must have as close a CTE mismatch as possible and be protected from mechanical stresses. A conformal coating should be considered.

**FIGURE 57.21** Schematic illustration of the strain in the solder during a thermal cycle for leaded and leadless surface-mount components. (After W. Engelmaier) (IPC-TP-797, Surface Mount Solder Joint Long-term Reliability: Design, Testing, Prediction.)

Ball grid arrays (BGAs) are a new style of leadless SMT component with an areal array of solder joints. The reliability of these components has come under intensive study. Plastic BGAs are less susceptible to solder joint fatigue failures than ceramic BGAs because the laminate and plastic body match the CTE of the PCB much better. At this time, it seems that there will be size and power limitations to ensure solder joint reliability.

**Lead Compliance.** As described, leadless components cause more reliability problems than leaded components because the entire displacement is imposed on the solder joint; however, there are also large differences in compliancy among leaded surface-mount components (see Fig. 57.22). Body height plays an important role because it determines the length of the

**FIGURE 57.22** Schematic illustration of different surface-mount component lead types with widely differing compliance: (left) J-lead, (right) gullwing leads.

compliant beam. Other important lead characteristics that affect compliance are lead shape (e.g., J-lead vs. gullwing) and lead thickness (stiffness is proportional to thickness cubed).

Lead frame material also plays a role in determining solder joint life, although it is not as important as lead frame geometry. Common lead frame materials are Cu and Alloy 42 (Fe-42Ni); Alloy 42 has a better CTE match to silicon (and a greater mismatch to the solder), but it is much stiffer than Cu (see Table 57.3)

Thin small-outline packages (TSOPs), which are becoming increasingly common memory packages, pose the greatest solder joint reliability risks of any packages commonly used today. These packages generally have Alloy 42 lead frames and very low standoff from the PCB, resulting in a very stiff lead that transfers most of the relative displacement between the component and the substrate to the solder joint. The situation is exaggerated for this component because the overall CTE of the package is quite low. While adequate solder joint reliability can be achieved with TSOPs in many situations, some vendors have opted to encapsulate the solder joints with a filled epoxy to better distribute the stresses.<sup>40</sup>

**57.5.3.2 Component Selection for Cleanliness.** If fluid cleaning is used to remove flux residues after assembly, then a minimum component standoff (distance between the component body and the seating plane of the leads) is critical to ensuring proper cleaning and drying, and, therefore, resistance to corrosion and moisture-related failures. Industry standards for low standoff components permit the components to have 0–0.25 mm standoff from the board. These low standoffs permit corrosive residues and the cleaning fluid to be trapped

**TABLE 57.3** CTE and Elastic Modulus at Room Temperature of Some Important Packaging Materials

	Cu	Alloy 42 (Fe-42Ni)	63Sn-37Pb Solder	Si
CTE, ppm/°C	17	5	25	3.5
E, GPa	130	145	~35	113

under the component. Poor fluid access can mean that flux residues are not removed. Drying is almost as important; it was not a major issue with highly volatile CFCs, but when the cleaning fluid is water, leaving it behind can promote moisture-driven failure mechanisms. Components which meet the standards for high standoff have a minimum standoff of 0.20 or 0.25 mm, which should be sufficient for cleaning and drying with water and most other cleaning fluids in use today. Using a no-clean process essentially eliminates these concerns about component standoff; however, an added concern is that any contamination of the external surface will remain. SIR testing should be conducted to ensure that the flux residues and other contaminants left on the board are not harmful.

**57.5.3.3 Component Termination Selection for Joint Integrity.** Surface-mount component termination finishes are generally tin-lead or tin, although other finishes are occasionally used. Good solderability is the foundation needed for forming a strong solder joint. Incoming cleanliness is another requirement that should go without saying, but has taken on increased importance with the advent of no-clean processes. With copper leads, formation of excessive quantities of  $\text{Cu}_3\text{Sn}$  and  $\text{Cu}_6\text{Sn}_5$  intermetallics can occur if reflow times and temperatures are excessive. With pure tin, whisker growth can be a concern. When Au is used as a metal finish, the Au can be expected to dissolve rapidly into the solder joint. To avoid embrittling the solder, the finished joint should contain less than 3 to 5 weight percent Au (see Sec. 57.5.1.3).

Ceramic and ferrite components such as multilayer ceramic capacitors, chip resistors, and chip inductors are generally terminated with a fired-on silver or silver palladium paste. Because silver dissolves easily into molten Sn-Pb solder, a Ni/Sn or Ni/Au overplate is recommended.

#### 57.5.4 Conformal Coatings

Conformal coatings are used for PCAs that require exceptional resistance to moisture, solvents, or abrasion. A wide variety of polymers are used to perform this function, including phenolic, silicone and urethane lacquers and silicone rubber, polystyrene, epoxy, and paraxyllylene coatings. Epoxy and polyurethane-based coatings are the most commonly used. If conformal coatings are used in conjunction with a solder mask, they must be chemically compatible.<sup>21,23</sup>

Conformal coatings work by keeping contaminants away from the circuitry and preventing moisture from accumulating on the surface of the assembly. Since all conformal coatings are permeable to moisture, interfacial adhesion is essential to their function. Contaminants on the board that reduce the adhesion of the coating or trap moisture can cause the coating to fail, as can thermal stresses. When contaminants trap moisture, the coating will bubble up (vessicate), providing gaps where corrosion can occur. An ionograph is not always the right tool to detect the harmful level of ionic contamination; cleaning with both polar and nonpolar solvents before application is recommended.

A conformal coating that is not well matched to the use environment can actually promote new failure mechanisms that would not be found in the uncoated assembly. If it fills the gap beneath the component, the coating may place additional stresses on solder joints in thermal cycling by reducing or eliminating the compliance in the leads. It may also generate excessive stresses on the components if the service temperature drops below the  $T_g$  of the coating. Some coatings are not stable in hot, humid conditions.

#### 57.6 BURN-IN, ACCEPTANCE TESTING, AND ACCELERATED RELIABILITY TESTING

---

This section reviews environmental stress testing procedures used to identify unacceptable parts or to estimate part life. These tests can be categorized by their intended goals: 100 percent screening to eliminate early failures (burn-in), acceptance testing on a sampling basis, and life

distribution estimation (accelerated reliability estimation). Burn-in, more generally known as environmental stress screening (ESS), is an important subject in its own right that has been extensively written about; only its goals are described here. Acceptance or qualification testing and accelerated reliability testing are discussed together in sections covering testing of PCBs and PCAs under various environmental stresses.

*Burn-in*, also known as *environmental stress screening* (ESS), is used to eliminate early failures when infant mortality due to latent defects is a problem by exposing all parts to worst-case, but realistic, conditions. The conditions should not be too severe because burn-in decreases the useful life of the parts. On the other hand, in addition to increasing the reliability of the parts that are shipped, burn-in provides rapid feedback on process defects that can cause field failures. The most common use of burn-in in electronics is for integrated circuits, particularly memory chips, designed into leading-edge integrated circuit manufacturing processes.

*Accelerated reliability tests* are designed to cause failures that would occur by wear-out sometime during the service life of the part and provide the data for estimating the *life distribution* of the part. Estimating the life distribution requires that the test be continued until a large percentage of the parts fail. *Qualification tests* may be conducted under similar or even more severe conditions, but they are essentially pass/fail tests that are terminated after a specified period of time. Because there are few if any failures in a successful qualification, little new reliability information can be gained from this type of test. These tests should not be used routinely on all parts because they will greatly shorten the life of the parts.

Unfortunately, there is no standard suite of reliability tests in the industry, nor is there likely to be in the near future. There are several reasons for this. First, there are numerous service environments. The IPC has identified seven major application segments for electronic assemblies. Second, within these categories, the environment experienced by the assembly may differ from the external service environment, depending on product-specific design parameters, such as power dissipation and cooling efficiency, which influence the temperature and humidity in the vicinity of the assembly. Third, the desired product life and acceptable failure rates vary widely among applications and manufacturers. Finally, but of equal importance, as technology evolves, the tests must evolve, too. Use of reliability tests that once made sense but now are either unduly conservative or do not bring out potential failure modes of new designs has a high price in overdesigned assemblies that are larger or more costly than necessary and field failures that could have been predicted and prevented. This section describes some commonly used tests and methodologies for designing tests for new technologies or new applications.

As stated at the outset, reliability can be defined only after the service environment has been identified, and the acceptable failure rate over a specified service life is specified. If this environment proves unacceptable, the design can be modified by improving cooling, package hermeticity, cleaning, etc. If it is unclear whether the PCA will achieve the designed reliability goals, accelerated reliability tests should be designed to estimate the life distribution.

### 57.6.1 Design of Accelerated Reliability Tests

There are seven steps in accelerated reliability test design.

1. *Identify the service environment and the acceptable failure rate over a specified service life.*
2. *Identify actual environment of the PCA (modified service environment).* The service environment should be translated into the ambient environment actually experienced by the PCA. For example, the temperature experienced by the PCA is influenced by both power dissipation and cooling. The mechanical environment is influenced by shock-absorbing material, resonances, and so on.
3. *Identify probable failure modes* (e.g., solder joint fatigue, conductive anodic filament growth). Accelerated reliability tests are based on the premise that the frequency and/or severity of the environmental exposure can be increased to accelerate the incidence of the failure that

occurs in service in a known way, i.e., that the data can be used to predict the life distribution in the in-service PCA environment. This assumption makes sense only if the same failure modes occur in the test as in real life. It cannot be overemphasized that the accelerated tests must be designed around the real failure modes. Probable failure modes may be identified from past service experience, the literature, or preliminary testing or analysis.

4. *For each failure mode, construct an acceleration model.* An acceleration model that allows test data to be interpreted in terms of the expected service environment is crucial to life distribution estimation. It is also extremely helpful in designing good tests, so ideally the acceleration model should be developed before the accelerated reliability tests are carried out. Equation 57.2 for solder joint reliability plus Eq. 57.1 for strain in solder joints to rigid components is an example of an acceleration model. It predicts that increasing strain will decrease the number of cycles to failure in a specific way. Within a certain temperature range, increasing the temperature cycling range is a way of increasing the strain.

In general, the acceleration model should be based on the rate-controlling step in the failure process. In some cases, the rate will be determined by an Arrhenius type equation; for example, if diffusion is the rate-controlling process:

$$D = D_o \exp\left(\frac{-E_a}{kT}\right) \quad \text{and} \quad x \propto \sqrt{Dt} \quad (57.3)$$

$$t_2 = \left(\frac{D_1}{D_2}\right) t_1 = t_1 \exp\left(\frac{-E_a}{k} \left[\frac{1}{T_1} - \frac{1}{T_2}\right]\right)$$

where  $D$  = diffusion rate  
 $D_o$  = diffusion constant  
 $E_a$  = activation energy for the process  
 $k$  = Boltzmann constant

and  $T_1$  and  $T_2$  and  $t_1$  and  $t_2$  are two temperatures and corresponding equivalent diffusion times

Note that even when temperature is an important factor, *an Arrhenius relationship may not exist*; in the preceding thermal cycling example, the failure rate is roughly proportional to  $(\Delta T)^2$ . Some acceleration models will be explored in the following sections.

The limits of applicability of an acceleration model are as important as the model itself. Increasing or decreasing the temperature too much may promote new failure modes that would not occur in service or invalidate the quantitative acceleration relationship. For example, if the temperature is elevated above the  $T_g$  of the board, the  $z$ -axis CTE increases sharply and the modulus decreases, which may actually lessen the strains imposed on solder joints, but may also promote PTH failures.

Finite element modeling (FEM) can be invaluable in developing and/or applying acceleration models for thermal and mechanical tests. Two-dimensional nonlinear modeling capability will usually be required in order to get meaningful results. Models can be constructed to estimate the stresses and strains in the material (e.g., the Cu in a PTH barrel or the solder in a surface-mount or through-hole joint) under operating conditions as well as under test conditions. These estimates will be far more accurate than the simple models provided in this overview because they can account for the interactions between materials in a complex structure and both elastic and plastic deformation.

5. *Design tests based on the acceleration models and accepted sampling procedures.* Using the acceleration model and the service environment and life, select test conditions and test times that simulate the life of the product in a much shorter period of time. The sample size must be large enough that it is possible to determine whether the reliability goal (acceptable number of failures over the service life) has been met.<sup>41</sup> Ideally, the life distribution in the accelerated test should be determined, even when the test period must be extended to do so.

6. *Analyze failures to confirm failure mode predictions.* Since an accelerated test is based on the assumption that a particular failure mode in the accelerated test is the same one that occurs in service, it is important to confirm by failure analysis that this assumption is valid. If the failure mode in the accelerated test is different from the one expected, several possibilities should be considered. (1) The accelerated test is introducing a new failure mode different from the one that will occur in service. Usually this means that the acceleration of one parameter (e.g., frequency, temperature, humidity) was too severe. (2) The initial determination of the dominant failure mode was incorrect. In this case, to understand the significance of the test results, a new acceleration model must be developed for this failure mode. The new failure mode may be promoted more or less effectively by the test conditions than the mode originally assumed. (3) There may be several failure modes. In this case, the two failure distributions should be considered separately, so that life predictions will be meaningful. The difficulty in determining which of the above scenarios holds is that for genuinely new technologies or service environments, the failure mode in service may not be known. In these situations, it is desirable to conduct a parallel test with less aggressive acceleration for comparison.
7. *Determine life distribution from accelerated life distribution.* The accelerated life distribution should be determined by fitting the data with the appropriate statistical distribution, such as the Weibull or log-normal distribution. The life distribution in service can be determined by transforming the time axis of the life distribution using the acceleration model. This predicted life distribution in service can then be used to estimate the number of failures in the specified service life.

The following discussion of testing for some specific failures will provide examples of this methodology.

## 57.6.2 Printed Circuit Board Reliability Tests

**57.6.2.1 Thermal.** PTH failures are the predominant source of PCB failures in service and predicting them is the primary goal of PCB testing at elevated temperatures. PTH reliability testing should simulate the thermal excursions of a PTH throughout its life. Generally, the most severe thermal cycles are experienced during assembly and rework.

Two basic types of tests are conducted: thermal stress or solder float tests, and thermal cycling tests. Both of these tests are intended to be accelerated tests for the PTH, not for the laminate; the thermal stress test, in particular, is expected to severely degrade the laminate. The delamination test is similar to a solder float test, but is conducted at a lower temperature specified by the laminate manufacturer; typically, a different fluid is required.

The most commonly accepted thermal stress test is MIL-P-55110 (also found in IPC-TM-650). Following baking at 120 to 150°C (250 to 300°F), the specimens are immersed in an RMA flux and floated in a eutectic (or near-eutectic) Sn-Pb solder bath at 288°C (550°F) for 10 s. Other investigators use a bath at 260°C. Following the test, the samples are cross-sectioned and the PTHs are examined for cracks. This is a severe test that ensures that the sample will survive a single wave-soldering or solder pot rework cycle.

Most thermal cycling tests for PCBs cycle the PCB repeatedly over a wide temperature range; many are actually thermal shock tests using liquid-liquid cycling. The results of five accelerated tests with different temperature extremes, ramp rates, and dwell times have been compared by the IPC, which also provides a simplified analytical model to estimate PTH life.<sup>3</sup> The results of all tests suggest the same approaches for maximizing PTH reliability, but they do not all correlate well quantitatively. Two of the most common tests are (1) oven cycling from -65 to +125°C, and (2) thermal shock cycling between oil or fluidized sand baths at +25 to 260°C. Figure 57.23 shows a suitable test coupon that contains 3000 PTHs interconnected in series, several PTH sizes, and varying annular ring sizes. The PTHs can be monitored during the testing. Figure 57.18b shows the type of data that can be collected in this type of test.

**FIGURE 57.23** PTH reliability test coupon. This coupon contains three sets of 1000 PTHs interconnected in series on four layers. Each set is a different hole size. The pad size is also varied. Similar designs are available from the IPC.

**57.6.2.2 Mechanical.** Printed circuit boards are rarely subjected to mechanical tests that could cause electrical failures; however, adhesion of both Cu and solder mask to the laminate is critical and is often tested. Loss of solder mask adhesion can provide a place for corrodants and moisture to accumulate, which can be the cause of electrical failures when the board is exposed to temperature and humidity.

Adhesion is commonly tested using the peel test described in IPC-TM-650, Method 2.4.28. The simplest version of this test is conducted by scribing the adherent and dividing it into small squares. If the Cu or solder mask pulls off with a piece of tape with strong adhesive, the adhesion is inadequate. More quantitative tests that measure the actual peel strength are performed primarily by laminate and solder mask suppliers.

**57.6.2.3 Temperature, Humidity, Bias.** These tests are designed to promote corrosion on the PCB surface and conductive anodic filament growth, either of which can cause insulation resistance failures.

Surface insulation tests utilize two interleaved Cu combs with an imposed dc bias across the combs. These combs may be designed into existing boards or a coupon such as the IPC-B-25 test board shown in Fig. 57.24 may be used. The measured resistance (ohms) from the comb pattern can be converted to surface resistivity (ohms per square) by multiplying the measured

**FIGURE 57.24** Test coupons used to check moisture, insulation, and metal migration resistance: (a) the IPC-B-25 test board, used to qualify the process; (b) The Y coupon, designed to be incorporated into production boards for statistical process control. From IPC-SM-840.

resistance by the square count of the pattern. The square count is determined geometrically by measuring the total length of the parallel traces between the anode and cathode and dividing by the separation distance. Special precautions are needed to make accurate measurements of insulation resistance.<sup>42</sup> Measurements of resistance above  $10^{12}$  are very difficult and require careful shielding. Measurements of resistance below  $10^{12}$  can be conducted in most laboratory environments if certain precautions are taken.

The actual tests are usually conducted at elevated temperature and humidity with an applied dc bias. A test for moisture and insulation resistance of bare printed circuit boards is included in IPC-SM-840A. The severity of the test depends on the intended use environment; for typical commercial products (Class 2), the test is conducted at  $50^{\circ}\text{C}$ , 90% RH, and  $100\text{ V}_{\text{dc}}$  bias for 7 days. The minimum insulation resistance requirement is  $10^8\ \Omega$ . The military test procedure for moisture and insulation resistance is specified in MIL-P-55110.<sup>43</sup> The moisture resistance test should be conducted in accordance with MIL-STD-202, Method 106, with

applied polarization voltage (100 V<sub>dc</sub>) and Method 402, Test condition A.<sup>44</sup> IPC-SM-840A also includes a test for electromigration resistance. The test is conducted at 85°C/90% RH at a 10 V<sub>dc</sub> bias with a limiting current of 1 mA for 7 days. A significant change in current constitutes a failure. The samples are also microscopically inspected for evidence of electrolytic metal migration. A common test for dendritic growth due to flux residues is 85/85/1000 h at -20 V<sub>dc</sub> bias. These tests are empirically based; however, several investigators have attempted to develop acceleration factors for these and similar tests.<sup>45,46</sup>

### 57.6.3 Printed Circuit Assembly Reliability Tests

**57.6.3.1 Thermal.** Most thermal cycling of PCAs is intended to accelerate solder joint thermal fatigue failures. In spite of the existence of an IPC standard, there is no standard accelerated test today that is suitable for all component and substrate combinations and all service environments. There are several acceleration models in the literature, each of which seems to fit the data well in at least some situations. All are based on a combination of empirical observations and fundamental arguments under simplifying assumptions. This topic remains a subject of active research since in some cases the predictions are significantly different. There is also a move to replace thermal cycling tests with mechanical cycling tests, which could be conducted in a shorter period of time; however, these tests are even further from standardization. Finally, for some components which dissipate a significant amount of power (usually 1 W or more), cycling the ambient temperature (which heats from the outside) may give quite different results from power cycling (in which heating occurs from the inside); for example, the failure location may shift from corner joints (which see the largest displacements) toward solder joints located near the chip (because they are hotter). Consequently, while thermal cycling will be adequate for most ASICs, memory chips, etc., power cycling should be considered for microprocessors, particularly those that dissipate more than a few watts.

Thermal shock testing is commonly used to test components, but it is not necessarily a substitute for thermal cycling. Because the temperature ramp is extremely rapid and the dwell at the extremes is generally short, there is little time for creep; consequently, the number of cycles to failure is increased. Furthermore, the rapid temperature change can induce differential thermal stresses that may be larger than those experienced during thermal cycling. These stresses can induce early failures, particularly if the failure is not in the solder.

There are some principles for designing thermal cycling tests to accelerate solder fatigue that seem to be generally agreed on. The following guidelines apply to gradual temperature cycling due to ambient heating inside a unit (e.g., due to power dissipation). If the unit will be subjected to extreme temperatures or thermal shock in service, these generalizations may not apply. A sample cycling protocol is shown in Fig. 57.25.

- The maximum test temperature should be below the  $T_g$  of the printed circuit board, for FR-4 below about 110°C. At  $T_g$ , the CTE of the board increases rapidly, but many other properties also change; for example, the elastic modulus of the board decreases. To avoid approaching the melting temperature of the solder and changing the mechanism of solder creep, the maximum temperature should also be kept below about  $0.9T_m$ , where  $T_m$  is the melting temperature of the solder in Kelvin. For eutectic Sn-Pb solder,  $T_m$  is 137°C, well above  $T_g$ . But for printed circuit board materials with high  $T_g$  values or low-melting-temperature solders, this restriction may take precedence. Using a peak temperature above these limits results in unpredictable acceleration.
- The minimum temperature should be high enough that creep is still the primary deformation mechanism of the solder, that is, at least  $0.5 T_m$ , or -45°C for eutectic Sn-Pb solder. Many investigators prefer a higher minimum temperature (-20 or 0°C) to ensure that creep occurs fast enough to relieve the imposed shear stress during the allowed dwell time. Using too low a minimum temperature may seem to increase the acceleration factor (increased  $\Delta T$ ) while actually decreasing it (decreased  $\Delta\epsilon$ ), resulting in an overly optimistic life prediction.

**FIGURE 57.25** Schematic thermal cycling profile for testing solder joint thermal fatigue.

- The rate of temperature cycling should not exceed 20°C/min and the dwell time at the temperature extremes should be at least 5 min. The purpose of controlling the cycling speed is to minimize thermal shock and the stresses associated with differential heating or cooling. The dwell time at the temperature extremes is an absolute minimum needed to permit creep to occur. A longer dwell time is recommended, particularly at the minimum temperature.

As described here, there are several acceleration factors in the literature that may be applied to make life estimations from the accelerated test data that may be obtained using a thermal profile that fits the preceding criteria. One of the simplest expressions is due to Norris and Landzberg:

$$\frac{N_{op}}{N_{test}} = \left( \frac{v_{op}}{v_{test}} \right)^{1/3} \left( \frac{\Delta T_{test}}{\Delta T_{op}} \right)^2 \left( \frac{\phi_{test}}{\phi_{op}} \right)$$

where  $N_{op}$  and  $N_{test}$  = life under operating and accelerated test conditions, respectively  
 $v$  = cycling frequency  
 $\phi$  = mean temperature<sup>47</sup>

Another widely used expression may be found in IPC-SM-785. This expression tries to account for the effect of power cycling and the dwell time in the thermal profile; it also makes it possible to make predictions for one component or solder joint geometry based on data for another similar one. In its most simplified form, the acceleration factor for tests meeting the preceding criteria for FR-4 and eutectic Sn-Pb solder joints may be approximated as

$$\frac{N_{op}}{N_{test}} = \frac{\Delta T_{op}^{2.4}}{\Delta T_{test}^{2.4}} \quad \text{for leadless surface-mount attachments}$$

$$\frac{N_{op}}{N_{test}} = \frac{\Delta T_{op}^4}{\Delta T_{test}^4} \quad \text{for compliant-leaded surface-mount attachments}$$

assuming the test assemblies are nearly identical to the assemblies that will be put into service.

Mechanical fatigue cycling is increasingly being used as a quick way to induce solder joint failures. The goal is to *simulate* the thermal fatigue failure process in a much shorter test. The validity of this approach is still being investigated; although the imposed strain in each cycle is intended to be the same, the mechanical test eliminates thermomechanical effects (including creep) because the cycles are about two orders of magnitude faster. Nonetheless, mechanical cycling can certainly provide useful comparisons between different designs or package

styles. The tests are usually conducted at a constant temperature with fixturing that puts the solder joints in shear when bending or tensile displacements are applied.

**57.6.3.2 Mechanical.** Mechanical vibration and shock can cause solder joint failures, particularly for large, rigid components or components with large, heavy heat sinks. Mechanical shock tests are usually modeled after drops that may occur during transportation or use. The test drops are generally quite severe, but few in number, since the system is not expected to be subjected to repeated drops in service. One common test uses a maximum acceleration of about 600 g, a maximum velocity of about 300 in/s, and a shock pulse of about 2.5 ms duration. The test setup is shown schematically in Fig. 57.26.

**FIGURE 57.26** Schematic of setup used to test the resistance of printed circuit assemblies to out-of-plane mechanical vibration and shock.

On the other hand, the PCA may be exposed to millions of mechanical vibration cycles during its lifetime.<sup>48</sup> Depending on the application, both in-plane and out-of-plane vibration may play an important role. The damage done by these cycles depends primarily on whether the cycling frequency is near a natural frequency of the board, where large deflections can take place. For in-plane vibration, random vibration over a wide excitation frequency range is performed at a constant power spectral density. Most surface-mount components have high natural frequencies, and solder joint failures are rarely observed. For out-of-plane vibration, the following procedure is recommended:

- Design and fixture the test board so that each specimen is clamped at both ends and contains a single component at the center (see Fig. 57.26).
- Impose the vibration using a shaker table with sinusoidal excitation.
- Find the natural frequency of the sample by sweeping the frequency at a low amplitude (to prevent inadvertent damage before the start of the test). This natural frequency is near, but not the same as, the natural frequency at the larger amplitude that will be used for testing.
- Conduct the test by sweeping the frequency in a narrow range around the natural frequency previously determined. The amplitude can be set to correspond to a certain power spectral density or to achieve a desired deflection of the PCB.

**57.6.3.3 Temperature, Humidity, Bias.** The primary purpose of these tests is to identify surface insulation resistance (SIR) degradation due to corrosive materials left on the board from the assembly process or due to galvanic couples set up in the assembly process. The usual test procedure is to use SIR comb patterns on the PCB, and to subject the assembly to 85°C/85 percent relative humidity/ $-20V_{dc}$  for 1000 h. The bias voltage is dependent on the test device or test vehicle chosen.

One acceleration model that is applied is the modified Eyring model, which was developed for moisture-induced corrosion in plastic packages:

$$t_{50\%} = \left[ A \exp\left(\frac{E_a}{kT}\right) \right] \left[ \exp\left(\frac{C}{H_r}\right) \right] \left[ D \exp\left(\frac{-V}{B}\right) \right] \quad (57.4)$$

where  $t_{50\%}$  = time at which 50 percent of parts have failed  
 $A, B, C,$  and  $D$  = empirical constants  
 $E_a$  = thermal activation energy  
 $k$  = Boltzmann constant  
 $T$  = temperature in degrees Kelvin  
 $H_r$  = relative humidity  
 $V$  = reverse-biasing voltage<sup>41,46</sup>

The time to failure is also dependent on the concentration of ionic contaminants. The default industrial ionic contamination limit comes from MIL-STD-28809A; it is the equivalent of 3.1  $\mu\text{g}/\text{cm}^2$  of NaCl. For small plastic packages, enough data have been collected to show that an empirical acceleration factor for temperature and relative humidity  $\text{AF}_{T,H_r}$  applies:

$$\text{AF}_{T,H_r} = 2^{(T+H_r)_{\text{test}} - (T+H_r)_{\text{service}}} \quad (57.5)$$

where  $\text{AF}$  = acceleration factor  
 $T$  = temperature in  $^{\circ}\text{C}$   
 $H_r$  = relative humidity in percent<sup>46,49</sup>

The rule of thumb for the effect of reverse bias is very device-specific; the following relationship was established for 20-V Schottky diodes in SOT-23 packages:<sup>46</sup>

$$\text{AF}_V = 7700 \exp\left(\frac{-V}{12.32}\right)$$

When both acceleration factors apply, the total acceleration factor is:

$$\text{AF}_{\text{total}} = (\text{AF}_{T,H_r})(\text{AF}_V)$$

## 57.7 SUMMARY

---

Reliability of electronic assemblies is a complex subject. This chapter has touched on only one aspect of the problem: understanding the primary failure mechanisms of printed circuit boards and the interconnects between these boards and the electronic components mounted on them. This approach provides the basis for analyzing the impact of design and materials choices and manufacturing processes on printed circuit assembly reliability. It also provides the foundation for developing accelerated testing schemes to determine reliability. It is hoped that the fundamental approach will enable the reader to apply this methodology to new problems not yet addressed in mainstream literature.

### 58.1 INTRODUCTION

---

The mandated conversion to lead free assemblies has led to the convergence of several critical issues in the microelectronics industry. The conversion has further compounded several other factors that have been pushing the envelope in Component to Printed Wiring Board (PWB) reliability, including

- Radical increases in package-to-board input/output (I/O)
- Rapid reduction in interconnect pitch
- Overall rise in surface-mount component density
- Higher speeds and correspondingly higher heat dissipation

All of these factors pose tremendous challenges with respect to reliability, and they cause complex design tradeoffs that must be considered while maintaining product reliability at required levels. Time to market and aggressive product life cycle pressures also require PWB designers to consider the impact that alternate designs and material sets may have on reliability, in a rapid fashion.

The PWB designer is faced with myriad packaged device types, field use environments, connectors, PWB materials, cost considerations, and real estate restrictions, which all must be optimized without degrading system reliability. Designers need tools to assess experimental reliability data, transform laboratory results into actual field loading conditions, and rapidly assess the reliability of different PWB layouts, material sets, and package types. Engineers must also have the capability for addressing complex loading conditions such as mini- and power-cycles and the knowledge of how they impact interconnect performance.

This chapter focuses on the design variables that impact the reliability of PWB-to-package interconnect (second- and third-level interconnect) of grid array devices and the impact of lead-free conversion on these design variables.

Some of the critical variables discussed in depth include:

- Double-sided construction
- PWB stiffness effect
- Multiple packages in a small area
- Package and PWB warpage; assembly and reliability challenges
- Solder joint geometry; assembly and reliability challenges
- Package and PWB pad size
- Heatsink design and attachment
- Package and PWB surface finish; Black Pad, Brittle Failure, and Kirkendall voiding
- PWB electrical test architecture
- Carrier chassis design
- Package design parameters such as overall size, silicon technology, ball array, ball size/pitch, heat spreader/stiffener, material selection, die/package aspect ratio, substrate material, low- $k$  dielectrics and so on

The chapter is broken up into the following sections.

Section 58.2, “Packaging Challenges,” outlines several of the performance challenges faced by next generation packages, and the key technical drivers behind these challenges.

Section 58.3, “Variables That Impact Reliability,” contains a discussion of the common design variables that could impact the reliability of a product; ranging from PWB design rules to package design parameters. The failure modes relating to the choice of different package design parameters are outlined, along with recommendations on ways to mitigate different manufacturing and test-related failure mechanisms.

## 58.2 PACKAGING CHALLENGES

The reliability of many types of leadframe components (see Figs. 58.1 and 58.2) has been assessed in great detail.<sup>1</sup> Figure 58.3 shows the typical definitions of interconnect levels in assemblies. While leadframe devices are by no means infinitely reliable at the first and second level interconnects, they have historically posed a lesser risk than grid-array packaged components, such as ceramic ball grid arrays (CBGAs), plastic ball grid arrays (PBGAs), ceramic solder column carriers

**FIGURE 58.1** Diagram of a quad flat pack. Note the copper (Cu) leads that are attached by gold wire bonds to the die. This is the primary (or first-level interconnect) between the die and the package. The second-level interconnect will be created when the Cu leadframe is soldered to a motherboard via some type of surface-mount attach process. (Courtesy of Amkor Technology, Inc.)

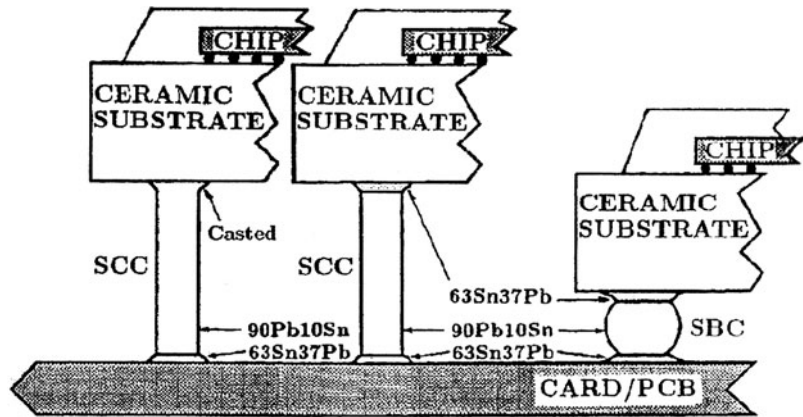

**FIGURE 58.2** J-leaded device oriented bottom side up. (Reprinted with permission from J. Lau, *Ball Grid Array Technology*, McGraw-Hill, New York, 1995, p. 20.)

**FIGURE 58.3** First-, second- and third-level interconnects defined, employing a flip-chip assembly as an example. The first-level interconnect is the primary connection between the silicon die and the package substrate. In this example it is created by the solder bumps between the die and the package. The second-level interconnect in this example is the “next” level of connection between the package substrate and the module substrate. The third-level interconnect in this example is created when the solder balls on the bottom side of the module substrate are attached via SMT to the PWB.

(CSCCs), flip-chip ball grid arrays (FCBGAs), and chip scale packages (CSPs). This is because the compliant leadframe in leadframe packages can absorb the differential strain induced in the solder joints, due to the mismatch in thermal expansivity between the silicon chip and the PWB. Ball grid array packages, on the other hand, rely entirely on the discrete solder balls absorbing the differential strain. Depending on the package construction, the solder joints at critical high strain locations could fail early, resulting in lower long-term reliability of the assembly. Figure 58.4 shows various grid array packaged devices.

To meet increasing I/O density requirements, many of these types of packages are either increasing in body size, decreasing in pitch, or both, to a point where the standard reliability envelope is being pushed to extreme levels. Additionally, most grid array packaged devices are high in cost (in many instances the grid array packaged devices are the most costly component on a printed circuit assembly) and thus cannot be deployed in a redundant design. Lack of redundancy creates critical path single points of failure (SPOFs). Failure of one of these devices can lead to catastrophic system-level failures. The proliferation of high-I/O, small-pitch grid array packaged devices throughout the electronics industry impacts almost all PWB engineers because any design has a high probability of containing one or more of these types of components.

**FIGURE 58.4** Cross-section of a ceramic solder column carrier and ceramic ball grid array (CBGA). Solder column carriers (SCC) and a solder ball carrier (SBC) are shown. The SBC is often referred to as a CBGA package due to the fact that it is a ceramic package substrate that employs solder balls to create a second-level interconnect between the package substrate and the PWB. The solder column carrier employs a column of high-lead solder (which is either casted onto the ceramic package substrate or attached by a layer of eutectic 63Sn/37Pb solder paste) to create a second-level interconnect between the ceramic package substrate and the PWB. A lead-free version of the SCC, made of copper columns is also being developed.<sup>2</sup> Typical ceramic ball grid array packages cannot achieve required reliability when body sizes exceed 32 mm per side. Ceramic packages having larger body sizes either employ SCC-type technology or connectors to create a second-level interconnect. (Reprinted with permission from J. Lau, *Ball Grid Array Technology*, McGraw-Hill, New York, 1995, p. 27.)

Moreover, at higher speeds, there is an ever increasing need for reduction in signal delay between processors and the memories they communicate with. These processors could be micro-processors, network processors, programmable logic devices (PLDs) and application-specific integrated circuits (ASICs). This has given rise to the prominence of System-in-Package (SiP) modules which significantly reduce the delay between on-PWB memory and ASICs (Fig. 58.5).

**FIGURE 58.5** System-in-Package (SiP) Module. SiP modules help reduce signal delay between a processor and the memory devices it communicates with. This SiP has one processor in the middle, surrounded by four discrete memory packages, all on one module. The module is soldered to the PWB via the solder balls on the back side of the module substrate.

**FIGURE 58.6** (a) Stacked-die package. Several dies are stacked within a single package and wirebonded to a single substrate. (b) Stacked package. Several wirebonded packages are stacked on top of each other with solder balls. (Courtesy of Amkor Technology, Inc.)

SiP modules can have more than eight memories communicating with a single ASIC. The ASIC package is typically a flip chip, whereas the memories could be CSPs, stacked packages or PBGAs.

Stacked die and stacked package memories have also become more prevalent in applications where space is a constraint (Fig. 58.6). Stacking helps compact more memory within the same foot print and in applications where height is not a critical constraint, they help conserve valuable PWB real estate while at the same time providing greater integration and performance. But stacking technology raises its own unique set of reliability challenges. These challenges include heat dissipation from the multiple dies, reworkability and the reliability of the interconnects between the individual stacked dies or stacked packages.

### 58.3 VARIABLES THAT IMPACT RELIABILITY

Electronic packages are composed of complex materials that are assembled via intricate processes and then subjected to a wide range of service environments. It is crucial to note that both the die-packaging processes and surface-mount technologies can impart stresses and create residual stresses in the final packaged assembly that impacts its interconnect reliability. Assessing the reliability of package devices requires that all variables that can hinder or enhance reliability be considered.

#### 58.3.1 Actual Product Environment

The actual product environment is what drives the reliability of the assembly. Printed circuit assemblies are deployed in a wide range of environments. Packages can be subjected to extreme temperatures and humidity. Automotive applications, for example, can see temperature ranges from  $-55^{\circ}\text{C}$  to well over  $95^{\circ}\text{C}$  along with up to 100 percent humidity. The rate at which temperature and humidity changes occur can be quite severe under the hood, causing components to transition from extreme cold to heat in a matter of minutes. This creates a very difficult environment to model, as the rate of occurrence of thermal and humidity cycles must be thoroughly understood. Severe shock and vibration can also be imparted to assemblies in this type of service environment, which adds to the complexity of reliability assessment. Great care must be taken when assessing these types of aggressive environments and their impact on packaging reliability. A thorough experimental analysis that employs thermocouples (to assess temperature conditions) and accelerometers (to assess shock and vibration loading conditions) should be employed to determine the actual end-use environmental conditions. These stressful environments are the primary driver for automotive applications

employing extreme protection measures such as full encapsulation/potting for electronic devices placed under the hood.

Computer room environments represent the other extreme, with temperatures and humidity controlled to very tight tolerances. While servers, switches, hubs, routers, and other devices are housed in a controlled environment, their extremely large packages, coupled with power and mini cycles (discussed in the next chapter), create a set of loading conditions that are different from those found in automotive applications, but that are equally challenging. Worst-case loading conditions for a variety of end-use environments can be found in Table 58.1. Note the broad variation in temperature extremes, frequency of thermal cycles, and expected service life.

**TABLE 58.1** Examples of Worst-Case Environments for Different Use Categories<sup>3</sup>

Use category	$T_{\min}$ (°C)	$T_{\max}$ (°C)	$t_D$ (hrs)	Cycles per year	Typical years of service	Approximated acceptable failure risk (percent)
Consumer	0	+60	35	12	1–3	1
Computers	+15	+60	2	1460	5	0.1
Telecom	–40	+85	12	365	7–20	0.01
Commercial aircraft	–55	+95	12	365	20	0.001
Industrial and automotive passenger compartment	–55	+95	12	20–185	10	0.1
Military ground and ship	–55	+95	12	100–265	10	0.1
Space	–55	+95	1–12	365–8760	5–30	0.001
Military avionics	–55	+95	1–2	365	10	0.01
Automotive under hood	–55	+125	1–2	40–1000	5	0.1

$T_{\min}$ , minimum temperature;  $T_{\max}$ , maximum temperature;  $t_D$ , dwell time at the operating temperature.

Prior to initiating any reliability assessment, it is crucial to understand the thermal, humidity, and mechanical loading conditions that a packaged device will be exposed to throughout its expected life time. Temperature maximums and minimums as well as the frequencies and rates at which the component cycles between extremes must be thoroughly understood. Complex thermal cycles (such as an outdoor product experiencing daily temperature changes coupled with a more local effect such as under-the-hood heating and cooling due to engine usage) must also be considered. Humidity and vibration loading conditions must also be evaluated as part of an overall package qualification process.

End-use conditions can be estimated by attaching thermocouples, humidity, and shock/vibration sensors in the final product because it is used in field operating conditions. This data needs to be analyzed over time and different expected field conditions to get useful estimates of the end-use environment as illustrated in Table 58.1.

Once this data is generated, it can be used in typical acceleration factor models relating accelerated stress tests to field data. For example, if it is determined that it takes  $x$  hours or cycles for an assembled package to fail in a laboratory test, the acceleration factor model can be used to extrapolate expected life of the device in typical field operating conditions. Details on acceleration factor models and sample calculations are provided in the next chapter.

Although environmental impact has a large effect on interconnect reliability, there are some basic design variables that can have a positive or negative impact on solder joint reliability. These critical design variables and their impact on reliability are discussed in the following sections.

### 58.3.2 Double-Sided (Mirrored BGA)

The high-density revolution has forced PWB designers to place increasingly complex surface-mount devices in smaller and smaller spaces. This PWB density increase (where density refers to the number of components per unit area of PWB) may force designers to consider mirror BGA placement (see Figs. 58.7 and 58.8) or to place multiple devices on one side of a PWB.

The beginning of the density revolution occurred when designers began implementing double-sided technologies to allow for the placement of surface-mount components on both sides of a PWB. The continued push toward device density has resulted in placement of BGA components in mirror and quasi-mirror configurations, shown in Figs. 58.7 and 58.8.

**FIGURE 58.7** Double-sided BGA in mirror configuration. Note that the PCA is an exact mirror about the center line of the PWB. In some instances the top- and bottom-side packages share common vias.

**FIGURE 58.8** Double-sided BGA in quasi-mirror configuration. Note that although the packages are not right over each other, there is some overlap when looking from the top down or from the bottom up.

While the double-sided configuration certainly reduces signal delay, the primary disadvantage is a significant reduction in the thermomechanical reliability of the solder joint interconnects between the packages and PWB. Placing BGA packages in mirror or quasi-mirror configurations tends to rigidize the PWB assembly such that it does not bend as much during temperature cycling. The increased stiffness of the PWB due to double-sided mounting means the solder joints have to absorb more differential strain between the packages and PWB, resulting in as much as a 50 percent reduction in solder joint fatigue life (Figs. 58.9 and 58.10).<sup>4</sup> In terms of solder joint strain, the effect is the same as having a thicker or stiffer PWB. The primary failure mode is cracking in the solder joints near the package/joint interface.

Due to the dramatic decrease in assembly reliability when attempting mirrored configurations, these types of configurations should be avoided whenever possible. When it is impossible to avoid a mirror configuration, a quasi-mirror configuration without common through-hole vias is recommended (see Fig. 58.8). Common through-hole vias in this configuration tend to rigidize the assembly and contribute to further reduction in solder fatigue life. A standard rule of 50 percent reduction in fatigue life when employing a mirror configuration may be taken as

$\beta_1 = 5.5657, \eta_1 = 610.0411, \rho = 0.9484$   
 $\beta_2 = 4.2934, \eta_2 = 1347.6534, \rho = 0.9858$

**FIGURE 58.9** Weibull plot of single and double-sided mounting of single lead-free extremely thin chip scale package (PS-etCSP®). (Reprinted with permission from Amkor Technology, Inc./© [2004] IEEE ECTC<sup>4</sup>)

$\beta_1 = 4.3555, \eta_1 = 544.1006, \rho = 0.9837$   
 $\beta_2 = 7.4308, \eta_2 = 976.0282, \rho = 0.9395$

**FIGURE 58.10** Weibull plot of single and double-sided mounting of stacked lead-free extremely thin chip scale package (PS-etCSP®). (Reprinted with permission from Amkor Technology, Inc./© [2004] IEEE ECTC<sup>4</sup>)

a first-pass approximation. Thermal cycle testing should be performed to ensure that the reliability degradation will still keep service life at an acceptable level when either a mirror or quasi-mirror configuration is considered.

**58.3.2.1 Effect of Lead-Free Conversion.** The reduction in lead-free package reliability when employing a mirrored double-sided configuration has been experimentally assessed.<sup>4</sup> Figure 58.9 and 58.10 show failure rates for single and stacked packages in single-sided and double-sided mirror positions.<sup>4</sup> Note the almost 50 percent reduction in fatigue performance when a single device is placed in a mirror configuration. The reduction is slightly less for the stacked packages, but the baseline reliability of the stacked package is 10 percent lower than that of the single package. The same trends have been shown with tin-lead eutectic assemblies, so it appears that the conversion to lead free would not mitigate this reduction in solder joint fatigue life due to double-sided mounting.

For details on Weibull distributions and failure life analysis, please refer to Sec. 59.2.2 in Chap. 59.

### 58.3.3 Board Stiffness Effect

As with the double-sided case described earlier, solder joint reliability generally decreases with PWB thickness. The thicker the PWB, the higher its stiffness, and the higher the differential strain that the solder joints have to absorb. However, the percent reduction in solder joint fatigue life due to board thickness varies for different package constructions (for example, CCGA, CSP, FCBGA, and PBGA).<sup>5</sup> The reduction is more pronounced in ceramic packages as compared to organic packages because of the higher mismatch in the coefficient of thermal expansion (CTE) between the package and PWB. Both thickness and number of layers of copper contribute to the stiffness of a PWB. As a result, the PWB thickness and layer count used to perform qualification testing should be representative of the end-use conditions in which the package would be used.

**58.3.3.1 Effect of Lead-Free Conversion.** The negative effect of PWB stiffness on solder joint reliability also applies to lead-free assemblies, as evidenced in Fig. 58.11. However, the amount of degradation could be different depending on the package type. Best practice recommendation is to use two different board thicknesses to perform temperature cycling qualification. This helps generate data for a specific package type over a range of board thicknesses. This recommendation is in line with the guidelines in the industry standard IPC 9701.<sup>6</sup>

**FIGURE 58.11** Effect of board thickness on solder joint reliability of stacked lead-free extremely thin CSP (PS-etCSP). (Reprinted with permission from Amkor Technology, Inc./© [2004] IEEE ECT<sup>4</sup>)

### 58.3.4 High Density Due to Multiple Packages in a Small Area

A second source of reliability degradation due to density increase can be observed when a designer attempts to place many BGA packages in a small area on a thin PWB (see Fig. 58.12). The effective CTE of the packaged die or module tends to be much lower than that of the actual PWB. During reflow, the PWB and packages are in a stress-free state. Upon cooling, however, the packaged die contracts at a reduced rate (due to the lower effective CTE) than the underside of the PWB, causing a convex-type curvature to be imparted to the PWB. Moreover, if the thermal mass of the packages on the top side is higher than that on the bottom side, this can lead to a skew in the temperature distribution across the assembly, which in turn exacerbates the warpage of the assembly. Thus, care should be taken to distribute the packages as uniformly as possible across the PWB on both sides, and also to balance the copper in the PWB itself.

**FIGURE 58.12** High-density placement of BGAs on top side of a PWB. This diagram illustrates the convex-type curvature of a PWB assembly where multiple BGA devices are all placed on one side of a board.

**58.3.4.1 Effect of Lead-Free Conversion.** Typical lead-free reflow temperatures (235 to 260°C) are higher than tin-lead reflow temperatures (220°C). As a result, the residual stresses built into the assembly after reflow could be higher in lead-free assemblies. These higher residual stresses are also a function of the cooling rate. Thus, it is important to not only control the heating side of the reflow profile, but the cooling side as well. The use of multiple zones for cooling is preferable, as it ensures better control. Moreover, forced convection ovens would be preferable over IR ovens for better control. Due to significant variations in the thermal mass of typical boards, it is difficult to provide universally applicable recommendations on reflow profiles.

### 58.3.5 Warpage Issues

The impact of warpage on a PWB assembly is multifaceted. First, warpage must typically be overcome when a PWB is placed in a card cage. Card cage placement of warped boards results in a rapid change in the loading of the solder joints that may lead to micro-crack formation or, in severe instances, solder joint fracture. Severe PWB warpage may create a card that physically cannot be placed in a card cage, resulting in a non-manufacturable product. Warped boards should be clamped in a controlled fashion to reduce the stress imparted to solder joints upon installation in a card cage.

**58.3.5.1 Effect of Lead-Free Conversion.** With the conversion to lead-free, it is imperative to ensure that the base material used in the PWB is compatible with the higher reflow temperatures. While more industry wide research is needed, the use of materials such as Dicyandiamide (DICY) cured FR-4 appears to be limited to applications with less than 240°C peak reflow temperature, whereas Phenolic cured PWBs are preferred for applications higher

than 240°C. This is because of the better resistance to delamination observed for the phenolics after multiple reflows.<sup>7,8</sup> The thermal mass of the components and the amount of copper in large panel boards could make it difficult to maintain temperatures below 240°C. Detailed temperature measurements and reflow profiling should be performed on large boards to ensure that the temperature rise across the PWB is compatible with the PWB material.

### 58.3.6 Die and Package Stress Issues

A second issue associated with board warpage is die and package stress. The package experiences an amount of stress as it constrains the PWB from contracting during cooling after reflow. If this stress is severe enough, the silicon may crack. Also, severe stress may create multiple types of package delamination and/or cracking. The extreme danger here is that a device could pass full first-level qualification (first-level qualification typically consists of thermal cycling, humidity and temperature exposure, extreme-temperature storage, and shock and vibration experiments performed on packaged devices not attached to a PWB) yet suffer from delamination/die cracking due to stresses imparted by a warped PWB. This is one of the primary reasons that many packaged IC suppliers and consumers require that second-level qualification test vehicles include daisy chains at the first-level interconnect. Inclusion of first-level joints or wire bonds allows for the impact of second-level attach on first-level reliability to be assessed simultaneously with second-level solder joint reliability during a second-level qualification.<sup>9</sup>

**58.3.6.1 Effect of Lead-Free Conversion.** Lead-free conversion exacerbates these potential silicon-level failures. Since the assembly is subjected to a higher temperature range than with tin-lead assemblies, there is a higher propensity for early failures due to residual stresses during cool down. In addition, there are potential concerns over the effect on low dielectric constant ( $k$ ) materials in the silicon during second level temperature cycling. This is discussed in more detail in Sec. 58.3.13.9. The effect of mold compound and underfill material selection on first-level interconnects is also discussed in more detail in Secs. 58.3.13.5 and 58.3.13.6 respectively.

### 58.3.7 Back-Side Component Issues

A third challenge related to warped PWBs concerns the back-side components in double-sided designs. During cool down after reflow, the top of the PWB is restrained from contraction due to the smaller effective CTE of the packaged device. This results in the bottom side of the PWB over contracting during cool down. The state of stress on the bottom solder joints due to warpage may be severe enough to fail solder joints or crack the die in bottom-side components. Additionally, the back-side components may be subject to residual stresses imparted after the second reflow (when the top-side components are attached via SMT) that may impact the long-term reliability of the devices on both sides and their second-level interconnects. As a result, it is important to characterize the thermomechanical reliability of the components that are mounted on the back-side by performing temperature cycling qualification.

### 58.3.8 Solder Joint Geometry Issues

Another consequence of severe warpage is the shape of the post-assembly solder joints. Joints can become excessively deformed, such that the cross section is too small to withstand fatigue. Joints can also become compressed or elongated, causing shorts or opens in some cases.

Moreover, with significant increases in body sizes of packages, there is a higher propensity for opens or bridges during reflow. For example, a 20 mm body-size package (1mm pitch)

**FIGURE 58.13** Warpage versus Max Diameter for Solder joint bridging © ASME [2005].<sup>11</sup>

would be easier to assemble on a relatively thin PWB, but with a 50 mm organic package, warpage is much more difficult to control, and it is a challenge to assemble it on a thick ( $\geq 125$  mil, 20 + layer) PWB.

Tolerances are also difficult to control on large-panel, thick PWBs. Typical tolerances on high end PWBs are  $\pm 4$  mils over the package site. Ensuring tolerances less than this is cost prohibitive. Current JEDEC guidelines<sup>10</sup> require  $\pm 8$  mil coplanarity across the package. However, there are no specifications on the maximum acceptable warpage of the package at or above the reflow temperature. The typical relationship between maximum diameter and warpage is shown in Fig. 58.13 and 58.14.

**FIGURE 58.14** Bridging of solder joints—wireframe (unwarped), contour (warped) © ASME [2005].

The joint parameters used in the analysis are:

Paste volume ( $\text{m}^3$ )	4.909576e-011
Solder ball volume ( $\text{m}^3$ )	1.130972e-010
Upper pad diameter (mm)	0.60
Lower pad diameter (mm)	0.55
Viscosity of solder (Pa-sec)	2e-3
Surface tension ( $\text{Nm}^{-1}$ ) (Tin-lead)	0.386

For a 1 mm pitch joint array, if the maximum diameter exceeds 40 mils (1.016 mm), bridging will occur. Based on the analysis results, if the effective warpage exceeds ~9 mils (0.23 mm) over a 7 mm distance along the package, the joints will bridge (Figs 58.13 and 58.14). Due to misregistration, bridging could occur at lower warpage levels. But, for the sake of clarity, the base of the solder joints has been assumed to have no warpage. Thus the predicted value (9 mils) is the *effective* warpage of the assembly. In practice, if the board has a concave warpage of 5 mils and the package has a convex warpage of 4 mils over 7 mm (above solder melting temperature), it could result in bridging.<sup>11</sup>

Given these values, there are a few critical points to note:

- a. Simply maintaining the JEDEC recommended 8 mils coplanarity could be insufficient in some applications (for example, large body size packages on thick PWBs).
- b. It is important to characterize the *effective* warpage between the package and PWB in addition to the warpage of the free standing package alone.
- c. This warpage characterization should be performed over the entire reflow temperature range, as opposed to at room temperature. Of critical value is the warpage at or above the melting temperature. The data should be recorded in accordance with the JEDEC high temperature package warpage measurement specification.<sup>12</sup>
- d. Where possible, the characterization should be performed on PWBs that are representative of actual PWBs used in volume production.

One useful way to mitigate solder bridging is to depopulate the corner-most balls of the package. In large body-size organic packages, a significant amount of warpage occurs at package corners, so depopulating the 6 corner-most balls at each corner could help absorb about 2 mils of effective warpage (Fig. 58.15). This helps minimize the likelihood of solder bridging/opens. Many package suppliers already depopulate the four corner balls to improve long term reliability of the solder joints.

**FIGURE 58.15** Depopulated corners to improve warpage-related assembly yield.

**58.3.8.1 Effect of Lead-Free Conversion.** It is important to note that the data presented in Figs. 58.13 and 58.14 is based on the surface tension of tin-lead solder. The surface tension<sup>13</sup> and contact angle of lead-free solders is higher than for tin-lead solders, but analytically, for the solder joint parameters analyzed, the warpage versus ball diameter curve is not significantly different from the data presented in Figs. 58.13 and 58.14. This is because the wetting area is presumed to be fixed in the analysis. For other solder geometries (gullwing, J-lead, QFN, and so on), the behavior of lead-free solders can be different.

### 58.3.9 PWB Pad Design

The size and shape of the pad used on the PWB has a significant impact on the reliability of BGA solder joints. In general, the reliability is optimal when the pad size/opening on the package side is the same size as that on the PWB side. Deviation from the same pad size could result in a reduction of up to 25 percent in solder joint fatigue life.<sup>14</sup> The side with the smaller pad size tends to fail earlier because the stress concentration is higher near the smaller pad. Generally, non-solder mask defined (NSMD) pads are used on the PWB for packages with solder pitches in the range 1.27mm to 0.8mm. As opposed to solder mask defined (SMD) pads, NSMD pads do not have a localized stress concentration around the solder joint, which tends to degrade the thermomechanical fatigue life of solder joints. (Fig. 58.16)

**FIGURE 58.16** Solder-mask defined (SMD) and non-solder mask defined (NSMD) pad construction. For optimum reliability, the pad size on the PWB should be kept within 80 to 100 percent of the wetted pad area on the package side. This allows the stresses to be vectored equally between both ends of the solder joint, and if the PWB pad is slightly smaller, it allows a slightly higher stand off height, which also tends to enhance solder joint reliability.

For packages with solder joint pitches less than 0.8mm, a mix of NSMD and SMD pads is sometimes inevitable. At small pitches, it is difficult to route the traces from the pads in the typical “dog bone” fashion. Thus, to allow routability, the common power and ground pads are “bussed” together to form one large pad. The connected pads are SMD, whereas the individual signal pads are kept NSMD.

In general, it appears that while SMD pads tend to improve the resistance of solder joints to mechanical shock loading conditions, they also tend to degrade the thermomechanical fatigue life of the joints. Therefore, when the choice of pad construction is made, the impact on both thermomechanical fatigue and shock conditions should be characterized. (Details of typical shock testing conditions are outlined in Chap. 59).

It is important to note that the pad size specified in the fabrication drawings is not always the pad size that actually comes on all the fabricated PWBs. Actual measurements of pads specified at 12 mils NSMD could range anywhere from 9 to 15 mils. This is particularly critical for small pitch packages, because the solder volume is smaller and such variations in pad sizes could significantly alter the shape and reliability of the solder joints. A tolerance analysis such as worst case (WC) or root sum squares (RSS) should be conducted and a pad size specified such that it would not significantly exceed the pad size specified on the package side. Refer to the IPC-7351 specification for details of such tolerance analysis.<sup>15</sup>

Finally, it is clear that one common theme in the foregoing recommendations is that the PWB pad size should be pegged to the package side solder wetted area. Across the industry, the challenge with this recommendation is that the package pad size/opening is not always provided by package suppliers in relevant datasheets and mechanical drawings. To address this issue, JEDEC revised the JEDEC Publication 95<sup>10</sup> in 2004 to include nomenclature showing the pad size and construction on the package mechanical drawings. Adoption of this JEDEC nomenclature by package suppliers would go a long way in ensuring that the PWB design used by end users does not deleteriously impact the reliability of the package.

**58.3.9.1 Effect of Lead-free Conversion.** The impact of un-optimized pad size selection is detrimental to both tin-lead and lead-free assemblies. Fine pitch components (<0.8 mm pitch), regardless of solder metallurgy are much more prone to pad size-related failures.

### 58.3.10 Heatsink Design Issues

As PWB designs get more complex and more densely populated, the power dissipation from single cards can be on the order of 1000 W. A lot of heat needs to be transferred from individual cards, and from the chassis as a whole. Consequently, heatsinks are becoming larger and heavier. Heatsinks as large as 10 sq. in., weighing more than 1 lb are not unheard of. If not designed correctly, large heatsinks could transfer a significant amount of compressive load to the packages they are meant to cool. This compressive load could result in cracks in the package/silicon, or cause the solder joints to deform and bridge.<sup>16</sup> On the other hand, smaller heatsinks that are anchored to the package substrate could impart additional bending moments on the substrate that could negatively impact the reliability of the package.<sup>17</sup>

For bolt-down heatsinks, a significant amount of the compressive load comes not from the heatsink weight but from the bolt down mechanism itself. Tolerance variations in package height, warpage, heatsink stand offs, and so on only make the applied load worse. The attachment mechanism should be such that it can accommodate these variations in tolerance without transferring excessive load to the package.

Some of the attachment methods that could help accommodate tolerance variations and minimize the amount of loading imparted on to the package are shown in Fig. 58.17. The trade offs of using each method are summarized in Table 58.2.

Pressure-indicating film can be used to verify the amount of load applied on the package. The film contains tiny microcapsules of colored dye. These microcapsules rupture depending on the amount of pressure applied on the film, producing a pressure footprint. The results are not extremely precise, but can be used to estimate the amount of load applied, as a first pass approximation.

To verify the impact of heatsink loading on package solder joint reliability, temperature cycling can be performed on packages with heatsinks and compared with control samples. However, there are two caveats:

1. The heatsinks tend to cool the packages during temperature cycling, thus producing improved reliability data. The improvement may simply be because the solder joints are cycled over a lower temperature range. Thus it is important to either thermally shield the heatsink fins or calibrate the thermal cycling chamber such that the solder joints run at the same temperature range as control samples; in spite of the heatsinks.
2. Packages thermal cycled under compressive load could undergo two failure mechanisms: cyclic loading (fatigue induced opens) and static compressive loading (bridges due to solder collapse). Temperature cycling can accelerate the cyclic loading portion, but not the static loading portion. Thus, simply performing temperature cycling and comparing with control samples may not suffice. The static-loading component should also be accelerated, for instance, by dwelling at a high static temperature.

Spring-Loaded Solution.

O-Ring Solution.

Integrated Cantilever Spring Solution.

**FIGURE 58.17** Heatsink attachment methods.

**TABLE 58.2** Comparison of Different Heatsink Attachment Methods

Attachment method	Advantage	Disadvantage
Spring-loaded solution	Useful for absorbing significant tolerance variations by varying spring constants.	Relatively expensive. Bulky
O-Ring solution	Less expensive. Less bulky.	Marginal control in tolerance stack-up induced pressure.
Integrated cantilever spring solution	More versatile. Could be designed to absorb a wide range of expected loads.	Requires custom heatsink design. Could be more cumbersome to install.

### 58.3.11 Surface Finish Issues

In recent years, the role of package surface finish in the robustness of BGA packages has gained more prominence. Several different surface finishes are used across the industry, and there are trade offs with the use of each one. The surface finish used could impact intermetallics formed in the solder joints, which in turn can impact the thermomechanical and mechanical reliability of the package.

In recent years, a number of surface finishes have become more prevalent. The surface finishes with which the effect on package reliability is relatively well known, are outlined in this section:

**58.3.11.1 Electroless Nickel Immersion Gold (ENIG).** This has been the surface finish of choice for most high-end, flip-chip BGA packages. It enables the routability of fine pitch traces in high pin count packages. Historically, ENiG produces excellent board level solder joint reliability.

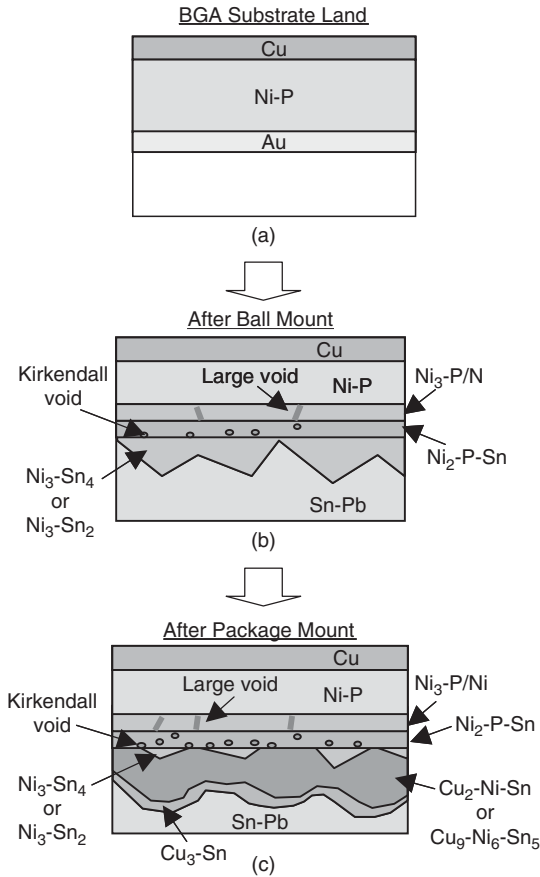

However, there are two primary concerns with ENiG:

1. **Brittle Fracture** This failure mode is seen in high strain/strain rate conditions, such as shipping, testing, and handling. A typical signature of this failure mode is a clean separation in the intermetallic between the pad and the solder joint. This failure typically has a low defect rate in production, but the ensuing line stops, customer returns, and root-cause analyses are quite expensive. Moreover, the unpredictability of the failure and the susceptibility to mechanical handling/testing/shipping conditions makes it quite undesirable.

There are a few failure mechanism theories proposed to explain brittle fracture,<sup>18</sup> but no conclusive failure mechanism has been agreed upon in the industry. The predominant theory is based on the formation of Kirkendall voids during reflow, in the phosphorus-rich Ni layer and Sn-Ni intermetallic interface. Kirkendall voids are voids that form at the interface of two dissimilar materials. They form because the two materials diffuse into each other at different rates. Other factors such as the concentration of P in the Ni-P+ layer and the density of mudflat cracks in the Ni-P+ layer have also been shown to have an influence on the propensity of brittle fracture. The intermetallics formed in the joint during the assembly process are shown in Fig. 58.18.

The presence of pervasive Kirkendall voids could reduce the strength of the solder joint. A mechanically applied strain could result in the sort of brittle solder joint failure shown in Figs. 58.19 and 58.20.

- **Ni-Cu-Sn Intermetallic** Another phenomenon reported to cause a similar failure is based on the formation of a Ni-Cu-Sn ternary intermetallic in the solder joint.<sup>20</sup> The Ni-Sn intermetallic forms on the component side during ball attach. When the part is mounted on the board, copper migrates from the board pad side, across the BGA ball, to form a Ni-Cu-Sn intermetallic on the component side. The thickness of this ternary intermetallic, typically 3 to 5  $\mu\text{m}$  thick, could grow with additional reflows.<sup>20</sup> Clearly, an important factor contributing to this phenomenon is the surface finish on the PWB side. If the surface finish has a barrier like Ni to prevent copper from migrating across the BGA ball, this ternary intermetallic is less likely to form on the component side.
- **Strain/Strain Rate** It has also been observed that the strain to failure of solder joints is a strong function of the strain rate. The higher the strain rate, the lower the strain-to-failure. One theory to explain this strain rate dependency is that the stiffness of bulk solder itself is strain rate dependent: at low strain rates, solder tends to deform and absorb some of the applied strain. Thus, less strain is actually transferred to the Kirkendall void-rich region. At high strain rate levels (typically above 5000  $\mu\text{e}/\text{sec}$ .), bulk solder behaves more like a linear elastic material and transfers more of the applied strain to the voids, causing brittle solder joint fracture. A graph illustrating the relationship between strain and strain rate for solder joint failure is given in Chap. 59.

**FIGURE 58.18** Solder joint intermetallic formation. (a) The constituent material stack up in a BGA substrate land pad. (b) After the ball is attached, a number of intermetallics are formed between the copper pad and the SnPb solder joint. Kirkendall voids are known to form at the phosphorus-rich Ni layer and Sn-Ni intermetallic interface. (c) After board level reflow, the interface region thickens and several more intermetallics are formed.<sup>19</sup> (Reprinted with permission from Renesas Technology Corp./© [2003] IEEE ECTC.)

**FIGURE 58.19** Brittle Solder Joint Failure.<sup>19</sup> A clear separation between the P-rich phase and IMC on the package side is shown. (Reprinted with permission from Renesas Technology Corp./© [2003] IEEE ECTC.)

**FIGURE 58.20** Intermetallics Formed In Solder Joint with Brittle Fracture.<sup>19</sup> (Reprinted with permission from Renesas Technology Corp./© [2003] IEEE ECTC.)

It is important to note that brittle solder fracture does not always occur exclusively. Frequently, it can be accompanied with pad lift, substrate cracking, or other intermetallic-related failure.

2. **“Black Pad” Corrosion Phenomenon**<sup>21</sup> This is a discoloration phenomenon caused by excessive oxidation of the Ni. This leads to increased contact resistance, which causes intermittent opens during electrical testing. It is believed that the “black pad” phenomenon is caused by impurities in the plating bath during the ENIG plating process. The impurities create pores in the gold plating, thus exposing the Ni to moisture and other contaminants. Consequently, the Ni oxidizes and manifests in varying extremes as a discoloration in the pad. Tighter process controls during the plating process and regular

purging of the plating bath can significantly mitigate this corrosion phenomenon. Failures stemming from black pad can be distinguished from brittle fracture by the following features: visible discoloration of the pads and a lot-to-lot dependency in failures due to impure plating baths.

**58.3.11.1.1 Effect of Lead-Free Conversion.** Given these known issues with ENIG, many package suppliers have moved away from it for lead-free applications. However, several package suppliers still use ENIG with standard tin-lead and lead-free solder. There isn't enough data to show the effect of ENIG on lead-free solder, but preliminary results indicate that the failure modes seen with tin-lead solder would also be seen with lead-free solder. In general, since lead-free solders are stiffer than tin-lead solders, they have higher strain/strain rate strength than tin-lead solders. More detail on tests to evaluate failure strength and failure modes is provided in the next chapter.

**58.3.11.2 Solder-On-Pad (SOP).** This is also known as “pre-applied solder” because it involves pre-applying a small amount of solder on the package substrate pad before the ball-attach process. Care must be taken to ensure that the height of solder applied on the pad does not exceed the thickness of the solder mask (Fig. 58.21).

**FIGURE 58.21** Solder-on-pad schematic.

Exceeding the height of the solder mask would result in alignment/registration issues during the assembly process. As with ENIG, there are concerns with the mechanical robustness of SOP solder joints. The Ni in ENIG serves as a diffusion barrier for the copper metallization. In the absence of Ni, copper diffusion occurs much faster and two intermetallics are known to form in SOP solder joints:  $\text{Cu}_6\text{Sn}_5$  and  $\text{Cu}_3\text{Sn}$ . Under high temperature aging conditions, these intermetallics are known to grow in thickness. Thus, if tin-lead or lead-free parts with SOP are aged at high temperature (either in lab testing or in field conditions), they could have a higher propensity for brittle fracture.<sup>22,23</sup> By extension, one concern is that if solder joints can become brittle when aged over time, what would happen if the product has been operating in the field at high nominal operating temperatures, and it is subjected to shock conditions? Would it fail early? For instance, what if the product is a cell phone with an SOP based BGA used in it? If the user drops the cell phone after sustained usage, is there a propensity for brittle fracture? According to some publications on shock testing of lead-free assemblies (Cheng et al.),<sup>22</sup> aged SOP joints subjected to shock conditions tend to fail relatively early. However, this has not been universally demonstrated. Moreover, the shock conditions to which hand held products are tested (~1500 G max), are much more aggressive than typical shock conditions for server environments (~500 G max). In tests performed on aged tin lead SOP samples subjected to lower shock conditions, the parts were not shown to fail due to brittle fracture, even though the presence of some Kirkendall voiding was observed (Mei et al.).<sup>24</sup> However, the amount of Kirkendall voiding observed was not as pervasive as that reported by Cheng et al.<sup>22</sup> (Fig. 58.22)

**FIGURE 58.22** SEM Backscattering Electron Image of Tested Sample with Solder-On-Pad Surface finish – Package/Ball Interface. The image shows the intermetallics formed at the joint/package interface. These intermetallics include a thick layer of  $Cu_6Sn_5$  and a thinner layer of  $Cu_3Sn$ . Small voids are seen at the  $Cu_6Sn_5$  and  $Cu_3Sn$  interface.<sup>24</sup> (Reprinted with permission from IEEE © [2005].)

A curve fit of the data by Cheng<sup>22</sup> et al. reported by Mei et al.<sup>24</sup> as a function of void area and aging time for different temperatures is shown in Fig. 58.23.

The fit equation from the Cheng et al.<sup>22</sup> data is given as<sup>24</sup>:

$$A = Ct^{0.5} \exp\left(\frac{-Q}{RT}\right) \tag{58.1}$$

**FIGURE 58.23** Curve fit of data at three different temperatures based on the data generated by Cheng et al.<sup>24</sup> The values are based on experimental measurements of void area versus time for different temperatures. (Reprinted with permission from IEEE © [2005].)

Where  $A$  = ratio of voided area to the joint interface area  
 $t$  = time in days  
 $Q$  = activation energy  
 $T$  = absolute temperature in K  
 $R$  = gas constant.  
 $C = 145590$  ( $\text{day}^{-0.5}$ )  
 $Q = 45413$  J/mol (0.47eV)

With this approximate curve fit, extrapolating to end-use conditions can give an estimate of the time it would take for the voiding to reach 50 percent of the interface area. For instance, at 50°C nominal operating temperature, it would take 6000 days (16.5 years) to reach 50 percent of the interface area. It is important to note that the mechanisms that control the propensity and pervasiveness of Kirkendall voiding are not clearly known at this time. There isn't enough experimental data in the industry at this time to conclusively validate the aforementioned relations.

The occurrence of Kirkendall voids is not limited to the package/solder joint interface. If OSP is used as the PWB surface finish, the same phenomenon is observed to occur on the PWB side.<sup>24</sup>

In terms of strain/strain rate strength, un-aged, SOP-based joints have been shown to have as much as twice the strength of ENiG joints. More details on comparison tests are outlined in the next chapter.

There are a number of other surface finishes used in the industry, such as Electroless Nickel Electroless Palladium Immersion Gold (NiPdAu), Immersion Silver, Immersion Gold, Immersion Tin, OSP and Electrolytic Nickel Gold. There are reliability and process trade offs with each surface finish. That is why it is recommended that strain/strain rate characterization and thermal cycling be performed for each set of surface finish before it is selected for the specific end-use conditions in which it will be used. The industry test methods used to evaluate different surface finishes are outlined in detail in the next chapter.

### 58.3.12 Final Electrical Test Architecture

During in-circuit testing (ICT), assemblies are subjected to high strains due to the number and distribution of test points applied underneath BGAs. Assemblies are also subjected to high strain rates in ICT because the speed of engagement of test points helps reduce the electrical contact resistance between the test probes and probe pads. Thus, from an electrical test perspective, high strain rates are desirable during ICT. However, there is a strain/strain rate range beyond which the likelihood of solder joint failure increases.

The actual strains induced in a printed circuit board assembly (PCBA) is a function not only of the number and layout of test points, but also the fixture design, package and PWB warpage, the surface finish used on the package and PWB, and the fixture actuation rate. During final test, it is very difficult, if not impossible to reduce the number of test points. Thus, if they are correctly designed-in early in the design process, it would minimize the likelihood of strain-induced failures in final testing.

A schematic showing the forces applied in the immediate vicinity of a BGA package in an ICT fixture is shown in Fig. 58.24. The distribution of test points underneath a BGA should be

FIGURE 58.24 Schematic of ICT loading conditions.

made as uniform as possible. Several ICT fixtures have push fingers on the top side, which push down on the board, countering the force of the test probes. The use of “push-pins” or “push-fingers” on the top side of the board is not recommended. Push fingers induce localized stress concentrations, resulting in high strain in their immediate vicinity. If used, push fingers should not be placed close to package corners. For some generic recommendations on ICT test point layout, refer to IPC7351.<sup>15</sup> An alternative to push fingers is the use of a Milled City or zero-flex top plate on the top side.

This is basically a rigid metal plate which has a negative image of the entire board milled out. Thus, as opposed to having several push fingers, the entire board is pressed against the Milled City plate. This significantly reduces local stress concentration, and could potentially be used to enable PCBAs to withstand more test points. Milled City plates are expensive, but considering the cost of line stops and customer-related issues due to strain-induced failures in ICT, the non-recurring cost of the Milled City is a worthwhile investment.

**58.3.12.1 Effect of Lead-Free Conversion.** The conversion to lead-free solder has given even more prominence to this issue. With lead-free solders, a higher temperature organic solderability preservative (OSP) could be used. As a result, it could take more force to establish contact with the test pads. This translates to higher force applied to the PCBA. Moreover, the effect of mechanical bending on lead-free solders is yet to be fully characterized. Thus, there is a greater need to characterize the mechanical force applied on lead-free assemblies.

For the same applied force, the strain on thinner PWBs is higher than that on thick PWBs. Thus, this is more critical on assemblies with relatively thin boards (<93 mils thick). However, depending on the package, warpage, surface finish, and number of test points, it could also be seen on thick boards.

Strain gage characterization should be performed on fixtures with actual boards, in order to verify that excessive strains are not applied on critical components. In an effort to standardize strain characterization, the JEDEC/IPC 9704<sup>25</sup> test method was published in June 2005. This test method outlines the procedures and best practices relating to strain measurement in a manufacturing environment.

### 58.3.13 Package Design Parameters

A key factor that impacts second-level interconnect reliability is the package itself. Although the primary function of the package is to pass signals, power, and ground from the silicon device to the PWB, the package also provides protection for the silicon and enables a more robust interconnect than a direct chip attach. The critical package design parameters which can have a significant impact on the reliability of the solder joints are discussed in this section.

**58.3.13.1 Overall Dimensions and Distance from Neutral Point (DNP).** Package size continues to grow as the number of I/Os increase to meet the demands of ever increasing IC functionality. As IC complexity increases, memory is embedded in devices, while as silicon feature sizes decrease, I/O counts continue to be driven upward. Package dimensions have surpassed 50 mm. Package layer counts for both ceramic and plastic material sets continue to increase rapidly.

In addition to the solder joint geometry issues outlined in Sec. 58.3.8, increases in overall size tend to coincide with increases in the distance from the center of the package to the outer ball (see Fig. 58.25). This dimension is referred to as the Distance from the Neutral Point (DNP). As DNP increases, the amount of stress and subsequent damage inflicted on solder joints increases, especially during thermal cycles encountered in field environments. Thus packages with larger DNPs (and with all other material and design parameters equivalent) will have lower interconnect reliability. This is crucial when assessing second-level reliability data.

Most packaged IC suppliers qualify their products by thermal cycle experiments. The most common board level temperature cycling methodology used across the industry is outlined in IPC 9701.<sup>6</sup> The resistance in each solder joint is typically monitored in real time by incorporating a daisy-chain package and some type of data acquisition system. The end results of

**FIGURE 58.25** Distance from Neutral Point (DNP) for a BGA-type package. The DNP increases when moving away from the center (center line) of the package. Pitch is also indicated in this diagram. Pitch is defined as the center-to-center distance between two adjacent interconnects (in this example, between two adjacent solder balls).

these experiments are failure distributions typically presented as Weibull plots (for details on Weibull distributions and failure life analysis, refer to Sec. 61.2.2 in the next chapter) that show failure percentage as a function of time.<sup>26</sup> Note that if a package with a larger DNP than was qualified is considered, then there could be severe degradation in reliability and a full assessment should be conducted. However, if a package with a smaller DNP (10 to 20 percent smaller) than the package qualified (with all other material and design parameters being equal) is considered, then the proposed package should be at least as reliable as the qualified package.

**58.3.13.2 Ball Pitch and Ball Size.** Ball pitch is the center-to-center distance between two adjacent solder balls (see Fig. 58.25). In theory one could change the ball pitch and keep the same solder joint size. In practical applications though, decreases in ball pitch also require a reduction in solder ball diameter and pad size for physically accommodating the decrease in distance between adjacent balls. This decrease in ball size, with decreasing pitch, results in the formation of smaller balls with smaller stand-off between the package and the PWB. Smaller solder balls and decreased stand-off have been shown to decrease solder joint reliability (see Fig. 58.26).

The dashed line in Fig. 58.26 represents the finite element analysis results for a 0.889mm (35 mil) ball. The solid line represents finite element analysis results for a 0.762 mm (30 mil) ball. Note that the 0.889 mm ball is 1.3 times more reliable than the 0.762 mm ball. Thus reduction in pitch can result in decreases in reliability due to the subsequent decreases in solder ball size necessary to accommodate adjacent balls and the reduced stand-off heights due to smaller solder balls.

The PWB designer is therefore faced with a dilemma when considering a reduction in ball pitch. Not only is there a risk of reduced assembly reliability, but there is also a design challenge. A direct consequence of decreased pitch is added complexity in the ability to route all traces out from the package to the PWB. Designers are also sometimes forced to add additional layers to PWBs in order to accommodate reduced-pitch parts. This layer increase results in increased price and in some instances, drastic reductions in capacity due to the increased complexity associated with fabricating high-layer-count PWBs.

**58.3.13.3 Ball Array (Full or Depopulated).** Ball array is another variable that has an indirect impact on solder joint reliability. There is a coupled effect between the location of the edge of the packaged die, the solder ball array, and the state of stress in the solder joints. The silicon has a much lower CTE than plastic substrates. Thus the die can create a state of overconstraint, producing excessive stress in the solder joints under and near its edge. This overconstraint tends to be worst in joints near the edge of the die.

Figure 58.27 contains schematics of one configuration where a full array is employed and the edge of the die falls over the solder joints. Fig. 58.28 illustrates an alternative design where a region near the perimeter of the die is depopulated of all solder balls (the depopulated configuration).

**FIGURE 58.26** Weibull plots for two different ball size/stand-off heights. The solid line indicates the finite element analysis (FEA) predicted failure distribution for an interconnect based on a 30-mil stand-off height. The dashed line indicates the FEA predicted failure distribution for an interconnect based on a 35-mil stand-off height. Note that a reduction in stand-off height correlates with a decrease in fatigue life.

Many plastic (laminated) package suppliers offer a depopulated option to enhance reliability by not placing solder joints in the worst-case regions under the perimeter of the die. Additionally, many package designers further reduce risk of CTE-induced joint failure by only placing redundant power and ground or nonfunctional thermal balls under the core. If redundant balls or thermal

**FIGURE 58.27** Full array with solder joints under the die perimeter. Solder ball locations are indicated by the array of circles. The die perimeter is indicated by the black dashed rectangular outline. Note that the die edge falls directly over solder joints.

**FIGURE 58.28** Depopulated array with no joints under the perimeter of the die. Solder ball locations are indicated by the array of circles. The die perimeter is indicated by the dashed rectangular outline. Note that the die edge falls in an area of depopulated solder balls.

balls do crack, the impact on device performance is negligible. Finally, in large laminate packages, the corner-most balls could also fail early. As a result, many package suppliers depopulate the corner balls of the package to enhance solder fatigue life.

**58.3.13.4 Heat Spreader/Stiffener.** A cross-sectional schematic of a flip-chip assembly, with a heat slug and stiffener, is shown in Fig. 58.29. The primary reason for employing a heat spreader lid is for thermal management. A secondary benefit is that the stiffener and heat slug reduce the potential for out-of-plane warpage occurring during reflow and thermal cycling. An additional benefit of incorporating a heat slug and stiffener into a laminate package design is improved ability to handle the package due to increased robustness of the packaged die.

**FIGURE 58.29** Flip-chip BGA with stiffener and heat slug. The stiffener provides added rigidity to the package and also provides mechanical support for the heat sink.

A variety of heat spreader materials have been used: copper, aluminum, steel, and aluminum silicon carbide (AlSiC). Copper provides the best thermal conductivity, but it has a high CTE. AlSiC has a slightly higher modulus than copper, but it has a lower CTE. As a result, in several applications, AlSiC is gaining more prevalence. Its thermal conductivity is lower than copper and comparable to aluminum (180 to 200 Wm<sup>-1</sup>K).

For cost reasons, several package suppliers also use an alternative to the heat spreader/stiffener design, namely a single piece lid design to act as a rigid support and provide heat transfer at the same time. This design is easier to manufacture and also reduces assembly steps (See Fig. 58.30 for more details).

The thickness of a single piece lid is typically less than that of the heat spreader/stiffener combination. Changing the stiffness of the package could alter its out-of-plane warpage, which

FIGURE 58.30 Single piece lid design.

in turn could impact the reliability of the solder joints. Therefore the effect on the overall stiffness should be characterized when using a single piece lid. One characterization method is to perform Moiré measurements on the free standing package, as a function of temperature.

Another variation of the standard heat spreader/stiffener design is the use of just a stiffener alone. This is usually for bare die applications where the wattage of the chip is so high that the thermal resistance between the chip and the heat spreader is unacceptable. In such cases, the stiffener is retained for stiffness and robustness, but the heat spreader is removed.

**58.3.13.5 Mold Compound Selection.** The overmold compound used in plastic ball grid array (PBGA) packages could significantly impact the assembly yield and reliability of solder joints. If the glass transition temperature ( $T_g$ ) of the mold compound is significantly below the peak reflow temperature and if its modulus and CTE drastically change above its  $T_g$ , the package could warp significantly as it is heated. As a result, when the package reaches liquidus, the effective warpage between the package and PWB could be such that solder joint opens/bridges could occur. In large PBGA packages (>40 mm), it would be more effective to use an integrated heat spreader in the molded package to rigidize it and minimize excessive warpage. Integrated heat spreaders are primarily used to improve thermal performance, but they also help rigidize the package for improved assembly yield.

With the conversion to lead-free materials, the mold compound selected needs to be such that it can withstand the higher reflow temperatures of lead-free assembly. If the mechanical material properties of the mold compound (elastic modulus, CTE, and  $T_g$ ) are not appropriately selected, the package could warp significantly at reflow temperatures and result in solder joint opens.

**58.3.13.6 Underfill Material Selection.** The underfill material selected in flip chip BGA (FCBGA) packages could significantly impact the reliability of the board mounted package. If the underfill material is too stiff, it would rigidize the assembly and thus transfer more strain to the silicon die. This could result in delamination at any of the critical interfaces: underfill/passivation, passivation/die, underfill/substrate, or within low- $k$  layers.

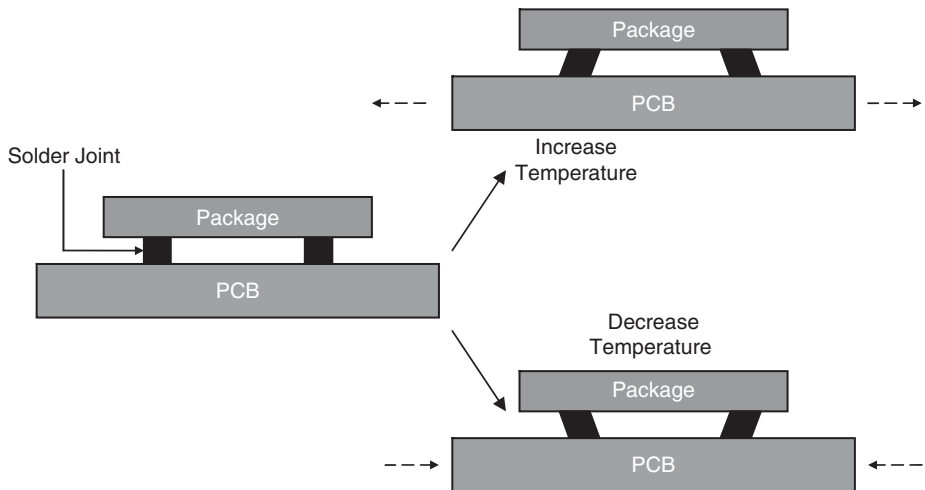

On the other hand, if the underfill material is too soft, it could result in first level interconnect failure. A less stiff underfill could also help reduce board level assembly warpage, which in turn helps the second-level interconnects. Thus, the stiffness of the underfill selected should be optimized such that it does not lead to delamination or first-level interconnect failures.<sup>9</sup> In addition to stiffness, CTE, and  $T_g$ , there are several other factors that dictate the underfill material selected, such as thixotropy, viscosity, shrinkage, curing temperature, and curing time.

The choice of underfill material is also influenced by the conversion to lead-free. For lead-free packages, even though there is a European exemption on the first level interconnects,<sup>27</sup> many package suppliers are looking at using lead-free first level interconnects. As a result, the underfill material selected has to be such that it can withstand the higher reflow temperatures, and has low shrinkage for the increased temperature range.

**58.3.13.7 Die/Package Aspect Ratio.** The size of the silicon die relative to the package body size could significantly impact the reliability of the package. This is especially applicable to PBGA packages. The larger the die relative to the package, the higher the CTE mismatch-driven strains imparted to the second level solder joints.<sup>28</sup> The degree of impact varies with package body size and absolute die size.

**58.3.13.8 Package Substrate Material.** The choice of package substrate material can have a large impact on solder joint reliability. Some substrates require employing solder ball alternatives (such as the ceramic solder column carriers shown in Fig. 58.4) or even the elimination of a soldered solution due to interconnect reliability considerations. A wealth of information regarding ceramic and plastic substrates can be found in the literature.<sup>26,29,30</sup> This section focuses on the impact of those materials on solder joint reliability.

The two key material properties of a substrate that impact interconnect reliability are modulus of elasticity ( $E$ ) and coefficient of thermal expansion (CTE). Modulus of elasticity is defined as the ratio of stress to strain and can be used to describe a material's ability to resist deformation when subjected to an applied load. CTE relates the change in length of material when heated or cooled and can be used to describe a material's deformation when subjected to temperature changes. Reference 31 contains detailed discussions of modulus of elasticity and coefficient of thermal expansion. A tremendous amount of material property data can be found in the literature.<sup>26,29,30</sup> Fig. 58.31 contains a sketch of a simplified solder joint interconnect. Note that the driving force for solder joint fatigue during field use is the coefficient of thermal expansion mismatch between the assembled package and the PWB. Additionally, the modulus of elasticity of the substrate can impact the fatigue life of solder joints by increasing (or decreasing) the driving force that is imparted to the solder interconnect.

**FIGURE 58.31** Simplified CTE mismatch effects. As the temperature increases, the PWB expands at a higher rate than the package due to the package having a lower effective CTE. As the temperature decreases, the opposite effect is observed.

Ceramic materials provide excellent CTE match between the die and package, which then reduces the risk of first-level solder bump failure in flip-chip applications. Unfortunately, this superb CTE match between the ceramic package and the silicon die creates a large CTE mismatch between the ceramic package and the PWB. This CTE mismatch creates severe stress on the second level interconnects (see Fig. 58.31). This CTE mismatch, combined with DNP issues

(previously discussed), limits ceramic BGA body sizes to approximately  $32 \times 32$  mm. Ceramics with larger body sizes typically employ solder columns (Fig. 58.4) or compression-type sockets for second-level interconnect.

The CTEs of plastic packages tend to match the CTEs of PWBs fairly well. This CTE match allows for larger package body sizes to be employed when using a laminate-based BGA than with a ceramic package. It is crucial to note that many other variables independent of second-level reliability must be taken into consideration when selecting a package. Power requirements, signal integrity, first-level reliability (interconnect between the die and package), and cost must all be balanced when selecting the correct package for a specific application.

**58.3.13.9 Impact of Low- $k$  Dielectrics.** Continued miniaturization and integration has led to the need for a multilevel interconnect layout to minimize the time delay due to parasitic resistance ( $R$ ) and capacitance ( $C$ ). The improvement in gate level device speed is negated by the propagation delay at the metal interconnects because of the increased RC time constant.<sup>32</sup> For instance, the RC delay of long interconnections contributes up to 50 percent of the time delay in devices with a gate length of 250 nm or less.<sup>33</sup> A reduction in the RC time constant requires the use of low resistivity interconnect materials and low capacitance interlayer films. The capacitance is a function of the material dielectric permittivity ( $\epsilon_i$ ), area ( $A$ ), and thickness ( $d$ ). ( $C = \epsilon_i A/d$ ). Increasing the area would require increased interconnect lengths, which in turn would result in high resistance. The thickness can also not be increased because it also increases resistance and poses manufacturing challenges in consistently filling the interlayer layers. Consequently, the dielectric constant ( $k$ ) needs to be reduced. Hence the need for low- $k$  materials. In addition to having a low dielectric constant, ideal low- $k$  materials need to have low residual stress, high planarization capability, high gap-filling capability, low deposition temperature, and ease of process integration.<sup>32</sup> A list of possible candidates for low- $k$  materials is outlined in Table 58.3.<sup>33</sup>

**TABLE 58.3** Typical Low- $k$  Materials<sup>33</sup>

Determinant	Materials	Dielectric constant
Vapor-phase deposition polymers	Fluorosilicate glass (FSG)	3.5–4.0
	Parylene N	2.6
	Parylene F	2.4–2.5
	Black diamond (C-doped oxide)	2.7–3.0
	Fluorinated hydrocarbon	2.0–2.4
	Teflon-AF	1.93
Spin-on polymers	HSQ/MSQ	2.8–3.0
	Polyimide	2.7–2.9
	SiLK (aromatic hydrocarbon polymer)	2.7
	PAE [poly(arylene ethers)]	2.6
	Fluorinated amorphous carbon	2.1
	Xerogels (porous silica)	1.1–2.0

However, several of the new low- $k$  materials are porous and structurally weak. This poses several challenges in the back-end assembly process: poor adhesion, residual stresses in the inner layer dielectric (ILD) films, and so on. In addition to optimizing and better monitoring the wafer-sawing process, the effect of chip-to-package interactions also needs to be characterized. The choice of material set, underfill, substrate, lid material, and so on could impact the reliability of the low- $k$  dielectric.

In flip-chip BGA (FCBGA) packages, the choice of underfill material in particular has been the subject of considerable interest.<sup>34–36</sup> In addition to a new material set and design rules, several packaging assembly manufacturers have evaluated the use of low glass transition

temperature ( $T_g$ ) underfills to reduce the stresses imparted to the silicon. However, while using a low  $T_g$  underfill may minimize the stresses on the low- $k$ , it could in turn transfer the stresses elsewhere, such as in the first-level interconnect.<sup>37</sup> Moreover, the effect of the material set on ILD delamination and solder joint reliability may be different when the free standing package is stressed, as opposed to when it is mounted on a printed circuit board and then stressed.

In wirebond BGA packages, the effect of the wirebonding process on the low- $k$  dielectric needs to be characterized.<sup>38</sup> In addition, the choice of mold compound material (modulus and CTE) could also impact the long term reliability of the low- $k$  dielectric in the fully assembled package. The package with the selected material set should be subjected to component level and second level temperature cycling, followed by scanning acoustic microscopy (SAM) to ensure that there are no delamination-induced failures in the low- $k$  dielectric or other critical interfaces.

### 59.1 INTRODUCTION

---

In Chap. 58, the critical design variables that could impact the reliability and manufacturability of printed circuit assemblies (PCAs) have been outlined. The use of various assessment tools to quantify the expected life of PCAs is an important aspect of design for reliability. Data collected from standard tests can be used with acceleration transforms and finite element analysis to assess the expected service life of any interconnect. Experimental data play a crucial role in reliability assessments. Poor data or data obtained under incorrect experimental conditions can lead to grossly inaccurate reliability assessments. “Garbage in equals garbage out” is nowhere more true than in interconnect reliability assessments. The history and experience gained over years of use of tin-lead solders are no longer applicable to lead-free assemblies because lead-free solders behave differently under the same end-use conditions and relatively little data are available on the characteristics of lead-free solders. The formulas for predicting the field life of solder joint interconnects would have to be revisited and validated with extensive experimental data. Moreover, the introduction of lead-free materials is accompanied by new failure mechanisms that are yet to be fully understood and mapped into field-life prediction models.

#### 59.1.1 Experimental Tests

The different levels of solder joint interconnects in a typical PCA are illustrated in Fig. 59.1.

A myriad of experimental tools have been developed to assess solder joint reliability rapidly. These include:

**FIGURE 59.1** First-, second-, and third-level interconnects defined, employing a flip-chip assembly as an example. The first-level interconnect is the primary connection between the silicon die and the package substrate. In this example, the connection is created by the solder bumps between the die and the package. The second-level interconnect in this example is the next level of connection between the package substrate and the module substrate. The third-level interconnect in this example is created when the solder balls on the bottom side of the module substrate are attached via surface-mount technology (SMT) to the printed wiring board (PWB).

- Thermal cycling
- Thermal shock
- Air-to-air cycling
- Liquid-to-liquid cycling
- Mechanical bending
- Mechanical deflection
- Hyper-Peltier cooled thermal cycling

It is crucial for the PWB designer to understand the techniques employed, the applicability of the results, and the quality of the data when assessing the reliability of any package that will be placed on his or her PWB. Although rapid assessments are desirable, their benefit diminishes if the failure modes are fictitious and not indicative of expected field failures.

### 59.1.2 Impact of Lead-Free Materials on Reliability

The conversion to lead-free materials requires a reassessment of these experimental tools and field-life assessment techniques. New materials and failure modes need to be adequately captured in numerical and experimental test methods to model correctly the sort of thermal and mechanical conditions that an interconnect would be exposed to in field operating conditions.

The following key aspects of quantitative reliability assessment are discussed at length in this chapter:

- Thermomechanical reliability:
  - Temperature cycling tests used to determine the thermomechanical reliability of tin-lead and lead-free assemblies
  - The role of Weibull plots in estimating the failure distribution and characteristic life of solder joints from temperature cycling data
  - The acceleration transforms that can be used to estimate the field life of tin-lead and lead-free solder joints based on the results of temperature cycling tests
  - The role of power and minicycles in predicting the field life of solder joints

- Examples illustrating the use of acceleration transforms to compare the fatigue life of packages tested in different thermal cycling and end-use conditions
- Mechanical reliability:
  - Bend test methodologies and test methods that could be used to perform a relative comparison between different package types and surface finishes
  - Sample experimental data showing the comparative difference between different surface finishes and solder metallurgies
  - Shock test methodologies that could be used to perform a relative comparison between different packages and end-use conditions
  - Ball adhesion test methodologies: high-speed shear, pull testing, and impact testing

In addition, this chapter outlines the role of numerical analysis techniques in analyzing and improving the reliability of solder joint interconnects. Detailed procedures illustrating the use of finite element analysis (FEA)<sup>1</sup> in estimating the thermomechanical fatigue life of solder joint interconnects and monotonic bend testing are also discussed.

## 59.2 THERMOMECHANICAL RELIABILITY

---

In field operating conditions, ball grid array (BGA) solder joints are continuously subjected to strains due to the coefficient of thermal expansion (CTE) mismatch between the package and the PWB. These strains, which are caused by small but frequent fluctuations in temperature, accumulate as the device is powered up or down. As a result, cracks initiate in the solder joint interconnects and can eventually propagate, leading to solder joint opens. The ability of the solder joint interconnects to withstand these differential strains during field operating conditions for a desired lifetime is generally referred to as *thermomechanical reliability*. The most common method for accelerating this failure in the lab is by thermally cycling the assembled device through extreme temperatures while recording any electrical opens that may occur during the test.

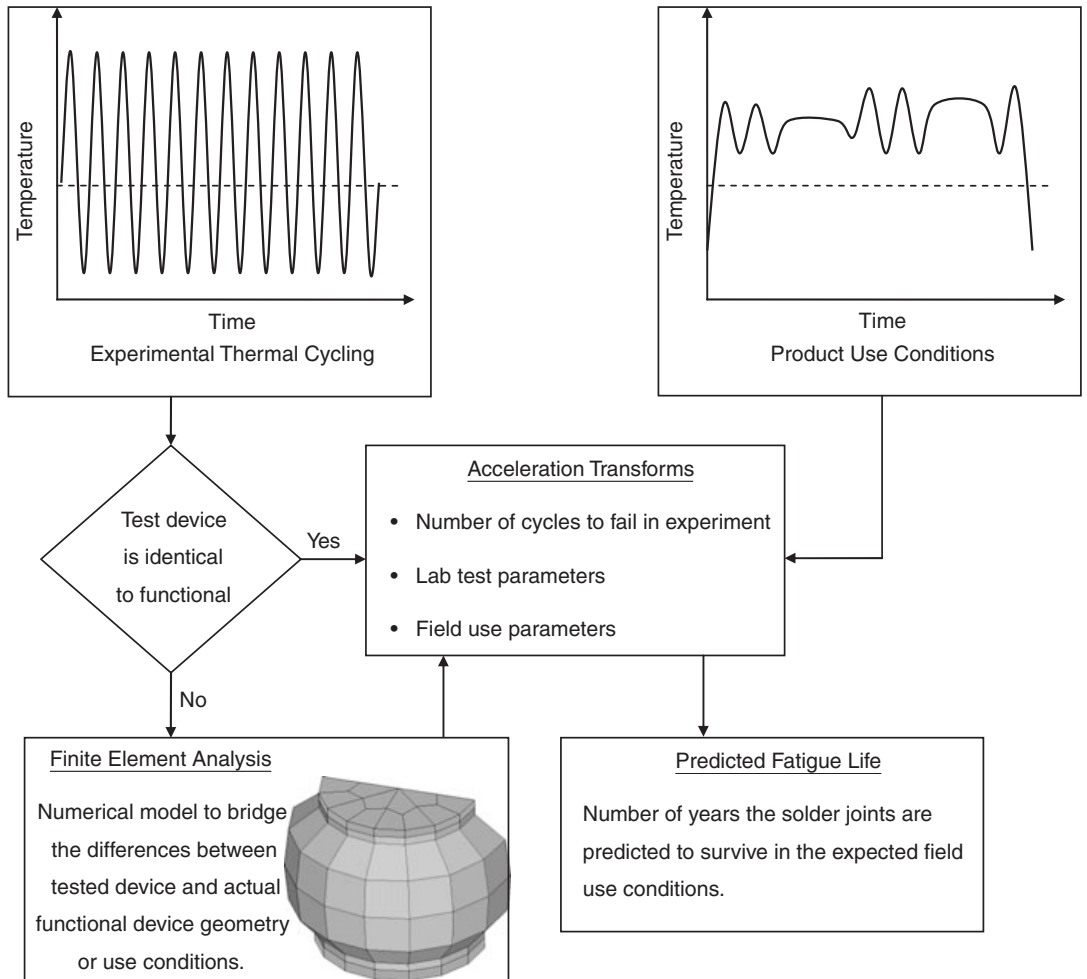

### 59.2.1 Temperature Cycling

Thermal cycle experiments have been the current industry standard for assessing second-level interconnect reliability. These types of tests tend to produce solder joint and solder joint-pad interfacial fractures that are typically seen in field failures. The fact that thermal cycle tests produce the same physical failures allows for detailed acceleration transformations and finite element-based life assessments to be made employing thermal cycle data as input.

The industry test method that is widely used for this testing is IPC-9701.<sup>2</sup> IPC-9701 provides detailed guidelines for the recommended temperature cycling test methods for evaluating the reliability of surface-mount solder joints. In addition, IPC-9701 also provides guidelines for estimating the performance of solder joints in different field-use conditions from the recommended accelerated thermal cycling tests.

An important benefit of performing industry standardized testing as recommended by IPC-9701 is that device suppliers can perform this test routinely for their devices, irrespective of where the device would be used. The results of the tests can then be used to determine whether the device will survive in a variety of end-use conditions. This saves significant testing cost and design time while providing a baseline for comparison of devices from different suppliers.

Where there are minor differences between the conditions in which the device is to be used, finite element analysis can be performed to bridge the differences between the tested

**FIGURE 59.2** Flowchart of the solder joint thermomechanical reliability qualification process. Experimental data generated in the lab environment is compared with the expected product end-use conditions. If the package tested is identical to that used in the product, the acceleration transforms are used to map the fatigue life in the lab to the fatigue life in the product end-use conditions. If the package tested is similar but not identical to that used in the product, FEA is performed to account numerically for the differences between the tested and actual package before using the acceleration transforms.

device and the actual environment in which a very similar device would be used. The entire process by which the reliability of a device can be assessed is illustrated in Fig. 59.2.

Thermal cycle experiments are typically performed in single-chamber ovens. Dual-chamber systems are sometimes employed, but single-chamber equipment tends to dominate the test space. The main drawback of a dual-chamber oven is the lack of control over the thermal loading profile when transferring from one chamber (or thermal zone) to the other. Regardless of whether a single or dual chamber is used, temperature is cycled from a maximum ( $T_{max}$ ) to a minimum ( $T_{min}$ ) value. Temperature is ramped from one temperature extreme to another at a controlled rate, referred to as the *ramp rate*. Temperature is also held at the maximum and minimum values for a predetermined time known as the  *dwell time*. Table 59.1 lists typical

**TABLE 59.1** Typical Thermal Cycle Test Parameters for Second-Level Reliability Qualification

Parameter	Value
Maximum temperature ( $T_{max}$ )	100°C
Minimum temperature ( $T_{min}$ )	0°C
Ramp rates from $T_{min}$ to $T_{max}$ and $T_{max}$ to $T_{min}$	10°C/min.
Dwell time at $T_{max}$ and $T_{min}$	10 min.

**FIGURE 59.3** Typical thermal cycle profile. In this plot,  $T_{max} = 100^{\circ}\text{C}$ ,  $T_{min} = -40^{\circ}\text{C}$ , and the cyclic frequency is 60 min.

experimental parameters for second-level reliability qualification. Figure 59.3 contains a plot of temperature versus time along with explanations of the key experimental parameters.

Data acquisition systems and/or event detectors (commonly referred to as *glitch detectors*) are employed to monitor resistance and/or scan for intermittent opens in real time. One of the early techniques for assessing solder joint integrity during thermal cycling was to remove parts periodically from the test chamber and measure resistance manually at room temperature.

The major risk associated with this technique is that opens are observed only at temperature extremes when the deformations due to CTE mismatch are largest. As the package cools to room temperature, most of the CTE-based deformations that pull cracked surfaces of solder joints are gone and there is a potential for cracked surfaces to be in enough physical contact to provide acceptable continuity. In some cases, the cycle number at which opens are observed at temperature extremes is much shorter than the cycle at which the same opens are observable at room temperature.

A schematic of a typical thermal cycling chamber, with the boards installed and connected to a data acquisition system, is shown in Fig. 59.4.

**FIGURE 59.4** Schematic of a typical thermal cycling chamber and data acquisition system.

**59.2.1.1 Effect of Lead-Free Conversion.** The thermal cycling profile listed in Table 59.1 is also applicable to lead-free solders. Most of the damage accumulation occurs during the high-temperature dwell phase. If the high-temperature dwell cycle is shortened, the damage accumulated per cycle would be reduced. It is desirable to maintain a high-temperature dwell long enough to allow creep saturation. However, practical limitations prevent this; as a result, the recommendations in IPC-9701-A<sup>3</sup> (Appendix B) are that a 10 min. dwell time be used, and where possible a 30 min. (or higher) dwell time could be used. Finite element analysis could be used to calibrate the experimental data and determine the effect of dwell time on long-term reliability.

**59.2.1.2 Thermal Shock.** Thermal shock experiments continuously cycle parts from a high to a low temperature very rapidly. These types of experiments are typically used as screening tools or to run parallel experiments on a known good part and a proposed new component to assess the relative performance of each part. Thermal shock experiments are quite rapid, with thermal shock test durations on the order of days rather than the months associated with thermal cycle test times.

The main drawback of thermal shock experiments lies in the fact that these types of tests tend to induce failure modes not observed in the field. Additionally, even if solder joint fatigue can be induced, it is very difficult to map the high ramp rates associated with thermal shock loading conditions to the more gradual thermal loading conditions that occur in the field. Consequently, this test technique is limited to relative comparisons between packages in which the failure modes have been shown to be comparable under the same thermal shock test conditions.

## 59.2.2 Weibull Distributions

The results of the temperature cycling tests described in Sec. 59.2.1 can be used to estimate the field operating life of the solder joint interconnects by using the acceleration transforms outlined in detail in Sec. 59.2.3.

However, to determine the field operating life, one needs to know the life of the parts in lab testing. The raw data obtained from the lab test could be fitted with a failure distribution to determine the mean life of the parts. Typical failure distributions include Weibull, Normal, Lognormal, and Exponential. For wear-out type of failures, the Weibull and Lognormal distributions are usually used, with Weibull being the most common. Weibull distributions are lowest value distributions derived from the weakest-link theory.<sup>4,5</sup> Solder joint interconnects can be considered as connected in series. Usually, the failure of one joint at a critical location could cause the entire device to fail. The joints that fail early are usually located at the highest stress locations in the package. Devices with more resilient joints would not fail early. A Weibull distribution captures the minimum solder joint life, and the shape parameter captures the quality of the joints as a function of their construction and the applied stress.<sup>4</sup> There are different types of Weibull distributions: one-parameter, two-parameter, and three-parameter. The three-parameter Weibull Probability Distribution Function (PDF)<sup>6</sup> is as shown in Eq. 59.1.

$$f(t) = \frac{\beta}{\eta} \left( \frac{t-\gamma}{\eta} \right)^{\beta-1} e^{-\left( \frac{t-\gamma}{\eta} \right)^{\beta}} \quad (59.1)$$

where  $f(t)$  = Probability Distribution Function

$\beta$  = shape parameter (which defines the shape of the distribution)

$\eta$  = scale parameter (which defines the characteristic life of the distribution; this is the time in which 63.2 percent of the tested samples would fail)

$\gamma$  = location parameter (which defines the location of the distribution in time)

$t$  = time

Two-parameter and three-parameter distributions are commonly used to fit the temperature cycling data. The two-parameter distribution fits a straight line though the data, whereas the three-parameter distribution fits a non-linear curve through the data. In general, the two-parameter distribution is more conservative than the three-parameter distribution. Best practice is to perform regression analysis to determine which distribution best fits the data.

Another important factor in the statistical assessment of test data is the *confidence interval*. Confidence intervals (or *confidence bounds*) take into account the quality of the data based on the number of samples tested.<sup>7</sup> When two separate experimental data sets are being compared, double-sided confidence bounds are useful in normalizing the data based on the number of samples tested in each data set. An example of upper and lower confidence bounds set at 90 percent is illustrated in Fig. 59.5.

### 59.2.3 Material Properties

A tremendous number of researchers have explored the reliability of Pb/Sn solder alloys.<sup>8</sup> A wealth of data, material properties, and proposed constitutive relationships have been captured in the literature.<sup>8,9,10</sup> However, there is relatively little information in the literature on the material properties of lead-free solders. Moreover, the material property information available is on slightly different compositions of lead-free solders, with tests performed in different ways.

One of the challenges with both Pb/Sn and lead-free solders is that they undergo viscoplastic deformation (creep) as a function of time, temperature, strain rate, and applied stress. A variety of creep deformation models have been used to model the viscoplastic behavior of lead-free solders. The Anand model has been successfully used to model the viscoplastic behavior of Pb/Sn solders. The model allows for the simultaneous incorporation of time-independent plastic deformation as well as time-dependent creep deformation.

$\beta_1 = 2.4926, \eta_1 = 3543.4549, \rho = 0.9927$   
 $\beta_2 = 18.0349, \eta_2 = 3552.6721, \rho = 0.9866$

**FIGURE 59.5** A typical two-parameter Weibull distribution. The plot shows two data sets with different shape parameter ( $\beta$ ) values but comparable characteristic life ( $\eta$ ). Extrapolating to 1 percent failure free life shows that the 90 percent lower-bound confidential interval for data set 1 is lower than that for data set 2, even though the characteristic lives are comparable.

The functional form of the Anand model is given as shown in Eqs. 59.2 through 59.5.<sup>11,12</sup>

$$\dot{\epsilon}_p = A \left[ \sinh \left( \xi \frac{\sigma}{s} \right) \right]^{\frac{1}{m}} \exp \left( \frac{-Q}{kT} \right) \tag{59.2}$$

- where
- $\dot{\epsilon}_p$  = inelastic strain rate
  - $A$  = experimentally determined empirical constant
  - $Q$  = activation energy
  - $R$  = gas constant
  - $\xi$  = stress multiplier
  - $\sigma$  = equivalent stress
  - $s$  = internal state variable
  - $m$  = strain rate sensitivity parameter

$$\dot{s} = \left\{ h_o \left( \frac{|B|}{|B|} \right)^a \frac{B}{|B|} \right\} \frac{d\epsilon_p}{dt} \tag{59.3}$$

$$B = 1 - \frac{s}{s^*} \tag{59.4}$$

$$s^* = \hat{s} \left\{ \frac{d\epsilon_p}{dt} \exp\left(\frac{Q}{kT}\right) \right\}^n \quad (59.5)$$

where  $h_o$  = hardening/softening constant  
 $a$  = hardening/softening strain rate sensitivity coefficient  
 $s^*$  = saturation value of  $s$  for a given set of temperature and strain rate data  
 $\hat{s}$  = saturation coefficient  
 $n$  = strain rate sensitivity coefficient for the saturation value of deformation resistance

The relevant material property information on the solder composition close to that recommended by iNEMI<sup>13</sup> (Sn3.9Ag0.6Cu) is listed in Table 59.2.

One disadvantage of the Anand model is that it mainly captures steady-state creep of solder, but it does not capture primary creep (see Fig. 59.6). Since a significant portion of solder joints' field life is spent in the primary creep phase, it is difficult to predict fatigue life driven by end-use conditions. In other words, although the Anand model can be successfully used in predicting the fatigue life of solder joints tested in laboratory conditions, it may not be very accurate in predicting the fatigue life of solder joints in field use conditions. What may be needed is a time-hardening creep model that can better capture primary, secondary (steady-state), and tertiary creep.

Another model that proposes the incorporation of primary and tertiary creep strain rates is the A- $\Omega$  model.<sup>17</sup> This model proposes that the primary creep strain rate be represented as an exponential decay function of increasing creep strain, and the tertiary creep strain rate be represented as an exponential growth function of increasing creep strain. However, this model is relatively new and has not been validated with independent experimental reliability data across the industry.

Other models available in the literature for different lead-free solder metallurgies are listed in Table 59.3.

A more comprehensive list of mechanical material properties of lead-free solders and other materials used in electronic packages can be found in Reference 22.

**FIGURE 59.6** A typical creep strain versus time curve for viscoplastic materials. The curve shows that creep strain starts out as a non-linear curve, becomes steady for a significant period, and then increases significantly into tertiary creep. Most of the life of a solder joint is spent in the primary and secondary creep strain range of the curve.

**59.2.4 Norris-Landzberg Acceleration Transformation**

PWB designers typically receive a failure distribution plot (see Fig. 59.5) as part of a second-level package qualification report. This failure distribution plot is typically obtained in a thermal cycle oven under controlled temperature profiles that include the maximum and minimum

temperatures ( $T_{max}$  and  $T_{min}$ , respectively) of the thermal cycle along with the frequency ( $f$ ) of the experimental thermal cycle. The designer must then relate these experimental data obtained under ideal conditions to a different thermal cycle condition (or conditions) encountered in the product end-use environment. Although relative comparisons of two packages thermally cycled under identical conditions can be made in a ranking sense, this type of analysis yields no information regarding the actual lifetime of the solder joints under field loading conditions. This section focuses on the mapping of a laboratory thermal cycle to different end-use thermal profiles using strain as a damage metric.

**59.2.4.1 Fatigue Behavior.** The fatigue behavior of many metals (including Pb/Sn and lead-free solder alloys) can be described by the Coffin-Manson relationship (Eq. 59.6),<sup>9</sup> which relates the fatigue life of a metal to the plastic strain the material experiences during loading. Elastic strain is the reversible or recoverable deformation that occurs during a loading cycle. Plastic strain is the amount of irreversible (or permanent) deformation that occurs during a loading cycle.

$$\varepsilon = \varepsilon_e + \varepsilon_p = AN_f^{-c} + BN_f^{-m} \quad (59.6)$$

where  $\varepsilon$  = total strain per cycle  
 $\varepsilon_p$  = plastic portion of the cyclic strain  
 $\varepsilon_e$  = elastic portion of the cyclic strain  
 $N_f$  = number of cycles to failure  
 $A, B, c, m$  = experimentally determined empirical constants

Most solder joints fail in the low cycle fatigue region (less than 10,000 cycles to failure),<sup>9</sup> where strain is primarily plastic. Thus, neglecting the elastic component of strain, Eq. 59.6 can be simplified and rearranged to yield a relationship between the number of cycles to failure and the plastic strain (see Eq. 59.7).<sup>9</sup>

$$N_f = (A/\varepsilon_p)^{1/m} \quad (59.7)$$

where  $\varepsilon_p$  = plastic portion of the cyclic strain  
 $N_f$  = number of cycles to failure  
 $A, m$  = experimentally determined constants

This can be further simplified to the most common form of the Coffin-Manson relationship shown in Eq. 59.8.<sup>9</sup>

$$N_f \propto \varepsilon_p^c \quad (59.8)$$

where  $\varepsilon_p$  = plastic portion of the cyclic strain  
 $N_f$  = number of cycles to failure  
 $c$  = an experimentally determined empirical constant

When any metal is cycled at a temperature above 50 percent of its melting temperature (homologous temperature), the strain rates, dwell times, and maximum temperature influence its fatigue life.<sup>9</sup> This is due to the occurrence of creep, along with plastic and elastic deformation, within these temperature regimes.<sup>9</sup> Norris and Landzberg proposed a modified version of the Coffin-Manson relationship that considers the effects of frequency ( $f$ ) and maximum temperature ( $T_{max}$ ) on solder joint fatigue life (Eq. 59.9).<sup>9,10</sup> This relationship is based on detailed physical and empirical analysis of the relationships between temperature and frequency on the thermal fatigue behavior of Pb/Sn solder alloys employed in interconnects.<sup>10</sup>

$$N_f = (A/\varepsilon_p)^{1.9} f^{1/3} \exp\left(\frac{0.123}{kT_{max}}\right) \quad (59.9)$$

where  $\epsilon_p$  = plastic portion of the cyclic strain  
 $N_f$  = number of cycles to failure  
 $k$  = Boltzmann's constant (eV)  
 $f$  = cyclic frequency  
 $T_{max}$  = maximum temperature of the thermal cycle (K)  
 $A$  = an experimentally determined empirical constant

**59.2.4.2 Acceleration Factors.** One of the challenges that must be addressed when attempting to employ Eq. 59.9 directly to assess fatigue life is the determination of the plastic strain and the value of the constant  $A$ . It is crucial to remember that the goal of this analysis is to develop an acceleration transform (or acceleration factor) that can be employed to use known fatigue-life data obtained under controlled laboratory conditions to estimate the number of cycles to failure under field conditions. The acceleration factor  $AF$  is defined as the ratio of the number of cycles to fail in the field  $N_{fF}$  to the number of cycles to fail in the lab  $N_{fL}$  (see Eq. 59.10).

$$AF = \frac{N_{fF}}{N_{fL}} \tag{59.10}$$

where  $AF$  = acceleration factor  
 $N_{fF}$  = number of cycles to failure in the field  
 $N_{fL}$  = number of cycles to failure in the lab

Substituting Eq. 59.9 for lab and field conditions into Eq. 59.10, one obtains 59.11.

$$AF = \frac{N_{fF}}{N_{fL}} = \frac{(A/\epsilon_{pF})^{1.9} f_F^{1/3} \exp\left(\frac{0.123}{kT_{maxF}}\right)}{(A/\epsilon_{pL})^{1.9} f_L^{1/3} \exp\left(\frac{0.123}{kT_{maxL}}\right)} \tag{59.11}$$

where  $AF$  = acceleration factor  
 $N_{fF}$  = number of cycles to failure in the field  
 $N_{fL}$  = number of cycles to failure in the lab  
 $\epsilon_{pF}$  = plastic portion of the cyclic strain in the field  
 $\epsilon_{pL}$  = plastic portion of the cyclic strain in the lab  
 $f_F$  = cyclic frequency  
 $f_L$  = cyclic frequency  
 $T_{maxF}$  = maximum temperature of the thermal cycle in the field (K)  
 $T_{maxL}$  = maximum temperature of the thermal cycle in the lab (K)  
 $k$  = Boltzmann's constant (eV)  
 $L$  = lab conditions  
 $F$  = field conditions

Equation 59.11 can be algebraically rearranged to yield Eq. 59.12. Note that the “max” subscripts on the maximum temperatures have been dropped to simplify the notation.

$$AF = \frac{N_{fF}}{N_{fL}} = \left[ \frac{\epsilon_{pL}}{\epsilon_{pF}} \right]^{1.9} \left[ \frac{f_F}{f_L} \right]^{1/3} \exp \left[ 1414 \left( \frac{1}{T_F} - \frac{1}{T_L} \right) \right] \tag{59.12}$$

where  $AF$  = acceleration factor  
 $\varepsilon_{pF}$  = plastic portion of the cyclic strain in the field  
 $\varepsilon_{pL}$  = plastic portion of the cyclic strain in the lab  
 $f_F$  = cyclic frequency in the field  
 $f_L$  = cyclic frequency in the lab  
 $T_F$  = maximum temperature of the thermal cycle in the field (K)  
 $T_L$  = maximum temperature of the thermal cycle in the lab (K)

When considering package interconnects of the same geometry and material set, one can reduce the strain term  $\varepsilon_p$  in Eq. 59.9 to the change in temperature.<sup>10</sup> This is a key feature that enables the development of an acceleration transform. The goal of this analysis is to develop a transform that allows one to map laboratory thermal cycle loading conditions to field loading conditions for the same package. Thus it is valid to assume that the strain term can be reduced to the change in temperature, as shown in Eq. 59.13.

$$\varepsilon_p \propto \Delta T \quad (59.13)$$

where  $\varepsilon_p$  = plastic portion of the cyclic strain  
 $\Delta T$  = difference between maximum and minimum temperature of the thermal cycle

Substitution of Eq. 59.12 (including  $_L$  and  $_F$  subscripts for lab and field, respectively) yields the final form of the acceleration factor relationship, which can be seen in Eq. 59.14.<sup>10</sup>

$$AF = \frac{N_{fF}}{N_{fL}} = \left[ \frac{\Delta T_L}{\Delta T_F} \right]^{1.9} \left[ \frac{f_F}{f_L} \right]^{1/3} \exp \left[ 1414 \left( \frac{1}{T_F} - \frac{1}{T_L} \right) \right] \quad (59.14)$$

where  $AF$  = acceleration factor  
 $f_F$  = cyclic frequency in the field  
 $f_L$  = cyclic frequency in the lab  
 $T_F$  = maximum temperature of the thermal cycle in the field (K)  
 $T_L$  = maximum temperature of the thermal cycle in the lab (K)  
 $\Delta T_F$  = difference between maximum and minimum temperature of the thermal cycle in the field  
 $\Delta T_L$  = difference between maximum and minimum temperature of the thermal cycle in the lab

Figure 59.7 contains experimental failure data for a ceramic ball grid array (CBGA) cycled under the same two conditions. The predicted acceleration factor was calculated to be 3.2 employing Eq. 59.14. This predicted value correlates quite well with the CBGA data (acceleration factor ranges from 2.9 to 3.6). Note that this approach tends to be overly conservative when mapping large lab  $\Delta T$  into small field  $\Delta T$  (in the case of minicycles, to be discussed in a subsequent section).

**59.2.4.3 Effect of Lead-Free Conversion.** The acceleration factor equation (Eq. 59.14) is specifically derived from experimental data for Pb/Sn solder joints. What remains to be conclusively demonstrated is an equivalent acceleration transform for lead-free solder joints. Several studies have been performed, but there are no acceleration transforms accepted industrywide for lead-free solders. One of the acceleration transforms proposed is discussed in this section. A more comprehensive list of other field life prediction studies can be found in the appendix of IPC-9701-A.<sup>3</sup>

**FIGURE 59.7** Weibull plots for a CBGA package cycled under two different loading conditions. Solid triangles and the dotted line are employed to indicate failures and associated failure distribution of a CBGA package cycled from 20 to 80°C (the least severe case presented in this figure). Solid squares and the dashed line indicate the failures and associated distribution for the identical package cycled from 0 to 100°C. Notice that an increase in the severity of the thermal cycle loading conditions (from 20 to 80°C to 0 to 100°C) creates an associated decrease in fatigue life. (Reprinted with permission from J. Lau, Ball Grid Array Technology, McGraw-Hill, 1995, p. 162.)

**59.2.4.4 Modified Norris-Landzberg Acceleration Transform for Lead-Free Solder.** Based on experimental data generated on a select variety of packages, Pan et al. proposed an updated form of the Norris-Landzberg acceleration transform (see Eq. 59.15).<sup>23</sup>

$$AF = \frac{N_{FF}}{N_{FL}} = \left[ \frac{\Delta T_L}{\Delta T_F} \right]^{2.65} \left[ \frac{t_F}{t_L} \right]^{0.136} \exp \left[ 2185 \left( \frac{1}{T_F} - \frac{1}{T_L} \right) \right] \quad (59.15)$$

- where
- AF = acceleration factor
  - $t_F$  = dwell time at high temperature in the field
  - $t_L$  = dwell time at high temperature in the lab
  - $T_F$  = maximum temperature of the thermal cycle in the field (K)
  - $T_L$  = maximum temperature of the thermal cycle in the lab (K)
  - $\Delta T_F$  = difference between maximum and minimum temperature of the thermal cycle in the field
  - $\Delta T_L$  = difference between maximum and minimum temperature of the thermal cycle in the lab

The primary differences between Eq. 59.14 and Eq. 59.15 are that the frequency term is replaced by the dwell time at high temperature, and the constants have been revised. This equation has been shown by Pan et al. to predict well within the temperature range of 0 to 100°C. However, predictions are less accurate for temperatures outside of this range.<sup>23</sup>

Although the aforementioned proposed acceleration transform is a first-order estimate, much more data would be needed to validate or improve this estimate. Several additional variables must be evaluated to study their impact on the acceleration transform. Some of the variables that impact the acceleration transform include the following:

- **Effect of different package types** The differential strain imparted on solder joints in a ceramic flip-chip ball grid array (FCBGA) is quite different from that imparted on a thin small outline package (TSOP) package, for example. As a result, the acceleration factors from one may not necessarily apply to the other. The construction and effective CTE mismatch of the packages to be qualified must be as close as possible to the packages tested.<sup>23</sup>
- **PWB thickness effect** A thick board is likely to constrain a package more rigidly than a thin board. Similarly, the number of layers in the board could significantly alter its overall stiffness. Tests are frequently done on thinner boards because they are less costly and easier to fabricate. However, if the end-use condition entails the use of a thicker board, IPC-9701 recommends performing the test on at least two different board thicknesses so that the data can be extrapolated to a range of board thicknesses. The effect of board stiffness on lead-free packages appears to be similar to that on Pb/Sn packages, as shown in Sec. 58.3.3 of Chap. 58.
- **Cycling frequency** As evidenced in the study performed by Pan et al.<sup>23</sup> and by Clech,<sup>24</sup> the temperature cycling frequency could have a significant effect on the reliability of the packages being tested. Both the ramp rate and the dwell time affect the results. Most of the damage accumulation during temperature cycling occurs in the hot dwell part of the cycle. A reduction in dwell time reduces the amount of damage accumulated per cycle, which in turn means longer solder fatigue life. A long hot dwell would result in almost complete creep stress relaxation in the solder joints. Consequently, some studies have indicated that a longer dwell time could result in eventual creep saturation.<sup>25,26,27</sup> Increasing the dwell time has shown some reduction in fatigue life in some studies, but the reduction was not very significant in some of those.<sup>28</sup> In addition to hot dwell time, ramp rate of heating and cooling also impacts the effective fatigue life of lead-free solder joints. The amount of reduction in lead-free solder fatigue life due to ramp rate is a function of the package type. Packages with higher effective CTE mismatched substrates (e.g., CBGAs) are more sensitive to the ramp rate than packages with a less differential strain (e.g., plastic ball grid arrays [PBGAs]).
- **Temp cycling range** Clearly, the higher the temperature cycling range, the lower the fatigue life of the solder joints. Some studies have also indicated that an increased average temperature could also result in a reduction in the fatigue life of lead-free solder joints. In other words, both factors—high maximum temperature and high average temperature—could contribute to a reduction in solder fatigue life.<sup>24</sup>
- **The Distance from neutral point (DNP) effect** This is the effective distance along the diagonal of the package, from the center to its outermost corner. Some studies have indicated that the DNP plays a significant role in altering the acceleration transforms of a lead-free package.<sup>24</sup>
- **Size and Orientation of tin (Sn) grains**<sup>29</sup> Depending on the cooling rate, Pb free solders containing a high percentage of Sn tend to have very large Sn grains with varied orientation. Sn has very anisotropic material properties, and consequently, the bulk properties of the Pb free solder joints could change significantly depending on the size and orientation of the Sn grains in any given solder joint. Consequently, the strength of the solder joints within a single BGA could vary significantly. In other words, the joints at the high stress regions may not be the first to fail. This random orientation of Sn grains within a solder joint poses a significant challenge in determining the fatigue life and acceleration factors of Pb free solder joints.<sup>29</sup>

It has also been observed that while the ductility of Pb/Sn increases with aging, the ductility of lead-free solders tends to decrease with aging.<sup>30</sup> In other words, the strain/strain rate characteristics of lead-free solders could change with aging. Further studies are also needed to quantify fully the aging effect and incorporate it into long-term field life prediction models.

**59.2.4.5 Backward Compatibility.** On small PWBs with relatively few components, it is possible to convert all the components to lead-free assemblies at once. However, in the transition to lead-free assemblies, there will be instances where not all the components on a complex

PWB can be converted to lead-free solder. This would inevitably create situations where both tin-lead and lead-free parts are attached on the same board.

Consequently, the use of Pb/Sn paste to assemble lead-free components (backward compatibility) would have to be studied. Component suppliers do not recommend the use of mixed solder metallurgies for a variety of reasons:

- The peak reflow temperature of lead-free solders is higher than that of tin-lead solders. Assembling lead-free components with Pb/Sn paste would involve limiting the peak reflow temperature to that of Pb/Sn components (~220°C). Consequently, the lead-free solders may not fully melt during reflow, resulting in unpredictable long-term solder joint reliability.
- The thermal gradients across components and the PWB could vary significantly, and as a result, it is difficult to ensure that the microstructure formed across the solder joints is consistent.
- There are no known and validated acceleration transforms to predict the field reliability of lead-free components assembled with Pb/Sn paste. Thus, even if the assembled parts pass temperature cycling relative to their Pb/Sn and lead-free counterparts, it is difficult to extrapolate to field conditions and predict how they will perform when subjected to actual end-use conditions.
- There is very little data on the bend/shock resistance of mixed-metallurgy solder joints. The intermetallics formed at the package-joint and PWB-joint interfaces can be quite complex and different. The resistance of these intermetallics to mechanical loading has not been characterized.

There is very little information in the literature on the process consistency of backward-compatible assemblies and their consequent long-term reliability. Some information can be found in References 28, 31, 32 and 34. Some reliability data have been shown to indicate that the reliability of backward-compatible assemblies can be significantly improved if the SnAgCu ball melts fully and good dissolution with the Pb/Sn paste is achieved.<sup>31</sup> However, the factors that influence the degree of dissolution, such as the peak temperature and time above liquidus (TAL), are generally difficult to control consistently. Moreover, the amount of dissolution obtained is a function of the solder ball volume relative to the volume of paste used. Consequently, packages with smaller solder ball pitch could also be more sensitive to assembly process variations in backward-compatible assemblies.

In view of all the unknowns and process dependencies outlined, the assembly of lead-free components with Pb/Sn paste is generally not recommended. If it has to be performed, detailed studies should be conducted to benchmark the consistency of the assembly process as well as the consequent effect on the long-term reliability (both thermomechanical and mechanical) of the assemblies.

### 59.2.5 Power and Minicycles

Consider a processor in a server. The server may only be powered down and back up one time per month (a conservative estimate). Power-downs and -ups are referred to as *power cycles*. A reliability estimate could be made assuming that one thermal cycle occurred per month from the operating temperature within the region of the package to ambient. This would yield a tremendously high lifetime estimate that would unfortunately be misleading. It is important to consider what happens to the packaged device during typical usage of the server. The device temperature will probably increase during usage and decrease when not in use. These smaller temperature rises can occur multiple times throughout a day. These types of thermal conditions are referred to as *minicycles* and can have a dramatic impact on the long-term reliability of an interconnect. Section 59.2.6.3 presents a technique for incorporating minicycles and power cycles in a lifetime assessment.

**59.2.5.1 Miner's Rule.** Miner's rule<sup>33</sup> is employed when attempting to assess fatigue life under multiple fatigue loading conditions. It is commonly used when addressing the combined power and minicycle thermal loading conditions described in the previous section. Miner's rule is based on the premise that fatigue damage accumulates over each cycle. When a critical quantity of damage has been imparted on a system, the system will fail.

Miner's rule states that the sum of the ratios of the actual number of cycles to fail of a given fatigue loading condition to the number of cycles to fail if only that fatigue loading condition occurs is equal to 1. Equation 59.16 contains a general expression of Miner's rule.<sup>9</sup>

$$\sum \frac{N_{ai}}{N_{oi}} = 1.0 \tag{59.16}$$

where  $N_{ai}$  = actual number of fatigue cycles that occur  
 $N_{oi}$  = number of cycles to fail if only that specific fatigue cycle occurred

Miner's rule can be expanded and rearranged for power cycle and minicycle considerations. Equation 59.17 contains that expression.

$$N_{poweractual}/N_{poweronly} + N_{miniactual}/N_{minionly} = 1.0 \tag{59.17}$$

where  $N_{poweractual}$  = actual number of power cycles that occur before failure  
 $N_{poweronly}$  = number of power cycles to fail if only power cycles occur  
 $N_{miniactual}$  = actual number of power cycles that occur before failure  
 $N_{minionly}$  = number of minicycles to fail if only minicycles occur

The Norris-Landzberg acceleration transformation can be combined with Miner's rule to estimate the fatigue life of a package. Note that the Norris-Landzberg method tends to be conservative when assessing minicycles whose changes in temperature are much smaller than the experimental temperature change applied when qualifying the part.

## 59.2.6 Practical Examples

### 59.2.6.1 Comparing the Reliability of Two Packages Qualified Under Different Thermal Loading Conditions

Given: Thermal cycle qualification data and test conditions for packages A and B (Table 59.4)

**TABLE 59.4** Package A and Package B Qualification Data

	Package A	Package B
$T_{max}$	110°C	100°C
$T_{min}$	-10°C	0°C
Frequency	1 cycle/hr	1 cycle/hr
$N_{50}$ (number of cycles to 50% failure)	2,291	3,575

Solution: It is necessary to decide which thermal profile will be kept as a constant and which one will be mapped. This problem can be solved both ways—each temperature cycling condition could be mapped into the other. Either method requires utilizing Eq. 59.10 and 59.14 to transform the number of cycles to failure. For clarity, let condition A refer to the thermal conditions that package A was qualified under, and let condition B refer to the qualification test conditions to which package B was exposed.

**59.2.6.2 Map Package A Lifetime into Package B Thermal Loading Conditions.** Using Eq. 59.10, one would derive Eq. 59.18.

$$AF = \frac{N_{fAA}}{N_{fAB}} \tag{59.18}$$

where  $AF$  = acceleration factor  
 $N_{fAA}$  = number of cycles to failure in package A cycled from -10 to 125°C (condition A)  
 $N_{fAB}$  = number of cycles to failure in package A cycled from 0 to 100°C (condition B)

Equation 59.14 can be rearranged to yield Eq. 59.19.

$$AF = \left[ \frac{\Delta T_B}{\Delta T_A} \right]^{1.9} \left[ \frac{f_A}{f_B} \right]^{1/3} \exp \left[ 1414 \left( \frac{1}{T_A} - \frac{1}{T_B} \right) \right] \tag{59.19}$$

where  $AF$  = acceleration factor  
 $f_A$  = cyclic frequency for condition A (1 cycle/hr)  
 $f_B$  = cyclic frequency for condition B (1 cycle/hr)  
 $T_A$  = maximum temperature for condition A (110°C, 383 K)  
 $T_B$  = maximum temperature for condition B (100°C, 373 K)  
 $\Delta T_A$  = difference between maximum and minimum temperature of condition A (120)  
 $\Delta T_B$  = difference between maximum and minimum temperature of condition B (100)

Substitution of the values in Table 59.4 into Eq. 59.19 yields an acceleration factor of 0.641. Package A would be expected to survive 3,574 cycles ( $N_{fAB} = N_{fAA}/AF = 2,291/0.641$ ) if subjected to condition B thermal loading conditions. The packages appear to be comparable.

**59.2.6.3 Assessing Expected Field Life of a New Package Based on Thermal Cycle Data**

Given: Thermal cycle qualification data for a new ball grid array package (use package B in Table 59.4) and estimates of field loading conditions (see Table 59.5)

**TABLE 59.5** Field Conditions for Example

	Power cycle	Minicycle
$T_{max}$ (°C)	65	80
$T_{min}$ (°C)	25	65
$\Delta T$ (°C)	40	15
Frequency	1 cycle per 30 days, 30 min. duration	4 cycles per day, 60 min. duration

**Solution:** The process for solving this problem is as follows. The experimentally obtained qualification data (presented in Table 59.4) must be mapped into number of power cycles to failure and number of minicycles to failure. These estimates assume that only power cycles occur and that only minicycles occur (that is the underlying assumption when mapping the experimental data to the end-use power cycle and minicycle conditions). After mapping the experimental data into field conditions, Miner’s rule is employed to assess the number of cycles to fail based on the simultaneous occurrence of both power cycles and minicycles throughout the package lifetime.

When employing Eq. 59.14 to map power cycles and minicycles, it is important to consider the implications of how the *frequency* term is interpreted. The Norris-Landzberg approach assumes that the frequency corresponds to the duration of the cycle, not how often that cycle occurs.

Equation 59.14 can be employed to determine the acceleration factors. Equations 59.20 and Eq. 59.21 contain the expressions for power cycles and minicycles, respectively.

$$AF = \left[ \frac{\Delta T_L}{\Delta T_p} \right]^{1.9} \left[ \frac{f_p}{f_f} \right]^{1/3} \exp \left[ 1414 \left( \frac{1}{T_p} - \frac{1}{T_L} \right) \right] \quad (59.20)$$

where  $AF$  = acceleration factor  
 $f_p$  = cyclic frequency for a power cycle (2 cycles/hr)  
 $f_L$  = cyclic frequency in the lab (1 cycle/hr)  
 $T_p$  = maximum temperature of a power cycle (65°C, 338 K)  
 $T_L$  = maximum temperature of the thermal cycle in the lab (100°C, 373 K)  
 $\Delta T_p$  = difference between maximum and minimum temperature of a power cycle (40)  
 $\Delta T_L$  = difference between maximum and minimum temperature of the thermal cycle in the lab (100)

$$AF = \left[ \frac{\Delta T_L}{\Delta T_M} \right]^{1.9} \left[ \frac{f_M}{f_L} \right]^{1/3} \exp \left[ 1414 \left( \frac{1}{T_M} - \frac{1}{T_L} \right) \right] \quad (59.21)$$

where  $AF$  = acceleration factor  
 $f_M$  = cyclic frequency for a minicycle (1 cycle/hr)  
 $f_L$  = cyclic frequency in the lab (1 cycle/hr)  
 $T_M$  = maximum temperature of a minicycle (80°C, 353 K)  
 $T_L$  = maximum temperature of the thermal cycle in the lab (100°C, 373 K)  
 $\Delta T_M$  = difference between maximum and minimum temperature of a minicycle (15)  
 $\Delta T_L$  = difference between maximum and minimum temperature of the thermal cycle in the lab (100)

Substitution of the data in Tables 59.4 and 59.5 yields a power cycle acceleration factor of 10.6 and a minicycle acceleration factor of 45.6. Equation 59.10 can be rearranged to yield Eq. 59.22.

$$N_{fi} = AF_i \times N_{fl} \quad (59.22)$$

where  $N_{fi}$  = number of cycles to fail under minicycle ( $i$ ) or power cycle ( $i$ )  
 $N_{fl}$  = number of cycles to fail in the lab  
 $AF_i$  = acceleration factor for minicycle ( $i$ ) or power cycle ( $i$ )

Substitution of the lab number of cycles to fail from Table 59.4 into Eq. 59.22 for minicycle and power cycles yields 37,895 power cycles to fail (assuming only power cycles occur) and 163,020 minicycles to fail (assuming only minicycles occur).

Miner's rule (Eq. 59.17) can now be applied to determine the actual number of cycles to fail. It is important to note that at this stage the number of minicycles to fail if only minicycles occur and the actual number of power cycles to fail if only power cycles occur is known. The actual number of minicycles and power cycles to fail remains unknown; thus Eq. 59.17 is only one equation, whereas two unknowns still exist:  $N_{poweractual}$  and  $N_{minicactual}$ .

Therefore, it is important to consider the number of minicycles that occur per power cycle. In this case, there is one power cycle per 30 days and 4 minicycles per day. This equates to 120 minicycles per power cycle. Equation 59.17 can now be written as shown in Eq. 59.23.

$$N_{poweractual}/N_{poweronly} + K^* N_{poweractual}/N_{minionly} = 1.0 \quad (59.23)$$

where  $N_{poweractual}$  = actual number of power cycles that occur before failure  
 $N_{poweronly}$  = number of power cycles to fail if only power cycles occur  
 $N_{miniactual}$  = actual number of minicycles that occur before failure  
 $N_{minionly}$  = number of minicycles to fail if only minicycles occur  
 $K$  = number of minicycles that occur per power cycle

Equation 59.23 can be solved for the number of power cycles to fail, which yields a value of 1,311 power cycles or 107.8 years. It is important to employ a confidence factor (safety factor). Taking 2 as a standard safety factor, the final fatigue life is estimated at 53.9 years.

### 59.3 MECHANICAL RELIABILITY

As discussed in Sec. 58.3.11 of Chap. 58 the surface finishes used on packages have been shown to have a significant impact on the mechanical robustness of BGA packages. With increased I/O density, finer pitch, and new substrate technologies (e.g., flex substrates), BGA packages tend to be more fragile and susceptible to mechanically induced failures. These failures are mostly catastrophic in nature, but the loading conditions could vary from bending during production assembly to shock due to shipping or accidental drops. Both monotonic and cyclic conditions could result in catastrophic failure either in manufacturing or field operating conditions. This section focuses on the test methodologies used in quantifying and benchmarking different mechanically induced loading conditions on printed circuit assemblies (PCAs). In general, the mechanical loading conditions that an assembly undergoes could be classified by the strain and strain rate level, as illustrated in Fig. 59.8. As Fig. 59.8 shows, bend and shock tests each cater to different ranges of the strain/strain rate spectrum.

**FIGURE 59.8** Spectrum of strain/strain rate in which mechanical testing fits with the assembly process. The monotonic and cyclic bend testing focuses on high-strain, low-strain rates, whereas the shock testing focuses on low-strain, high-strain rates.

#### 59.3.1 Monotonic Bend Testing

Monotonic (bend-to-failure) testing is designed to simulate the assembly conditions to which a PCA is subjected in manufacturing. A variety of assembly steps impart loading conditions that are similar to a monotonic bend test, such as heatsink attachment, connector attachment, in-circuit test (ICT), handling, and card-cage installation. These assembly steps could mechanically

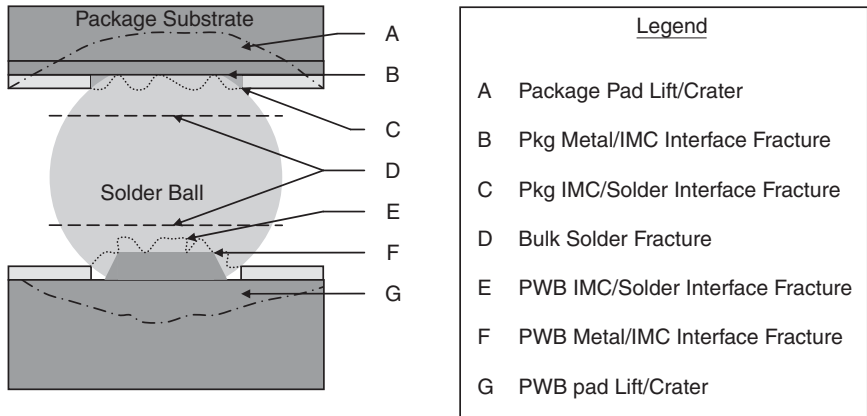

induce several different failure modes. Monotonic bend testing in a controlled condition serves two critical purposes:

- A comparative assessment can be performed between different package types and material sets.
- The failure modes induced at different strain levels can be catalogued. Production operations can then be characterized with strain gauges and compared with the monotonic bend test data to determine whether excessive strain was applied on the PCA during any given assembly step.

To ensure consistency in results and to allow for ease of comparison, an industry standard test method has been developed and published jointly by IPC and JEDEC (IPC/JEDEC-9702).<sup>35</sup> This test method outlines in detail the requirements of the monotonic bend test method. The test setup is illustrated in Fig. 59.9. The typical failure modes observed at the solder joint interconnects are shown in Fig. 59.10.

**FIGURE 59.9** Schematic of four-point bend test setup. A four-point bend test setup is used to determine the strains-to-failure rate of the BGA solder joints.

**FIGURE 59.10** Different interconnect failure modes.

**59.3.1.1 Strain Measurement in Production.** A common procedure for performing strain measurements on live PCAs during production is outlined in IPC/JEDEC 9704.<sup>36</sup> This provides a comprehensive guideline on ways to perform strain measurements and reporting the recorded data. It also includes sample guidelines on the amount of strain/strain rate considered acceptable as a function of board thickness. One assembly process that is particularly susceptible to

**FIGURE 59.11** Strain versus time plot of an actual ICT fixture as it is engaged, the test is performed, and the fixture is subsequently disengaged. The sharp increase in strain during engagement and disengagement is the source of the high strain rate. The fixture is engaged at high speed to improve electrical contact between the probe pins and the PWB test pads.

high strain/strain rates is ICT. Once the ICT fixture is engaged, there is a sudden spike in strain (high strain rate), which is again repeated when the fixture is disengaged, as shown in Fig. 59.11.

Based on experimentally generated data on the production floor and in controlled four-point bend tests described earlier, guidelines can be developed on the maximum range of strain for a given strain rate that would be acceptable for a package in different production operations. A typical example of such a guideline is given in Fig. 59.12. It is important to note that this is just a sample guideline.

**59.3.1.2 Effect of Lead-Free Conversion.** Because of the conversion to lead-free solder, the intermetallics formed at the package-joint and PWB-joint interface would be different from those in Pb/Sn assemblies. Consequently, the response to bending of a lead-free assembly would be significantly different from that of a Pb/Sn assembly. There are relatively little experimental data in the industry comparing the mechanical reliability of lead-free soldered assemblies with Pb/Sn assemblies. One data set showing a relative comparison between Pb/Sn and SnAgCu for two different surface finishes is shown in Fig. 59.13.<sup>37</sup>

The results in Fig. 59.13 show the following:

- For ENIG surface finish packages, the average force-to-failure value for the SnAgCu assemblies is almost three times that of the Pb/Sn assemblies. This is because the SnAgCu joints are stiffer than the Pb/Sn joints.
- Failure mode A is significantly more pervasive in the Pb/Sn assemblies but not as much in the SnAgCu assemblies. Thus, the propensity for brittle solder joint fracture is higher in the Pb/Sn assemblies with ENIG.
- The introduction of a small amount of copper in the Pb/Sn assemblies tends to increase the bending strength of the Pb/Sn assemblies by more than two times.
- The average force to failure with a solder-on-copper (SOC or SOP) surface finish is higher than that with ENIG, especially for the Pb/Sn solder joints. For the SnAgCu joints, there is a marginal increase in relative strength.

Thus, mechanical bend strength is a function of the solder metallurgy and the surface finish used. These results indicate that SnAgCu solder joints are stiffer and have a higher average

PWB strain = max. principal strain (absolute value) measured immediately adjacent to cornermost solder joint  
 Strain rate = change in strain (absolute value) between consecutive readings  
 Max. allowable strain =  $\sqrt{2.35/(PWB \text{ thickness})} * [550 + 2.2e6/(strain \ rate + 4000)]$

Units:  
 Strain [uStrain]  
 Strain rate [uStrain/sec]  
 PWB thickness [mm]

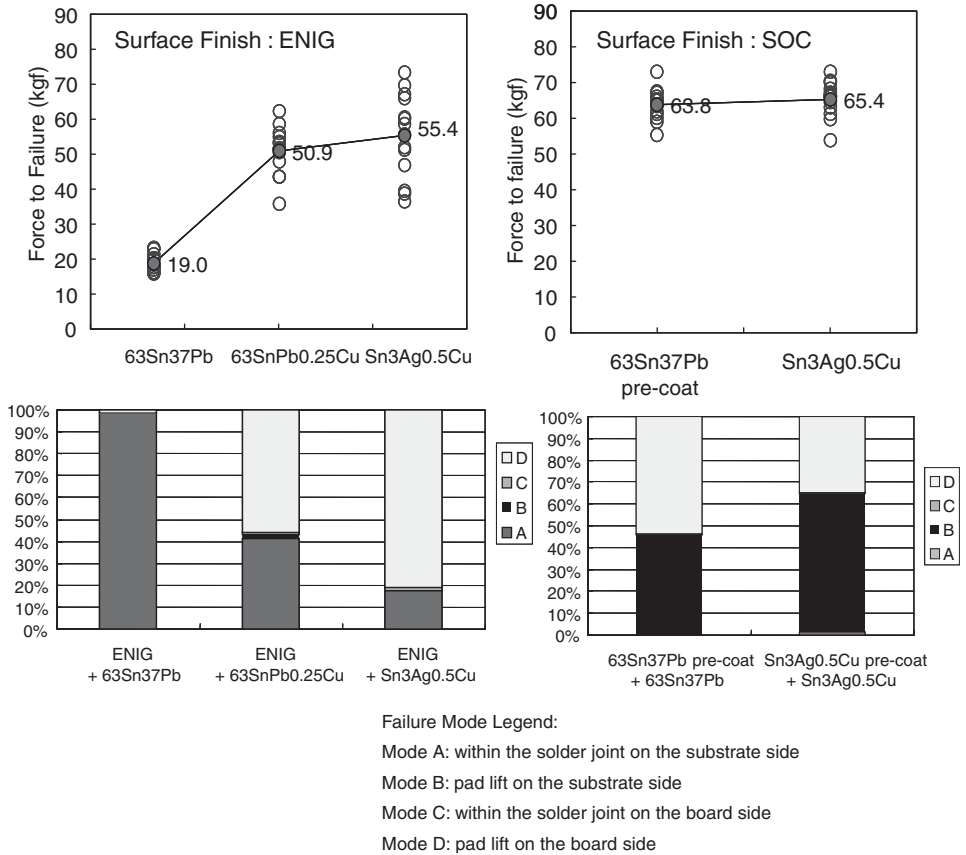

**FIGURE 59.12** Typical example of strain/strain rate limits as a function of PWB thickness for BGA solder joint interconnect failure. Note that the acceptable strain limit decreases with increasing strain rate. Note also that for a given strain rate, the maximum acceptable strain limit decreases as the PWB thickness decreases. (Reprinted with permission from Sun Microsystems, Inc.)

force-to-failure value compared to Pb/Sn joints with the same surface finish. Another important factor in the bend strength of solder joints is the time after reflow, as shown in Fig. 59.14<sup>37</sup>.

The results in Fig. 59.14 show the following:

- For ENIG surface finish packages, Pb/Sn joints are more sensitive to time after reflow than SnAgCu joints. The average force-to-failure value of Pb/Sn joints with ENIG increased by more than 50 percent, whereas the average force-to-failure value of SnAgCu with ENIG did not change noticeably over time.
- For solder pre-coat (SOP) packages, the strength of Pb/Sn joints increased by slightly more than 10 percent over three weeks, whereas the strength of SnAgCu joints with SOP does not change noticeably over time.

Thus, mechanical bend strength is a function of the time after reflow along with solder metallurgy and surface finish. The underlying failure mechanisms have not been understood clearly enough to explain the dependence on time after reflow.

**FIGURE 59.13** Data set comparing the force-to-failure rate of Pb/Sn, Pb/Sn/Cu and Sn/Ag/Cu assemblies for two different surface finishes (ENIG and SOC). The histograms show a comparison of the different failure modes obtained in the bend tests.<sup>37</sup> All samples were tested within one day of board assembly. (Reprinted with permission from Kyocera SLC Technologies. /© [2005] IEEE.)

### 59.3.2 Cyclic Bend Testing

In addition to monotonic loading conditions, certain repetitive operations could also lead to mechanical failures. A typical example is a PWB used in cell-phone applications. The PWB could be subjected to multiple small deflections each time the cell-phone keypad is pressed. This can cause an incremental deterioration in the mechanical response of the PWB and lead to solder joint interconnect failures in BGAs mounted on the PWB. This sort of failure mechanism is more prevalent in relatively thin PWBs used in cell-phone applications. However, similar failures could also occur if, for example, multiple runs of ICT are performed on PCAs in high-end server/network applications. An industry standard test method has been developed by JEDEC to characterize the response of a PCA to cyclic loading conditions (JESD22-B113).<sup>38</sup> The layout of the test board as specified in the test method is similar to that for the monotonic four-point bend test. Some data on the cyclic bend response of SnAgCu solder joints can be found in Reference 39.

**FIGURE 59.14** Data set comparing the force-to-failure value of Pb/Sn and Sn/Ag/Cu assemblies for two different surface finishes (ENIG and SOP) as a function of time after reflow. The histograms show a comparison of the different failure modes obtained in the bend tests. (Reprinted with permission from Kyocera SLC Technologies. /© [2005] IEEE.)

### 59.3.3 Shock Testing

As with bend testing, a shock test methodology is needed to simulate the shock conditions that a PCA may undergo during assembly, shipping, and handling conditions. Shock test conditions usually induce strain rates on the order of 100,000  $\mu\epsilon/\text{sec}$ . (microstrain per second), whereas typical monotonic bend test strains are on the order of 10,000  $\mu\epsilon/\text{sec}$ . Thus, the strains to failure under typical shock test conditions are lower than the strains to failure under typical bend test conditions. However, the failure modes could be different. Hence the need to characterize both bend and shock conditions. There are different classifications of typical shock conditions. For example, those experienced by handheld products (cell-phones, personal digital assistants [PDAs], etc.) are different from those experienced by typical network/server products. The former requires resistance to more stringent shock levels (~1500 G),<sup>40</sup> whereas the latter requires resistance to shock levels on the order of ~500 G. An example of the typical shock test conditions applicable to these product categories is summarized in Table 59.6.

**TABLE 59.6** Examples of Typical Shock Conditions Used for Different End-Use Environments (the Specific Conditions Tested Depend on the End Users)

Test parameters	Typical field conditions	
	Handheld products	Network/server products
Acceleration peak (G)	1,500–2,900	100–400
Pulse duration (ms)	0.3–0.5	1.2–2

In addition to shock testing, several component suppliers also perform drop testing. For handheld products in particular, some suppliers prefer to perform board level drop testing instead. Details of the drop test method are outlined in JESD22-B111.<sup>41</sup> Several component suppliers perform vibration testing in addition to shock testing to simulate shipping conditions.

The design of the carrier tray or chassis in which the PWB is installed could significantly impact the reliability of printed circuit board assemblies (PCBAs). If the resonant frequency of the PCBA matches that of the chassis, and the mode shapes corresponding to the resonant frequency are such that they induce a strain above the critical solder joint failure strain, brittle fracture can occur. Accelerometers and strain gages should be used to characterize both mode shapes and strains in the PWB assemblies mounted on carrier trays or in chassis. The chassis design should be optimized to ensure that the strains that might impact the PCBAs are minimized, especially at the critical locations. Ways to do this include adding stiffeners, frames, and struts in the chassis at critical, high-strain locations.

Finally, an additional way to mitigate shipping failures is to use shock indicators in the shipped product. A typical shock indicator changes color if the applied G values exceed a preset threshold. The use of a shock indicator in products can help in root cause analysis of failed parts.

### 59.3.4 Ball Shear/Pull Testing

Ball shear testers are employed to quantify the strength of the interface between a solder ball and its package prior to second-level attach. Ball shear experiments can also be employed to assess the solder ball-package pad interface qualitatively. This is accomplished by assessing the failure mode observed during a ball shear experiment.

However, certain failure modes are a function of the speed of the test. The failure modes observed at relatively low speeds (0.0001 to 0.0006 m/sec.) are different from those observed at high speeds (0.01 to 1.0 m/sec.). In general, solder shear strength tends to increase with shear speed. It is therefore important that failure mode characterization as a function of shear speed be performed before this technique can be used effectively as an inline monitoring tool to control the quality of substrate lots. To address this, JEDEC has published a revised version of the standard ball shear test to include high speed shear testing procedures (JESD22-B117A<sup>42</sup>).

In addition to speed, a number of other factors could impact the fracture strength of solder joints, including surface finish, pad size, ball diameter, ball metallurgy, and pad construction. All these need to be taken into account when comparing ball shear data across different packages. Another important factor that could impact the force-to-failure and the failure modes induced is the time after reflow. It is preferable to perform the test as early as possible after reflow.<sup>43</sup>

In addition to the high-speed shear/pull test, other methodologies are also being explored to characterize the interface strength of solder joints. One is a Charpy impact type of test.<sup>44</sup> This involves impacting the ball with a pendulum. The amount of energy imparted into the ball is estimated and the failure modes as a function of impact toughness are catalogued. This test is a sort of mini-shock test designed to produce an effect comparable to the high-speed shear test. Another methodology is the use of a hot pin pull test in which a heated pin is inserted into the solder ball, cooled, and then pulled at high speed. Efforts are being made to measure the force to cause failure, so that pull/shear force or impact energy could be used as a metric to assess the strength or weakness of a joint.

**59.3.4.1 Effect of Lead-Free Conversion.** Depending on the surface finish, the intermetallics formed in SnAgCu solders are different from those formed in Pb/Sn joints. Refer to Sec. 60.3.11 in Chap. 60 for more details. Preliminary results on high-speed pull/shear testing of SnAgCu joints indicate a higher interfacial fracture rate than Pb/Sn joint. However, the SnAgCu joints exhibited moderately higher fracture strength.<sup>43</sup>

## 59.4 FINITE ELEMENT ANALYSIS (FEA)

FEA is a numerical technique used to solve complex boundary value problems. It involves discretizing a complex geometry into smaller simpler geometries that can be represented by a set of differential equations. These equations can then be solved numerically to determine the deformation of the overall structure subjected to structural, thermal, or other loading conditions. FEA is a powerful numerical tool that has been used to assess the reliability of solder joints. FEA can be employed to:

- Estimate the fatigue life of a new package
- Compare reliabilities of different packaging options
- Assess impact on reliability due to material and design changes to the package
- Assess impact on reliability due to PWB material and design changes
- Determine changes in warpage due to package density and location

FEA has been used effectively in simulating thermomechanical, bending, and shock conditions. This section focuses on the use of FEA to determine the lifetime of packages subjected to thermomechanical strains, and the use of bend test simulations to determine the factors that influence the bend strength of a package.

### 59.4.1 FEA for Thermomechanical Lifetime Assessment

FEA lifetime assessments are typically broken down into four phases:

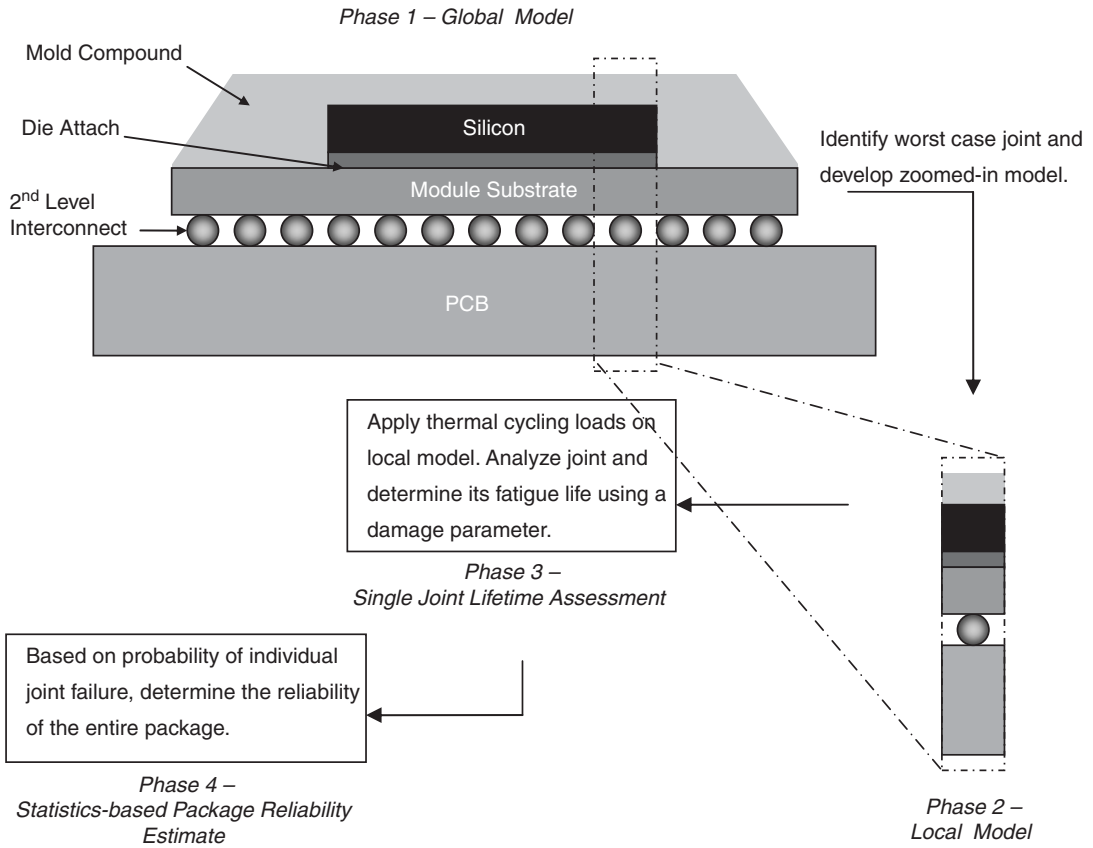

- Phase 1: global model
- Phase 2: local model
- Phase 3: single-joint lifetime assessment
- Phase 4: statistics-based package reliability estimate

Figure 59.15 shows the interrelationships between these four phases.

**59.4.1.1 Phase 1: Global Model.** Phase 1 involves building a global geometric model of the package. Models in FEA can be two-dimensional, 2.5-dimensional (strip), or three-dimensional. Two-dimensional models (plane strain or plane stress) are computationally very efficient as only a two-dimensional cross section of the assembled package is modeled. However, they are based on the assumption that the out-of-plane deformation and stresses in the assembly are negligible, which is not the case with discrete solder joints. Thus, although they are useful for providing qualitative deformation and stress comparisons, they are not useful for quantitative fatigue-life estimates. A 2.5-dimensional or strip model has a thickness, but it is very small—just enough to capture the round shape of the solder joints. While it is an improvement over a two-dimensional model, it does not capture the increased stress concentration at package corners. A three-dimensional model is a much closer representation of an assembled package. Although it is computationally challenging, it is the best way to estimate the deformation and stresses induced in an assembled package. A global model of one-eighth of a BGA package can be found in Figs. 59.16.

Note that only one-eighth of the package is modeled (Fig. 59.16). This is due to the fact that the package is octant symmetric, and thus symmetry boundary conditions can be employed to reduce the model size, which in turn increases the speed at which a solution can be obtained.<sup>46</sup> Wherever possible, the deformation results of the global FEA model should be verified with experimental warpage measurement (using tools like Shadow Moiré<sup>45</sup>).

A unit temperature rise is applied to the global model, the worst-case joint is determined, and the displacements of the worst-case joints are calculated. Worst-case joint determination

**FIGURE 59.15** FEA flowchart. Phase 1 involves creating the global model to determine global strains and displacements across the entire package. The global model also helps identify the locations of maximum stress. Phase 2 entails zooming into the location with the maximum strain. The boundary conditions applied around the local model are extracted from the global model. Phase 3 involves applying thermal cycling loads on the local model and determining the fatigue life of the worst-case solder joint in the local model. Phase 4 entails the use of statistical assessment tools to determine the reliability of the other solder joints relative to the worst case and thus estimating the solder joint reliability of the entire package.

is typically based on a maximum stress or strain in the solder joints. It is essential to obtain the displacements of the worst-case joint because those displacements can now be incorporated in a local model that will simulate multiple thermal cycles on a worst-case joint.

Only a unit temperature rise is applied to the global model to reduce the computational run time. An additional assumption employed in global models to reduce run time is that all materials are linear-elastic and temperature-independent. Because the goal of the global model is to determine the worst-case joint and the corresponding displacement, this approach is typically valid. Reference 46 contains a series of experimental cases and corresponding FEA predictions that validate the global/local approach and the linear elastic, temperature-independent unit temperature rise technique for the packages studied.

**59.4.1.2 Phase 2: Local Model.** A local model of the worst-case joint is created and subjected to simultaneous temperature cycle and temperature-scaled displacement-loading conditions obtained from the global model. The displacement field of the worst-case joint obtained

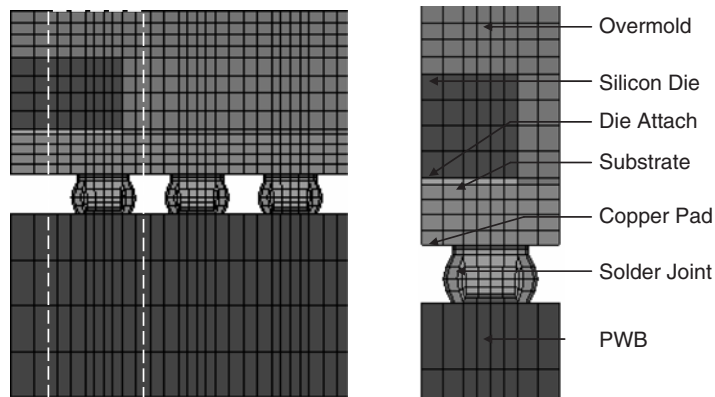

**FIGURE 59.16** Global FEA model of one-eighth of a BGA. Note the PWB, package substrate, die, and overmold are all created by a series of elements.

in the global model when subjected to a unit temperature rise is scaled to match the expected displacement when the local model is subjected to actual thermal cycles. The advantage of this approach is that the local model can incorporate time and temperature material dependence because a reduced number of elements are employed when compared to the global model.

A local model of a solder joint can be found in Fig. 59.17. The local model is subjected to multiple thermal cycles and a final damage parameter is extracted. A typical thermal cycling loading profile to which the model is subjected is similar to that shown in Fig. 59.3. About two to four cycles are run to achieve stability of the hysteresis loop.

**FIGURE 59.17** Close-up of three solder joints. The local model is created from one of the solder joints and its associated PWB, package substrate, die, and overmold. In this figure, the leftmost ball and associated material for the local model are indicated by the area inside the dashed rectangle.

Plastic work and plastic strain are two of the most common local damage parameters employed in solder joint lifetime estimations. The type of damage parameter selected is usually dictated by the experimental data available for a specific joint type (BGA, CCGA) that correlate damage with fatigue life. A methodology that employs plastic work and a correlation between plastic work and crack initiation and propagation can be found in References 10 and 46.

**59.4.1.3 Phase 3: Solder Joint Fatigue-Life Assessment.** The local model damage parameter is then employed to determine the fatigue life of a given joint. Techniques for assessing lifetime based on a damage parameter range from employing plastic strain (Coffin-Manson relationship, Eq. 59.8) to complex considerations of crack initiation and crack growth rates correlated with plastic work.<sup>10,46</sup> Regardless of the technique, the output of this phase is an estimate of the reliability of one joint: the worst-case solder joint.

Some of the fatigue-life prediction models that have been employed for lead-free solder joints are outlined in Table 59.7. In addition, other models for predicting fatigue life from the finite element models and performing relative comparative analysis can be found in References 16 and 47.

**TABLE 59.7** Different Fatigue-Life Models for Predicting Fatigue Life from the Finite Element Model Results<sup>18</sup>

Fatigue-life model	Constants	Test conditions	Reference
$N_f = C_1(\epsilon_{cr})^{C_2}$ $N_f$ = Number of cycles to fail $\epsilon_{cr}$ = Average equivalent creep strain	$C_1 = 4.5$ $C_2 = -1.295$	Flip-chip bumps with and without underfill. Wirebonded PBGA packages mounted on PWB	Schubert <sup>48</sup>
$N_f = C_1(\Delta W_{cr})^{C_2}$ $W_{cr}$ = Average viscoplastic strain energy density/cycle	$C_1 = 345$ $C_2 = -1.02$	Flip-chip bumps with and without underfill. Wirebonded PBGA packages mounted on PWB.	Schubert <sup>48</sup>
$N_f = C_1(\epsilon_{cr})^{C_2}$	$C_1 = 0.0468$ $C_2 = -1$	Several different BGA packages: CABGA, CBGA, FlexBGA, PBGA, TSCSP, etc. Double power law creep constitutive relations. <sup>20</sup>	Syed <sup>49</sup>
$N_f = C_1(\Delta W_{cr})^{C_2}$	$C_1 = 0.0015$ $C_2 = -1$	Several different BGA packages: CABGA, CBGA, FlexBGA, PBGA, TSCSP, etc. Double power law creep constitutive relations. <sup>20</sup>	Syed <sup>49</sup>
$1/N_f = 1/N_{fp} + 1/N_{fc}$ $N_{fp} = (W_p/W_{p0})^{1/c}$ $N_{fc} = (W_c/W_{c0})^{1/d}$ $N_{fp}$ = Number of cycles to failure due to plastic damage $N_{fc}$ = Number of cycles to failure due to creep damage $W_p$ = Plastic work density calculated per load cycle $W_c$ = Creep work density calculated per load cycle	$W_{p0} = 106.45$ $W_{c0} = 30.025$ $c = -0.51$ $d = -0.44$	Solder joint samples attached to copper coupons, subjected to cyclic loading. One-dimensional analytical model to derive constants.	Zhang <sup>50</sup>

A comparison of the results obtained by Schubert's<sup>48</sup> model with those obtained by Syed's<sup>49</sup> model can be found in Reference 51. It is important to note that these models are a function of the way that the material properties of the solder joints are modeled. In other words, the solder material properties used to derive these models play a significant role in the accuracy of the models. If a particular fatigue-life model is selected, the corresponding solder constitutive model used to derive the model constants should be used in the analysis.

In addition, several other factors could significantly alter the accuracy of a model, such as time step size, mesh density, material properties, reference temperature, element size, element type, and even software. All these need to be taken into account when using a model to predict fatigue life. Best practice recommendation is to run not just one, but a set of fatigue-life models and calibrate with existing experimental data before using the models to make fatigue-life predictions on packages on which no experimental data are available. Finally, it is important to note that these models only provide guidance on trends and relative comparisons. They should not be used as a substitute for experimental thermal cycle data for a given package under consideration.

**59.4.1.4 Phase 4: Statistics-Based Package Reliability Assessment.** This final phase considers the reliability of all of the solder joints when determining the reliability of the package. Techniques employed here range from simply assuming that all joints are of equal reliability to performing a series reliability calculation to solve simultaneously an assumed distribution of failures (such as a Weibull distribution; see Sec. 59.2.2) considering each joint. It is also common to weigh the reliability of joints other than the worst-case joint by considering the displacement of all joints with respect to the displacement of the worst-case joint.<sup>46</sup> This allows for the impact of DNP to be incorporated in the potential distribution of failures among joints at different locations.

**59.4.1.5 Temperature-Dependent Material Properties.** As mentioned earlier, the aforementioned procedure is based on the assumption that the mechanical properties of the package material set do not change significantly with temperature. There are certain packages, however, for which this technique is not applicable. A typical example is an FCBGA package in which the underfill material has a glass transition temperature ( $T_g$ ) around 70 to 100°C and undergoes several orders of magnitude change in modulus above the  $T_g$ . Clearly, the properties of such a material are strongly dependent on temperature. In such a case, the following procedure can be followed:

1. The global model is cooled from its stress-free temperature (which is usually the adhesive cure temperature) to the lowest temperature to which the package has been thermal cycled (0°C if a 0 to 100°C thermal profile is used).
2. Cut boundary interpolation is performed at small temperature steps (such as 5 or 10°C), recording the deformation of the nodes at each temperature step. This information is stored in a set of data files.
3. A submodel is created of the worst-case solder joint (the one that shows the most stress or deformation in the global model). The files stored in step 2 are applied as load boundary conditions on the nodes forming the submodel boundary at each temperature step. Temperature-dependent material properties should be used in both models.
4. On completing the analysis, one can use the plastic work or strain accumulated to determine the expected fatigue life of the package based on the worst-case solder joint, as outlined in Phase 3 of the previous section.

If computer resources are available, a complete global model could be used to determine the plastic work or strain per solder joint. However, this could be very time-consuming depending on the complexity of the package under consideration.

**59.4.1.6 Impact on First-Level Interconnect.** In FCBGA-type packages using temperature-dependent material properties, failure resulting from solder joint fatigue may occur not

**FIGURE 59.18** Three-dimensional submodel detail showing the flip-chip bumps and underfill included in the model. The submodel can be used to determine the fatigue life of the flip-chip bumps and the BGA solder joint underneath at the same time.

only at the board-level interconnect but also at the first-level interconnect (between the silicon die and substrate). The flip-chip bumps are encapsulated by the underfill to improve their thermomechanical reliability by evenly distributing the CTE-mismatch-induced strains between the die and substrate. If the underfill material properties are such that the underfill softens drastically above its  $T_g$ , then there is a possibility that the flip-chip bumps may fail early during thermal cycling.<sup>52</sup> To simulate this, the global-submodel approach outlined earlier can be used. In this case, the flip-chip bumps would also be incorporated in the submodel as shown in Fig 59.18.

#### 59.4.2 FEA for Monotonic Bend Testing

FEA simulations of monotonic bend testing involve a quarter-symmetry model of the assembly placed between anvils and deformed while monitoring the strains induced in the package, solder joint interconnects, and the PWB. The details of the quarter-symmetry model are shown in Fig. 59.19.

**FIGURE 59.19** Three-dimensional quarter-symmetry model showing an FCBGA package mounted on a PWB between support anvils. Contact elements between the anvils and the PWB simulate the flexure of the PWB as one anvil set is moved vertically relative to the other. Detail A of the model is shown in Fig. 59.20.

Bend test FEA simulations achieve two primary objectives:

- To determine the relationship between PWB strain and critical joint strain. This in turn helps bridge differences between the controlled conditions in which the bend testing is performed and the conditions in which bending occurs during assembly.
- To perform a comparative assessment of different packages. FEA can be used to derive solder joint strains from experimental PWB strain data for different test conditions.

The FEA model is shown in Figs. 59.19 and 59.20. Solid structural elements are used to model the PWB, solder joints, and package details. Based on the premise that at high strain rates, the solder material becomes brittle and behaves almost like a linear elastic material, the solder joint elements are modeled as linear elastic. Contact elements are used at the interface between the PWB and anvils to simulate contact between the PWB and the anvils as the assembly is deformed. The solder joint geometry is modeled as closely as possible to the solder joints' actual shape after reflow.

**FIGURE 59.20** Detail A of the image model shown in Fig. 59.19. The image on the left shows the package (quarter-symmetry). The zoomed-in image on the right shows all the details of the FCBGA package construction.

A variety of different parametric analyses can be performed to determine the effect of different geometric variables on the critical joint strain. A few examples of such analyses are described in this section.

**59.4.2.1 Strain Distribution Around the Package.** Per IPC/JEDEC-9702, it is recommended that three strain gauges be placed around a package during four-point bend testing (see Fig. 59.21). These gauges are to be used to characterize the strain response of the given package

**FIGURE 59.21** Nomenclature for the four-point bend test set up as outlined in IPC/JEDEC-9702. Three strain gauges are placed on the board to measure the strain distribution around the package. Gauge 1 is placed under the package, directly below the corner most solder joint. Gauge 2 sits directly below the package center. Gauge 3 is placed next to the package on the PCB topside, midway between the package edge and the anvil.

**FIGURE 59.22** Solder joint-to-PWB strain relationship for three gauge locations. The results indicate that the gradient at locations 1 and 3 are relatively close. The gradient at location 2 is quite low. This indicates that the PWB strain at location 2 is least sensitive to variations in critical solder joint strain. The nomenclature for the strain gauge locations is given in Fig. 59.21.

mounted on a board of a certain thickness. FEA was used to determine the joint-to-board strain ratio for each case, which in turn can be used to determine which strain gauge location is most or least sensitive to board flexure. The results of the simulation are shown in Fig. 59.22.

The results indicate that the highest sensitivity to solder joint strain is obtained at locations 1 and 3 (see Fig. 59.21). Location 2 reflects the global bending of the entire assembly. These results are in line with measured experimental data. The absolute strain value and the change in strain at location 2 is least sensitive to the critical solder joint failure strain.

**59.4.2.2 Effect of Package Pad Size on Joint-to-Board Strain.** FEA can also be used to estimate the effect of changes in solder joint pad size on the joint-to-board strain ratio. Two different package pad sizes were used: 0.53 mm, solder mask defined, (pad design 1) and 0.4 mm, solder mask defined, (pad design 2) while the PCB pad design was kept constant (0.5 mm, non-solder mask defined) The results in terms of the joint-to-board strain at location 3 are shown in Fig. 59.23.

The results in Fig. 59.23 indicate that pad size change could have a significant impact on the strain in critical solder joints. As a result, care should be taken in using data generated with one pad size to qualify or accept the bending strength with another pad size, unless the absolute strain-to-failure value is much higher than the required strength.

**FIGURE 59.23** Two different solder joint pad sizes analyzed. The results indicate that for the same PWB strain, the solder joint strain is ~18 percent higher for pad design 2 as compared to pad design 1.

### 60.1 INTRODUCTION

---

In the past, manufacturers of printed circuit boards have relied on end-of-pipe treatment and disposal for hazardous wastes generated in the fabrication process. These technologies are no longer optimal strategies for managing waste for two reasons. First, the potential liabilities involved with the handling and disposal of waste have increased and will continue to increase, and second, waste disposal costs have gone up significantly due to restrictions placed on land disposal. As a result, the industry is faced with the challenge of finding alternative methods for managing hazardous waste. This chapter presents a brief overview of some of the alternatives available to address this challenge, as well as a summary of some of the issues involved in implementation.

---

### 60.2 REGULATORY COMPLIANCE

---

Fabricators of printed circuit boards today are faced with a complex set of environmental requirements. In the United States there are three basic environmental statutes impacting the fabrication and assembly of printed circuit boards.

- Clean Water Act
- Clean Air Act
- Resource Conservation and Recovery Act (RCRA)

---

\* This chapter is reprinted from the 4th edition. The basic issues, regulations, and processes are considered accurately stated and relevant to the 6th edition. For specific actions, however, it is recommended that waste treatment engineering and legal professionals be consulted to ensure that latest government expectations are understood at all levels of jurisdiction and that appropriate technology is applied to the resolution of specific issues.

### 60.2.1 Clean Water Act

The goals of the Clean Water Act are to “restore and maintain the chemical, physical, and biological integrity of the nation’s waters.” To accomplish these goals, discharges of industrial wastewater are subject to pretreatment requirements of federal, state, or municipal regulations. Industrial waste discharges are typically directed to a sewage treatment plant. Most sewage treatment plants use bacteria to biodegrade the organic matter present in the waste stream. Toxic materials such as copper, nickel, and lead from industrial discharges can pose a problem in two ways. These materials end up in the sludge from the sewage treatment process and can lead to disposal problems. Secondly, in high concentrations they can kill the bacteria in the treatment process, resulting in significant pollution of the receiving water. As a result, fabricators of printed circuit boards are required to pretreat their wastewater to specified levels prior to discharge to the sanitary sewer. The stringency of the requirements is ultimately determined by the use of the receiving water, as even minute amounts of toxics have been shown to have a negative impact on the aquatic environment. While the federal Clean Water Act specifies minimum pretreatment standards for fabricators of printed circuit boards, in most cases, state and local requirements may be more stringent. See Table 60.1 for an example of pretreatment requirements.

**TABLE 60.1** Typical Pretreatment Requirements

Parameter	Limit, mg/L
pH	6.5–9.0
Copper	1.0
Nickel	0.5
Chromium	1.0
Silver	0.05
Cadmium	0.07
Zinc	0.5
Lead	0.2
Mercury	0.05
Aluminum	1.0
Selenium	0.2
Iron	2.0
Manganese	2.0
Tin	5.0
Cyanide	0.01
Phenol	0.05

### 60.2.2 Clean Air Act

The Clean Air Act established National Ambient Air Quality Standards (NAAQS) to achieve two goals:

1. Improve air quality in areas which fail to meet the standards.
2. Prevent significant deterioration of the air quality in clean air areas.

The states are responsible for achieving these standards by setting emission limitations and establishing timetables for compliance by sources. Printed circuit fabrication and assembly involves several processes that have an impact on air quality. Drilling, routing, sawing, and sanding create dust or airborne particulates. The plating process creates acid fumes and the etching process can generate ammonia if an ammoniacal etchant is used. Volatile organic compounds (VOCs) and lead particulates from the assembly process can pose a potential air pollution problem as well.

The technologies available for control of air pollutants include the following:

1. Electrostatic precipitators, baghouses (a type of dust collector with fabric bags mounted on frames), and cyclone separators are available to control airborne particulates.
2. Wet scrubbers containing a packed bed to provide surface area and water sprays are utilized for removing acid fumes. Addition of an acidic feed to the scrubbing liquid allows for the removal of ammonia. Addition of a caustic feed improves the scrubbing efficiency for other materials. Wet scrubbers are often used to prevent entrance of fumes back into the building from fresh air intakes.
3. Activated carbon filtration systems are utilized for removing chlorinated solvents and volatile organic compounds (VOCs). These can be regenerated on- or off-site.

### 60.2.3 Resource Conservation and Recovery Act

The Resource Conservation and Recovery Act (RCRA) goals are to protect human health and the environment by reducing or eliminating the generation of hazardous waste. To achieve this, the regulation mandates a system for managing hazardous wastes from cradle to grave. Anyone who generates, stores, treats, transports, or disposes of hazardous waste is subject to this regulation. The specific definitions of hazardous waste are spelled out in the federal statutes (40CFR Parts 260-280). Typically, however, the states have more stringent definitions. The states are responsible for the implementation and enforcement of RCRA. Wastes captured under this regulation in a printed circuit board fabrication facility include aqueous solutions with metals, acid or alkaline solutions with metals, sludges containing metals, etc. As a result, fabricators must comply with the following requirements.

1. Obtain an EPA identification number and apply for permits to generate, treat, store, or dispose of hazardous waste as appropriate.
2. Use appropriate containers for storage and disposal and approved manifests and labels for shipping.
3. Comply with technical requirements for on-site treatment of hazardous waste, including tank integrity standards, labeling, and secondary containment.
4. Keep records as appropriate for reporting to regulatory agencies.

A critical part of the regulation is to reduce and, where possible, eliminate the generation of hazardous waste. Waste minimization was specifically mandated in the 1984 Hazardous and Solid Wastes Amendments to the Resource Conservation and Recovery Act. This has had an enormous impact on the way waste is handled by printed circuit board facilities. Prevention of pollution has become the overriding goal in design with recycle and reuse technologies implemented only where pollution prevention is not feasible for technical and/or economic reasons. Chemical treatment of wastes should be utilized only where no other options exist.

## 60.3 MAJOR SOURCES AND AMOUNTS OF WASTEWATER IN A PRINTED CIRCUIT BOARD FABRICATION FACILITY

---

### 60.3.1 Major Sources of Waste

The following table indicates the major operations in the production of printed circuit boards with the waste streams they generate.

Source	Waste stream	Composition
1. Cleaning and surface preparation	Spent acid/alkaline baths Waste rinse waters	Metals, acids, alkalis
2. Electroless plating and deposition	Spent electroless copper bath Waste rinse water	Acids, palladium, complexed metals, chelating agents, formaldehyde
3. Pattern printing and masking	Spent stripper and developer solutions Waste rinse waters	Vinyl polymers, chlorinated solvents, organic solvents, alkalis
4. Electroplating	Spent plating bath Waste rinse waters	Metals, cyanide, sulfate
5. Etching	Spent etchant Waste rinse water	Ammonia, chromium, copper, iron, acids
6. Assembly	Aqueous and semiaqueous wastewaters	Lead, organics

### 60.3.2 Typical Amounts of Waste Materials

It is important to evaluate the waste generated in printed circuit board manufacturing in terms of the relative amounts of copper wasted from different processes in order to prioritize efforts at waste minimization. A waste audit should be performed to determine the types and amounts of waste generated. Figures 60.1 and 60.2 present two comparisons of copper-bearing wastes. The data presented are from two different printed circuit board fabrication facilities.

In Fig. 60.1, approximately 93 percent of the total amount of copper discharged was from the innerlayer and outerlayer etching process. The amount of copper discharged from the microetch baths (using sodium persulfate) was approximately the same as the copper contained in the rinses following acid copper and the microetch baths. That exact relationship is not always valid for every printed circuit board factory.

Figure 60.2 presents the results of an environmental audit at another printed circuit board facility in grams per hour of waste copper, excluding the large amounts of waste from I/L and O/L etching. The results presented in Fig. 60.2 closely resemble a “common” PCB factory.

The facility used to prepare Fig. 60.2 produced up to 1500 completed multilayer panels (18 in × 24 in) per 20-h day of production.

## 60.4 WASTE MINIMIZATION

### 60.4.1 Definitions

Waste minimization includes the procedures, operations, and equipment required to minimize the amount of waste produced. It includes anything that reduces the load on hazardous waste treatment or disposal facilities by reducing the quantity or toxicity of hazardous waste. Waste minimization should be approached as a hierarchy of options. The first step is *pollution prevention* or source reduction.

**60.4.1.1 Pollution Prevention.** Pollution prevention is the use of materials, processes, or practices that reduce or eliminate the creation of pollutants or wastes. Pollution prevention is often cost-effective because it may reduce raw material losses; reduce reliance on expensive end-of-pipe treatment technologies and disposal practices; conserve energy, water, chemicals, and other inputs; and reduce the potential liability associated with waste generation. Pollution prevention opportunities are intended to

**FIGURE 60.1** Amount of copper wasted for various waste streams expressed as a percent of total copper discharge.

1. Reduce the rinse water flow rate and volume.
2. Extend process bath life and reduce the dragout of a concentrated liquid (containing a contaminant such as copper).
3. Substitute materials where possible to eliminate or reduce the hazard of a particular waste.

**60.4.1.2 Recycling and Recovery.** The next step in the hierarchy of waste minimization options is *recycling* or *recovery* of any waste that cannot be reduced or eliminated at the source. It includes reuse of waste in the process or recovery of metals from a waste before disposal. Recycling and recovery can occur both on- or off-site.

**60.4.1.3 Alternative Treatment.** The last step in the waste minimization hierarchy is *alternative treatment*. Alternative treatments are selected to minimize the volume or hazard associated with a particular waste.

The benefits for implementing a waste minimization program can include savings in equipment and operating cost, recovery of natural resources, and significant reduction in risk of the liabilities associated with the disposal of hazardous waste. One measure of the effectiveness of a waste minimization project is the project's effect on the organization's cash flow. These projects should pay for themselves through reduced waste management and raw material costs.

**FIGURE 60.2** Major sources of copper expressed in grams per hour discharged. Inner- and outerlayer etching is excluded from this figure since it is so large in relation to the other contributors.

## 60.5 POLLUTION PREVENTION TECHNIQUES

Some common techniques available for pollution prevention in a printed circuit board fabrication facility are listed as follows. While this list is not all-inclusive, it provides an overview of the types of things that are important to consider. A brief description of each option is presented in the next section.

### ***Rinse Water Reduction***

1. Particulate filtration on deburr and panel-scrubbing operations with total or partial rinse water recycling
2. Etcher and conveyORIZED equipment design modifications
3. Immersion-type counterflow rinses
4. Alternating side spray rinses
5. Flexible orifice-type flow restrictors
6. DI and soft water for rinsing

### ***Extend Bath Life***

1. Filtration
2. Acid purification systems

3. In-tank electrolytic permanganate regeneration
4. Proper rack design and maintenance
5. Dragout recovery tanks
6. Monitor solution activity

#### ***Dragout Reduction***

1. Etcher design
2. Automation
3. Rack design
4. DI and soft water for rinsing

#### ***Material Substitution***

1. Acid tin as an etch resist
2. Eliminate thiourea from tin/lead stripping baths
3. Permanganate desmear
4. Direct metallization to eliminate electroless deposition and the use of formaldehyde
5. Nonaqueous waste resists
6. Use of nonproprietary chemistry to avoid chelating agents

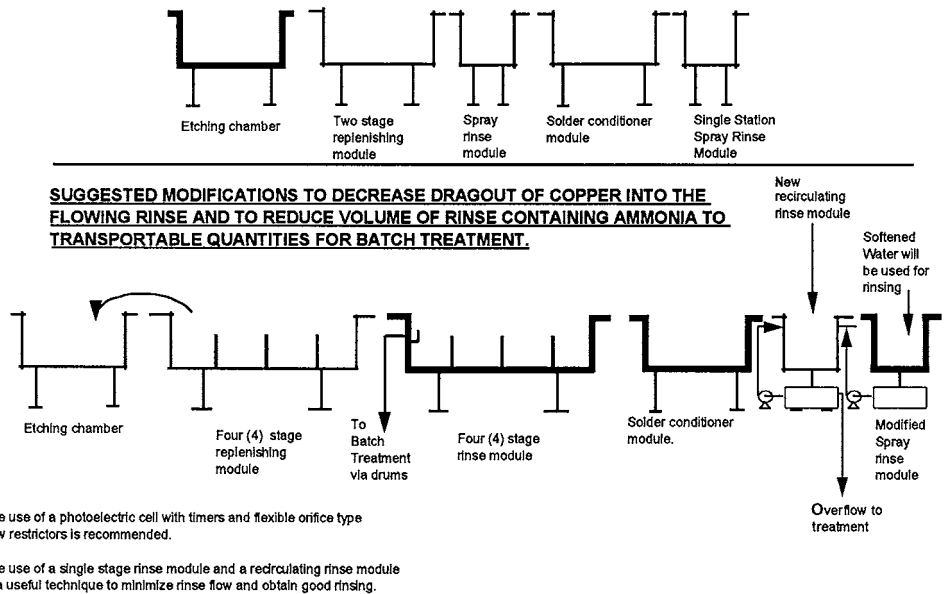

### **60.5.1 Rinse Water Reduction**

Most of the waste generated in the manufacture of printed circuit boards is from cleaning, plating, stripping, and etching. This section describes some of the techniques available for reducing the volume of rinse water used.

**60.5.1.1 Particulate Filtration on Deburr and Panel-Scrubbing Operations.** Deburrers are used to remove stubs of copper formed after the drilling of holes in double-sided and multilayer panels before they enter the copper deposition process where copper is deposited within the holes recently drilled in the panel. Scrubbers are used to remove oxides from printed circuit laminates, clean the surface prior to a surface coating to provide better adhesion, and remove residuals after etching or stripping. In deburring and board scrubbing, particulate materials are added to the water and are removed by various methods based on size and the weight of the copper particle such that the wash water becomes suitable for up to 100 percent recycle. The types of filtration available for this operation are cloth, sand, centrifugation, and gravity settling with filtration.

**60.5.1.2 Etcher and Conveyorized Equipment Design Modifications.** Use of recirculating rinse modules in the etcher and other conveyorized equipment will decrease the required flow rate of rinse water for that process step by about 50 percent without requiring significantly more floor space, compared to single-station spray rinse chambers (without recirculating rinses). In this application, fresh water is used for the final top and bottom nozzles in a rinse module. This water is collected in a sump located below the rinsing compartment. A pump recirculates this water through the first set of top and bottom nozzles (instead of using fresh water). As more fresh water enters the sump, the excess water overflows through a pipe fitting to drain. See Fig. 60.3.

Conveyorized equipment can also be used for, at least, innerlayer and outerlayer photoresist stripping and innerlayer and outerlayer photoresist developing, deburring, and panel scrubbing. Similar techniques to reduce water flow can be applied to these operations.

**TYPICAL INNER/OUTER LAYER ETCHER****FIGURE 60.3** Suggested modifications to inner/outerlayer etching equipment.

**60.5.1.3 Immersion-Type Counterflow Rinses.** Counterflow rinsing, employing several single-stage rinse tanks in series, is one of the most powerful waste reduction and water management techniques for innerlayer processing and in the electroless copper process. In counterflow rinsing, the plated part, after exiting the process bath, moves through several rinse contact stages, while water flows from stage to stage in the opposite direction. Over time, the first rinse reaches a steady-state concentration of process dragout contaminants that is lower than the process solution. The second rinse (away from the process bath) stabilizes at even a lower concentration. This enables less water to be used to produce the same cleanliness compared to a single-station rinse tank. The higher the number of rinse stations connected in series, the lower the rinse rate needed for adequate removal of the process solution from the panel. A reduction in rinse water use for a given process step of up to 90 percent over what would be used without counterflow rinsing can be achieved with this technique.

A multistage counterflow rinse system allows greater contact time between the panels and the rinse water, greater diffusion of the process chemicals into the rinse water, and more rinse water to come into contact with each panel. The disadvantage of multistage rinsing is that more steps are required and additional equipment and work space is required.

**60.5.1.4 Alternating Side Spray Rinses.** Alternating side spray rinses can be used in place of or with immersion rinses in acid copper or solder plating lines. With this technique, rinse water pulsates on each side of a panel at different times so that penetration through holes can be achieved. The reduction in water consumption using an alternating side spray rinse for any given process step is about 85 to 90 percent of that consumed using single-stage immersion-type rinse. Another advantage of spray rinsing is that it will eliminate the need to dump the entire contents of an immersion-type rinse tank, for cleaning purposes, on a periodic basis.

**60.5.1.5 Flexible Orifice-Type Flow Restrictors.** Flow restrictors are available with flexible diaphragms and are rated for a specific flow rate in a specific pipe size. Typically a 2- to 3-gpm flow restrictor is recommended for a two-stage counterflow rinse tank. As long as a minimum water pressure exists in the water inlet line (about 20 lb/in<sup>2</sup> is considered minimum), the water flow into a rinse tank should not vary, although the water pressure will most likely vary. Flow restrictors are not adjustable after they are installed. By providing pipe union fittings both up and downstream from the flow restrictor fitting, the flow rate can be changed if necessary.

## 60.5.2 Extended Bath Life

Although process bath solutions are discarded infrequently, when spent or contaminated, they must be replaced. The resulting waste contains high concentrations of hazardous constituents. Bath life extension is thus an important means of minimizing waste in a printed circuit board manufacturing facility.

**60.5.2.1 Filtration.** Baths should be continuously filtered to remove impurities. Most manufacturers utilize spiral-wound cylindrical polypropylene-type filters with nominal pore-size ratings. Some manufacturers have decreased or actually eliminated the need to dump selected process baths, such as the brown oxide bath, by using a more expensive absolute-type mechanical filter.

The filter, in the brown oxide case, removes black copper metallic particles and other solids. Proper filtration will eliminate the cloudiness that may presently build up in the bath. A side benefit for filtering the brown oxide bath is the increased mechanical agitation in the bath that may improve the coating uniformity.

The filtration requirements for every bath should be reviewed with an objective to clean the bath and to decrease or eliminate its dumping frequency.

**60.5.2.2 Acid Purification Systems.** In the circuit board industry, mineral and semiaqueous acid solutions are used for activating metal and plastic surfaces and for the etching, cleaning, and stripping of racks and defective parts. These solutions become contaminated and lose strength (lowering the acid concentration) as a function of usage due to the increasing concentration of contaminants such as metals and the continuous dilution of the acid concentration. These less active acidic solutions are customarily disposed of by periodically dumping the bath at once, or slowly withdrawing a portion of, the bath.

From a process point of view, if the concentration of contaminants can be maintained low and the acid concentration maintained at the desired level, an improvement in performance of the acid solution will result (in other words, better quality control is provided using continuous bath purification).

Finding an economic method to continuously reuse 90 to 95 percent of an acid will (1) reduce incoming chemical consumption (for the factory), (2) reduce the cost to process parts (fewer rejects), (3) provide better quality control, and (4) reduce the chemicals (for example, caustic soda) required to neutralize the spent acid before discharge. Eliminating the need to handle spent acids will decrease the exposure of hazardous materials to employees and will reduce the wastewater treatment burden. This type of bath purification system may eliminate the need to dump selected concentrated wastes.

One technology for acid purification uses diffusion dialysis. Diffusion dialysis units utilize a membrane which allows anions to pass (i.e., Cl<sup>-</sup> in the case of hydrochloric acid) while metal cations remain behind. This is the dialysis part of the process. At the same time, water molecules diffuse through the membrane in the other direction.

Each recovery unit produces two streams: a reclaimed acid stream, which is high in acid content and low in metal content, and a waste stream which contains a high concentration of metals and a low concentration of acid. The only required utilities are soft water and single-phase power.

The following commonly used acids found in the printed circuit industry can be purified using this technology:

Hydrochloric	Fluoboric
Hydrofluoric	Methane sulfonic
Nitric	Ferric chloride-hydrochloric acid
Nitric-hydrofluoric	Sulfuric acid

Methane sulfonic acid (MSA) is a relatively expensive acid used to strip (remove) solder (tin/lead) and copper metals. This acid is also used to condition metal surfaces prior to fluoborate free-solder electroplating when applying a final etch resist of solder onto multilayer printed circuit boards. By continuously recirculating the acid bath through a diffusion dialysis unit, a 95 percent reduction of chemical purchases (required by the process steps indicated in the first paragraph of this section) may result, producing less than a six-month return on the initial capital investment (ROI). Typically, 80 to 90 percent of the acid is recovered with 70 to 90 percent of the metals removed in an equal volume of dilute acid.

Another system uses only water in its process. The heart of this product is a shallow bed of special adsorption resin. This resin has the unique ability to adsorb strong mineral acids yet exclude metal salts. This is not an ion exchange process since only water is used, in a counter-current fashion, to desorb the acid from the resin.

**60.5.2.3 In-tank Electrolytic Permanganate Regeneration.** Because permanganate is a powerful oxidizing agent only in basic conditions, desmear solutions usually contain 5 to 10 percent caustic soda. However, the alkalinity at high temperatures causes the permanganate ( $\text{MnO}_4^-$ ) ion to break down to manganate. The manganate reacts with water to form manganese dioxide ( $\text{MnO}_2$ ), eventually forming a black sludge of  $\text{MnO}_2$  which settles to the bottom of the desmear tank. This requires that the bath be dumped.

Oxidizing electrolytic regeneration systems are available to inhibit this reaction. A typical electrolytic regeneration system employs an in-tank probe composed of a copper rod as the cathode which is connected to a power supply. When current is applied, oxygen is generated in the permanganate solution which functions as the regenerate for the manganate. The efficiency of the system depends on the rate of manganate buildup, the amount of amperage generated, and the power supply to the in-tank regenerator. These probes attach to the top rim of the desmear tank and are always operating (as the permanganate ions will break down even when the bath is not active). In most cases, the use of this equipment has eliminated the need to dump this bath.

**60.5.2.4 Proper Rack Design and Maintenance.** By using plastic-coated racks, only the tips and contactors (which electrically and physically connect and support the panel to the carrying rack), have exposed conductive metal and must be stripped. If one of these is removable, then the amount of metal to be chemically or electronically removed from the rack is also reduced. This should lengthen the useful life of the stripping bath and further reduce the cost for hauling away or on-site treatment (if nitric acid is used) of the spent rack stripper. Use of racks with disposable contactors eliminates the need to strip the racks and could eliminate the use of nitric acid.

**60.5.2.5 Dragout Recovery Tanks.** The dragout tank's primary purpose is to collect most of the solution dragout before the panel enters the rinse tank. The dragout (recovery) tank is a rinse tank that operates without a continuous flow of feed water. It is positioned between a process bath and its rinse tank. The dragout tank can be either an immersion application (for the electroless and innerlayer operations) or a spray type application (on conveyORIZED equipment or for pattern- or panel-plating operations). After the panels have been removed from the process bath, they are immersed or sprayed in the dragout tank before they are rinsed in another tank. The concentrated rinse water can be collected separately from its following rinse.

Eventually, the concentration of the tank solution will increase to a point such that it provides an opportunity to

1. Recover metals.
2. Recycle a process bath since it is the same chemistry.

The disadvantage is that this opportunity may require additional production floor space.

A drip pan (also called a drain board) is one of the simplest methods for dragout recovery. The drip pan is located either under the rack while in transit or between tanks, and will capture drips of process solution from racks and panels as these are transferred between tanks. Drip pans not only save chemicals and reduce rinse water requirements, they also improve housekeeping by keeping the floor dry.

**60.5.2.6 Monitor Solution Activity.** Bath life can be extended by monitoring the bath activity and replenishing stabilizers and reagents. This will reduce dump frequencies and result in a reduction in waste.

### 60.5.3 Dragout Reduction

Dragout reduction is desirable as a waste minimization step because it results in the saving of process chemicals as well as a reduction in sludge generation.

**60.5.3.1 Etcher Design.** Etching machines can be the single largest source of copper waste in the discharge from a PCB facility. The amount of copper discharged and the rinse flow rate from that machine are a function of the machine design. An older etching machine often contains a single-stage etchant replenishing module positioned between the etching chamber and its continuously flowing single or multiple-stage water rinse chamber. Fresh etchant is fed to the replenishing module to wash the panels and that etchant (now containing copper washed off of the freshly etched panels), then flows (in a direction opposite to the direction of the panel movement) into the etching chamber. The continuous water rinse can contain from 100 to 500 mg/l or ppm of copper. Companies that use this type of equipment, with single-station rinse module, normally have floor space restrictions in their production area. See Fig. 60.3.

By way of comparison, adding a second stage replenisher station will reduce the range of copper concentration in the following rinse from 50 to 300 mg/l. Using a four-stage replenisher module and combination recirculating and then a single-stage rinse modules, will produce a rinse containing from less than 1.0 up to 2.0 mg/l of copper.

**60.5.3.2 Automation.** Computerized process control systems can be used for panel handling and process bath monitoring to prevent unexpected decomposition of a process bath, controlled rinse flow, and uniform panel withdrawal from each process bath. Since these systems require a significant capital expense for initial installation, typically only large printed circuit board companies will find this to be a cost-effective alternative.

**60.5.3.3 Rack Design.** Some plating rack designs allow the panels to be tilted to one side and the panel mounted at an angle (relative to the horizontal) to allow better solution drainage off of the panel. This will decrease the dragout.

**60.5.3.4 DI and Soft Water for Rinsing.** Natural contaminants found in water used for production purposes can contribute to the volume of sludge produced in waste treatment because they precipitate as carbonates and phosphates. Another advantage is that pretreated rinse water is cleaner; therefore, the normal diffusion of contaminants from the panel into the rinse water occurs more quickly. As a result, water requirements for each rinse may be reduced since rinse efficiency is improved.

## 60.5.4 Material Substitution

Material substitution is a waste minimization technique that should result in a reduced hazard associated with a particular waste or a simplified means of waste treatment. It is important that all process impacts are thoroughly understood prior to instituting any material changes.

**60.5.4.1 Acid Tin as Etch Resist.** Acid solder baths are often used as an etch resist before final etching of an assembled multilayer printed circuit board. The lead and fluoride present in this bath must then be removed in the waste treatment process. Acid tin can be used as the etch resist in place of solder under certain circumstances. An advantage of this bath is that it does not contain lead ions or fluorides. Use of this bath will eliminate these materials from the discharge.

**60.5.4.2 Eliminate Thiourea.** Thiourea is a known carcinogen which has been used as a chelating agent in Sn/Pb stripping baths. A peroxide-based bath can be substituted when the etch resist is acid tin, thus eliminating this concern.

**60.5.4.3 Permanganate Desmear.** To reduce the amount and toxicity of waste, most printed circuit board factories in the United States use the alkaline permanganate process instead of chromic acid for desmear. This technique has gained favor due to the wastewater treatment equipment requirements to reduce the chromic acid and the control problems (especially in humid environments) of 96 percent sulfuric acid. The plasma desmear process produces the least amount of hazardous waste, but that technique is used primarily for small batch operations and not high-volume continuous operations.

**60.5.4.4 Direct Metallization.** Alternatives to the electroless copper process have emerged to avoid the use of formaldehyde, a toxic and carcinogenic material. The use of formaldehyde has recently (as of June 1993) required extensive in-plant air monitoring and will require employers to have their affected employees periodically checked by a medical doctor. This is an additional unwanted expense for each PCB factory owner.

One alternative to the electroless process utilizes conductive polymers. Polymer thick film (PTF) technology is a method of screening polymer conductors, resistors, dielectrics, and protective coatings on a substrate or printed wire board to create basic circuitry or interconnections. The use of screened-on conductive films in place of the formaldehyde-containing electroless copper process is gaining acceptance in Asia (more so than in the United States at this time).

Other technologies are being applied commercially which use palladium or graphite to provide conductive pathways in the holes of multilayer printed circuit boards.

**60.5.4.5 Nonaqueous Waste Resists.** One of the most exciting waste minimization techniques currently being tested is the elimination of the need for rinsing from both photoresist developing and stripping operations. This new process may eliminate spent developer wastes and will eliminate the spent resist stripper bath dump.

The photoresist, being demonstrated at Circuit Center (Dayton, Ohio) and at E. G. & G. Mound, is applied in a production process as a thin film from a liquid solution onto a circuit board and air dried. When exposed to a high-intensity ultraviolet light source, these photoresists will decompose and vaporize as inert gas. There appears to be no rinsing required for these operations. In fact, these operations, as we currently know them, will be eliminated, thus reducing the cost of waste treatment. The existing 30-month demonstration project is a cooperative effort between the University of Dayton Research Institute, the Air Force, the U.S. Environmental Protection Agency, and the Edison Materials Technology Center (EMTEC).

Depending on the actual chemistry used, the use of this new process may reduce the hazardous air emissions from these processes commonly produced with conventional semiaqueous and aqueous chemistries containing butyl cellosolve or butyl carbitol.

**60.5.4.6 Use of Nonproprietary Chemistry to Avoid Chelating Agents.** Chelating agents are molecules that form a charged complex with a metal ion such as copper. They are used to enhance solubility and keep the metal ions in solution. Typical chelating agents used in printed circuit board fabrication include ferrocyanide, ethylenediaminetetraacetic acid (EDTA), phosphates, and ammonia. Chelated baths are intended to enhance etching, cleaning, and electroless plating but make waste treatment much more difficult because the metals are tightly bound in the complex, which inhibits precipitation. Often ferrous sulfate must be added to wastewaters to break the chelators prior to precipitation of metal hydroxides. The iron is precipitated as well as other metals, thus increasing the amount of sludge produced. Use of nonchelated chemistry where possible will eliminate this problem. If some chelating chemistry is required in the process, proper waste segregation should be implemented to minimize the volume of any chelated waste streams.

## 60.6 RECYCLING AND RECOVERY TECHNIQUES

### 60.6.1 Copper Sulfate Crystallization

**60.6.1.1 Theory of Operation.** The sulfuric acid/hydrogen peroxide etching reaction is:

Systems employing crystallizers are designed to

1. Lower the solution temperature to lower the solubility of copper.
2. Then remove copper in the form of copper sulfate pentahydrate crystals ( $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ ).
3. Then reheat the bath (to prevent copper from clogging the return pipe line if the bath temperature is lowered further) before transferring the bath back to its working tank.

An advantage, from a waste treatment point of view, is that the bath is recycled and not routinely dumped. Other microetchants must be dumped when the copper concentration increases. The most significant advantage, from a process point of view, is that a low copper concentration can be maintained and the printed circuit board factory will minimize its purchase of microetchant chemicals.

A disadvantage to this process is that, at the time of this writing, there are no outlets available to receive and recycle the crystals, so the only alternative for manufacturers using crystallizers is to dissolve the copper sulfate crystals in spent dilute (10 percent) sulfuric acid. After the copper has dissolved, this material can be pumped to another holding tank for recirculation through an electroplating cell for reclaim of the copper.

### 60.6.2 Rinse Water Recycling

Rinse waters can be treated and reused in the process. This can be accomplished in two ways. Rinse water recycling can be accomplished with a point-of-source system. In this system, the flow from selected rinses is recirculated through cation and anion exchange columns and then returned to the point of origin. It may be necessary to add a carbon filtration step for rinses containing organics.

The second method would involve a central system. Selected rinses could be run through an ion exchange system for copper removal. Following this step, these rinses would pass through a general resin for cation removal, a general resin for anion removal, systems for organic removal such as activated carbon, ozonation or UV peroxide, and final filtration. In some cases, reverse osmosis could be substituted for the general ion exchange steps. Given the complexity of this treatment process, it would be cost-effective only for large printed circuit board facilities with high water use rates.

### 60.6.3 Copper Recovery via Electrowinning

**60.6.3.1 Theory of Operation.** Electrowinning is the reduction of copper ions to solid metallic copper at a cathode. The following are the chemical reactions governing copper recovery in an acidic solution. The reduction reactions that occur at the *cathode* are:

The reaction that occurs at the *anode* is:

The first reaction describes the principal objective of electroplating (the reduction of copper to its solid form on the cathode). As electroplating proceeds, the waste becomes more acidic, as noted in Eq. 60.4.

The speed of these reactions will be inhibited if oxidizing chemicals are present. Typical oxidizing agents include peroxides and persulfates, which are normal components of microetching baths. If these oxidizers are not chemically reduced in the solution entering an electroplating module, additional reaction time must be anticipated to reduce the oxidizers electrically. Following that, the reduction of copper will occur. For this reason, a chemical reduction step (addition of sodium bisulfite ( $\text{NaHSO}_3$ ) or sodium metabisulfite ( $\text{Na}_2\text{S}_2\text{O}_5$ )) is recommended before the waste is recirculated through an electroplating module.

**60.6.3.2 Central Systems.** Copper can be recovered in a central system from the following sources:

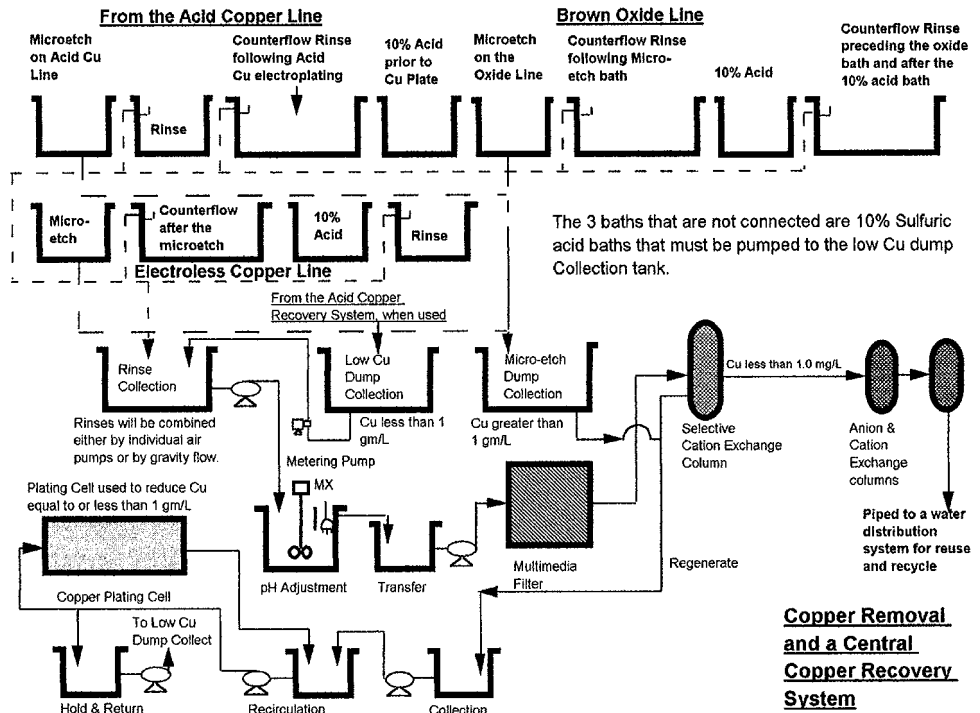

1. Sulfuric acid regeneration of selective cation columns
2. Spent microetch baths
3. Dragout tanks
4. Copper sulfate electroplating bath bailout
5. Dissolved copper sulfate crystals from a crystallizer

The typical concentration of the preceding mixture (or any component of it) may range from 5 to 30 g of copper per liter. A central electrowinning system is shown in Fig. 60.4.

**60.6.3.3 Parallel Plate Electrowinning Systems.** The purpose of parallel plating, in a central system, is to recover copper as a 99.9 percent pure metal sheet (for resale) and to reduce the copper concentration in the liquid being recirculated to 1.0 g/l, or less. The efficiency of the reaction drops significantly below 1.0 g of copper per liter, as observed by the generation of heat in the bath by the electroplating process.

Many factors affect the ability of an electrolytic cell to recover copper. Important design parameters center around improving the mass transport. These include solution agitation and cathode agitation. Air agitation of the waste within the electroplating cell is used to increase the efficiency of the cell. Control of the air inlet rate, bubble size, current density and distribution are all critical to maintaining high efficiency in each parallel plate cell. Particles (so-called *dendrites*) or fines of metal can be dislodged and accumulate in dead spots with the plating cell tank. Electrical shorting out of the anode to cathode can occur when particles accumulate, creating the possibility of isolated locations where burning of the cell may occur.

**60.6.3.4 High-Surface-Area Electrowinning Systems (HSA).** HSA systems can be used to recover copper from a variety of solutions, including electroless copper concentrates and rinses. The use of high-surface-area cathodes improves the mass transport characteristics over flat plate cathodes. The HSA cathodes reduce electrode polarization potential and improve

**FIGURE 60.4** Central copper recovery system utilizing ion exchange for copper removal and electrowinning for copper recovery.

ion diffusion potential, allowing the copper to deposit rapidly on an HSA cathode from wastes with both high and low copper concentrations. HSA cathodes promote solution agitation by creating numerous bonding sites for copper. Expanded mesh carbon fibers or catalyzed foam are typical materials of construction in HSA cathodes. Some HSA systems require the purchase of new cathodes, while the cathodes in some systems can be regenerated for a period of time. To regenerate these cathodes they must be stripped of copper metal.

Stripping the cathode takes place in a second plating tank. The cathodes from the first tank must be manually removed and placed into the anodic position within the stripping tank. The copper is then recovered as a metal by electroplating the copper onto either a stainless steel or a copper laminate in a copper pyrophosphate electrolyte. The *reusable cathodes* are then available to be repositioned back to the first cell.

HSA systems can reduce the copper levels to low levels in an incoming waste stream, but it is important to note that copper is not recovered unless the stripping step takes place in the second plating tank.

**60.6.3.5 Point-of-Source Systems.** Dragout tanks can be located between a process bath (for example, a copper-plating bath in the pattern-plating line) and its following rinse tank. Typically, dragout tanks are positioned *only* adjacent to the process tanks containing the most difficult wastes. These include the etching baths (if not conveyorized), the microetch baths (which produce the most copper), and the copper electroplating (usually sulfate-based) baths.

The contents of each dragout bath can be recirculated through its own plating cell for copper recovery, then back to the dragout tank. In this way, the concentration of copper is

maintained at a low level. The plating cell, for this application, could be either a parallel plate or an HSA system.

If dedicated electroplating cells are not used to recover copper directly from a dragout bath, the dragout bath can periodically be discharged to a dilute (or concentrated) copper collection tank for recovery through an ion exchange system (or a central electroplating system, respectively).

## 60.7 ALTERNATIVE TREATMENTS

### 60.7.1 Selective Ion Exchange

Ion exchange is a process in which ions, which are held by electrostatic forces to charged functional groups on the surface of the ion exchange resin, are exchanged for ions of similar charge in a solution in which a resin is immersed. Ion exchange is classified as an adsorption process because the exchange occurs on the surface of a solid (a resin bead), and the exchanging ion must undergo a phase transfer from the solution phase to the surface of the solid. A single-pass selective cation exchange column can reduce the copper concentration in the influent stream to less than 1.0 mg/l. If two cation exchange columns are in series, as indicated in Fig. 60.4, the expected copper effluent concentration should be less than 0.5 mg/l. Organics present in the incoming waste can foul the resin and render it unusable; therefore, a carbon filtration step occurs ahead of the ion exchange column. Wastes with significant levels of organic material are not treated with this technology.

**60.7.1.1 Theory of Operation.** Copper ions are normally present in their divalent (+2) state. The removal mechanism of divalent copper from an aqueous waste by ion exchange resins is:

where R = a cation exchange resin. Here the copper is "attached" to the resin beads.

Ion exchange equipment suppliers will usually furnish a water meter that totalizes the quantity of waste processed through the column. After the system has been calibrated by the equipment supplier, the water meter will activate an alarm after a specified volume of waste has been processed. An alarm will sound if the system requires manual regeneration. If the system is supplied with automatic regeneration, the water meter will deactivate a column while regeneration takes place. Where multiple columns are included within a system, valves must be adjusted to accommodate regeneration. This will be accomplished by manual or automated (pneumatic-, electric-, or hydraulic-actuated) techniques.

**60.7.1.2 Regeneration.** To recover the copper, the cation resins are first rinsed with water and then washed with 5 to 15 percent by volume sulfuric acid. This proceeds by the following reaction:

where R = a cation exchange resin.

Copper is displaced from the resin by a proton (or hydrogen atom). The resulting sulfuric acid solution containing copper can be directed to an electroplating system to recover copper from the acidic solution. The remaining resin is washed with water to remove the residual sulfuric acid.

**60.7.1.3 Spent Baths.** Certain spent baths can be bled into the ion exchange system. These typically include the copper sulfate electroplating dragout, acid cleaners, predrips, microetch and rinses, rinses following cupric chloride and ammoniacal etchants, and copper waste from electrowinning after reduction to 1.0 ppm or less.

### 60.7.2 Removal of Copper from the Electroless Copper Bath

**60.7.2.1 Theory of Operation.** It is well known that copper metal can be deposited onto metal (usually copper or palladium) within a PCB hole. Dissolved copper is automatically reduced (using formaldehyde as its reducing agent) to a solid metal and deposits itself onto the palladium inside of the hole while the panel is immersed in the electroless copper bath. The chemical reaction of copper deposition may be represented by

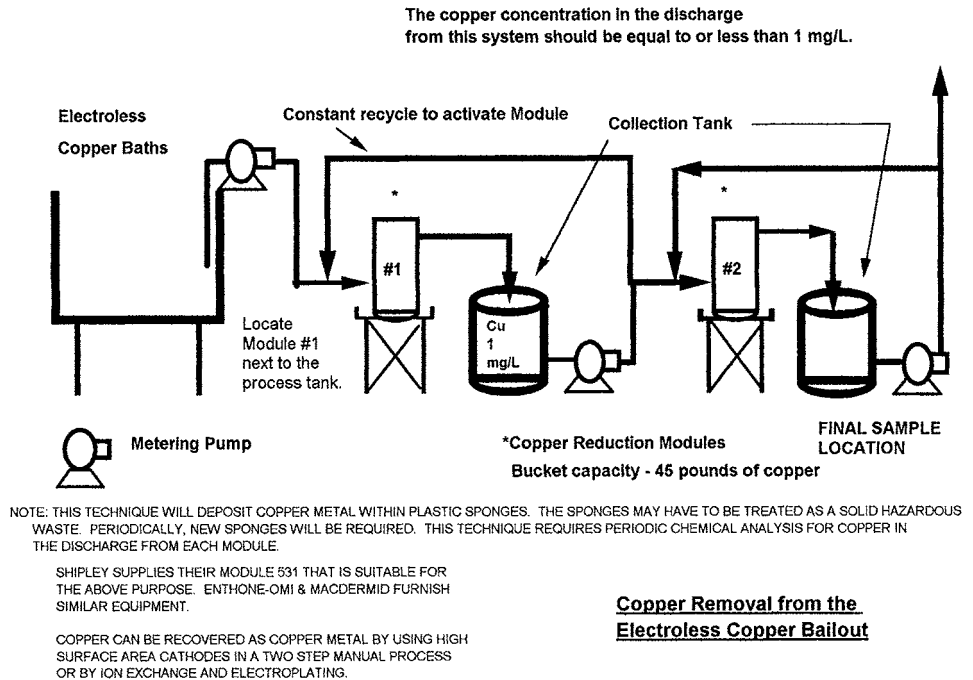

This process can be utilized to remove copper from the electroless copper baths and bailout. Products on the market include canisters or modules which contain a proprietary spongelike material deposited with palladium and copper. The electroless copper solution passes through the canister where the copper is autocatalytically reduced, trapped by the spongelike media and filtered out of the waste stream. See Fig. 60.5

Typically, a minimum of two canisters are connected in series. As the copper concentration in the first canister approaches 1.0 mg/L, the sponge material is replaced by the material in the second canister. New sponge material is added to the second canister.

### 60.7.3 Sodium Borohydride Reduction

Although not as common or as inexpensive as the autocatalytic method, one of the simplest methods for the treatment of electroless copper is by the use of another strong reducing

**FIGURE 60.5** Copper removal from electroless copper bailout using copper reduction.

agent, sodium borohydride ( $\text{NaBH}_4$ ). This chemical is commercially available as a solution of 40 percent caustic soda containing 12 percent by weight of sodium borohydride. The chemical reaction can be represented by

where M is the cation with +1 valence and X is the anion.

The spent electroless bath has to be in an active state for this method to work efficiently. Adding sodium hydroxide ( $\text{NaOH}$ ) and/or formaldehyde ( $\text{HCHO}$ ) to the bath will shift the equilibrium in the bath to this reactive stage. When this stage is reached, a small addition of sodium borohydride will catalyze the reaction, and reduced copper will precipitate out as metallic fines.

A typical process for using sodium borohydride requires the use of an open-top batch tank that is located in a well-ventilated area. Since  $\text{NaBH}_4$  can react to release hydrogen as a side reaction, any source of flames or sparks must be eliminated. A 0.5 to 1 percent, by volume,  $\text{NaBH}_4$  solution is added slowly to the batch reaction tank that contains the spent electroless copper solution. After a few minutes, the solution will effervesce vigorously and fine, pink copper particles will begin to form and become visible to the naked eye. Small bubbles of flammable hydrogen gas will also evolve from the solution, and these must be rapidly removed by appropriate exhausts. Usually within about one hour, the solution will turn clear and copper will precipitate from the solution. These fines will eventually settle to the bottom of the batch tank and the copper fines should be removed as soon as the reaction has been completed. Otherwise the copper fines may reoxidize and dissolve back into solution. More  $\text{NaBH}_4$  will then be necessary to remove the copper. After the copper fines have been removed, hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) can be added to the clear solution to oxidize any excess formaldehyde to the less toxic formic acid.

This process can be used for other metal-bearing waste streams besides electroless copper. However, it is typically not a cost-effective means of treating nonchelated waste.

#### 60.7.4 Aqueous and Semiaqueous Photoresist Stripping Bath Treatment

A significant volume of waste produced from PCB factory is from the stripping of resists. Resist stripping machines can utilize on-line or off-line equipment to remove semisolid photoresists on a continuous basis from the operating bath. Removing the suspended solids within the solution provides a longer life and more efficient usage.

In any case, there will be times when the bath becomes spent and must be dumped. Waste from this process should be segregated for treatment so that the sludge produced can be classified as nonhazardous. In addition, good engineering practice dictates that spent photoresist stripping baths not enter a continuous precipitation system since organic photopolymers may not always settle in a clarifier. Under some conditions (at certain temperatures or with certain organics), stratification of the organic material in the clarifier can occur. As a result, the organic solids can float and any metal hydroxide particles nearby may become attached to the floating material.

The treatment procedure for this waste uses chemical precipitation (caused by lowering the pH) and filtration (to remove the photoresist and residual metals). The treated wastes can be slowly discharged into the existing final pH adjustment tank. The specific treatment procedure follows.

The untreated pH of this waste is approximately 12.0 pH units. Sulfuric acid is slowly added to lower the pH to about 9.0. After a stable pH is achieved, the pH will be lowered to about 6.0 by the addition of acidic proprietary chemicals available at the time of this writing. At this low pH, the dissolved resist will precipitate out of solution and the solids formed can be removed by pumping the waste through a filter press.

## 60.8 CHEMICAL TREATMENT SYSTEMS

---

### 60.8.1 Definition

Chemical treatment of wastes involves the addition of chemicals to precipitate metals out of solution. This results in a sludge which must be disposed of. The sludge is then typically sent to a reclaimer for recovery of the metals or licensed disposal site. The latter option is becoming increasingly difficult and expensive. It should be avoided due to the unknown risks associated with the landfill of hazardous wastes. Chemical treatment of wastes should be utilized only when pollution prevention or recycling is not technically or economically feasible.

### 60.8.2 Treatment Process

Nonchelated metal rinses and dumps are typically treated in a two-stage process. In the first stage, rough pH control is accomplished with the addition of caustic soda and sulfuric acid. In the second stage, the pH is elevated with caustic to precipitate the metals in the hydroxide form. Lime has been used in this step in the past, but its use has been discouraged since it increases the sludge volume significantly.

Alternatively, the metals can be precipitated as in the sulfide form with the addition of FeS at pH 9. This process is more difficult to control and presents a potential hazard due to the possible evolution of H<sub>2</sub>S. However, the lower solubility of the metal sulfides provides an advantage where discharge limits are more stringent.

Chelated metal rinses and dumps such as those from the electroless copper process provide more challenge in chemical treatment since the chelating agents bind the metals and keep them in solution. This problem is often addressed by the addition of ferrous sulfate to break down the chelated metal complexes, allowing the metal to precipitate as the hydroxide. It is often necessary to add large quantities of this reagent such that the ratio of iron to copper is 8:1. The disadvantage of this method is that iron will precipitate out as well, thus significantly increasing the volume of sludge produced.

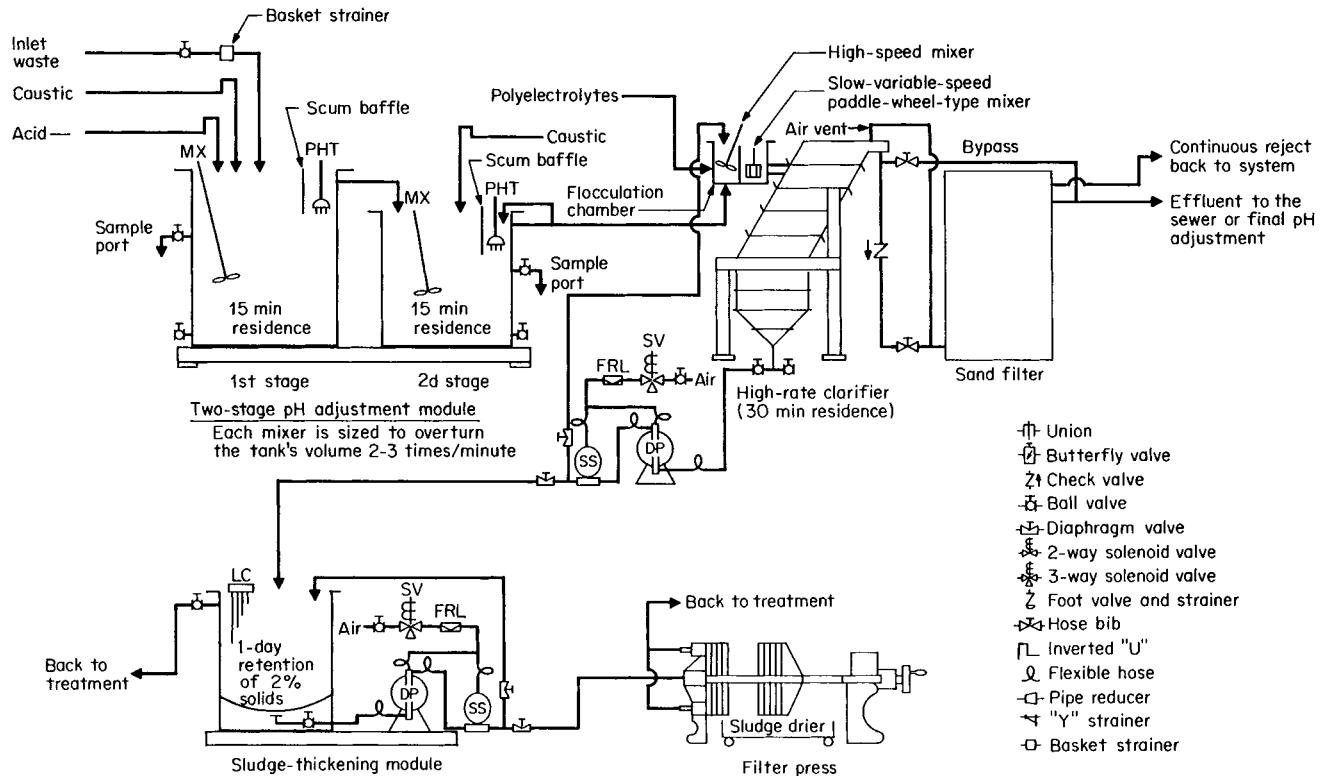

Regardless of the specific treatment chemistry used, there are common components to all chemical treatment systems.

### 60.8.3 Collection System

The collection system is the tank or group of tanks where wastes are collected prior to treatment. The collection tanks should be sized to provide a minimum residence time of 20 min. Segregation of wastes can improve the efficiency of the waste treatment system. For example, process bath dumps can be collected in separate tanks and metered into the rinse waste stream at a low flow rate. Also, chelated wastes can be collected and treated separately from nonchelated streams, thus minimizing the use of ferrous sulfate.

### 60.8.4 pH Adjust

This is typically a dual-tank system where the pH is elevated and metals are precipitated as either the hydroxide or the sulfide, as previously described. Each stage must be adequately sized to provide adequate retention time (usually a minimum of 30 min) to ensure the completion of the reaction. Each tank is equipped with a mixer, pH probe, and controller. In addition, pH recorders should be provided to effectively monitor system performance.

**TABLE 60.2** Advantages and Disadvantages of Various PCB Wastewater Treatment Alternatives

Categories of major wastes	Category of waste minimization or treatment	Advantages	Disadvantages
1. Copper-containing acidic rinses.	Selective rinse water recycling with copper recovery.	Recovered copper metal can be sold. Recycling will reduce the quantity of waste being discharged. Reduced sewer use charges.	Most expensive. Requires flow control. Requires thorough and periodic bath analysis. Must address spent process baths.
	Copper removal from preselected rinses using selective ion exchange with copper recovery by electroplating.	Recovered copper metal can be sold. Minimizes the quantity of copper discharged.	More expensive equipment than used for chemical treatment. Requires expensive selective cation resins. Must address spent baths.
	Chemical treatment to precipitate copper.	Least capital cost. Requires clarification with filtration and proper pretreatment chemistry.	Produces sludge. Increasing liability. Requires intensive effort for labor. Must address spent process baths.
2. Copper-containing acidic spent process baths.	Bath purification with partial or total reuse using crystallization, ion exchange, filtration, and/or diffusion dialysis.	Reduce or eliminate the need to dump a bath. Recovered copper can be sold.	Requires thorough and periodic bath analysis. Optimum application is copper removal from rinse waters.
	Bleed spent bath into rinses for copper removal with copper recovery.	Recovered copper can be sold. Minimizes quantity of copper discharged.	More expensive equipment than used for chemical treatment.
	Allow a higher contaminant concentration before dumping.	Less frequent need to dump a process bath.	Requires thorough and periodic bath analysis.
	Copper recovery from microetchants.	Most copper recovery using least floor space and cost.	Requires that these wastes be collected and processed separately.
	Chemical treatment to precipitate copper.	Used to concentrate copper into sludge.	Produces sludge. Increasing liability. Requires intensive effort for labor.
3. Ammonium chloride etchants and rinses.	Recycle 95 percent etchant and rinse water.	Reduces fresh chemical and hauling purchases. Recovered copper can be sold. Reduces waste quantity.	May be justified only when both inner and outer layers are etched with this chemistry. Ammonium sulfate etchant requires a different method for recycling.
	Pipe rinse into copper removal with copper recovery system.	Recovered copper can be sold.	More expensive equipment than used for chemical treatment. Must continue to haul spent etchant.

4. Electroless copper bath growth.	Process chemistry substitution using palladium-based and/or graphite-based alternatives.	Eliminates formaldehyde.	May produce excess organic wastes. May not be suitable for all applications.
	Copper recovery.	Reduces copper discharge.	Expensive compared to other methods.
	Autocatalytic copper removal onto a sponge.	Effective removal of copper metal complexed with EDTA. Possible copper recovery.	Produces a waste to be transported. Continuous activation, heat, and monitoring are required.
	Chemical treatment.	Least capital cost.	Produces sludge. Chelating agents are still present in the treated waste.
5. Develop/Resist Strip.	Use resists which do not emit wastes.	Eliminates hauling solids.	May not be universally applicable.
	Chemical treatment to reduce volume compared to hauling spent process baths off-site for disposal or dumping waste to the sewer.	Reduces quantity of this material to be hauled for off-site disposal.	Solids handling could be a problem. Expensive proprietary chemicals. Minimal organic load reduction in treated waste. Requires segregation.
6. Other wastes including tin, tin/lead, nickel, and gold.	Recover metal and chemistry from dragout tank.	Bath and metal recovery and recycling are possible.	Requires space to install dragout tanks. Requires more waste segregation and can be expensive as more recycling and recovery is required.
	Chemical treatment and membrane filtration.	Least capital cost.	Produces sludge. Increasing liability. Requires intensive effort for labor.
7. Printed circuit assembly cleaning wastes.	Use of water-soluble solder mask and flux.	Eliminates toxic chemicals. Allows rinse recycling.	Not universally applicable.
	Use of semiaqueous or saponified cleaners for RMA fluxes.	Eliminates use of CFCs.	Possible chemical treatment of bath VOC emission from semiaqueous baths.

---

### 60.8.5 Settling Process

Following the second-stage pH adjust, waste flows to the flocculation chamber in a clarifier where polyelectrolytes and recycled sludge are added and rapidly mixed. The waste then enters a second stage where a slow-speed mixer is used to enlarge the hydroxides to make settling more effective. Finally, the flocculated waste will flow down the clarifier. The precipitated solids settle to the bottom of the clarifier and the clarified liquid is discharged to a final pH adjust system or in some cases to a sand filter prior to final pH adjust if required to meet discharge standards. (See Fig. 60.6.)

### 60.8.6 Cross-Flow Microfiltration

Cross-flow microfiltration systems are used in place of a clarifier and sand filter where the maximum discharge limit for copper is below 1.0 mg/l. Treated wastes are collected in a recirculation tank and pumped at turbulent flow and 10 to 35 psig through a series of capsules containing tubular filters. The majority of the recirculated wastewater plus all the suspended solids returns to the recirculation tank. The suspended solids free water will pass through the side walls of the tubular filter. Sludge is withdrawn near the discharge of the recirculation pump. The 3 percent (total suspended solids) sludge is pumped to a sludge holding tank and then pumped to a filter press. (See Fig. 60.7.)

### 60.8.7 Sludge Thickening and Dewatering

The purpose of the sludge thickening tank is to increase the concentration of the 1 to 2 percent sludge from the clarifier to approximately 3 percent. This is accomplished by continuously decanting the water from the sludge thickening tank and directing it back to the rinse collection tank. The solids from the sludge thickening or holding tanks are then pumped to a filter press for dewatering to reduce sludge volume.

The total suspended solids in the sludge can be increased to about 35 percent with a filter press. In addition, sludge dryers are available which increase the solids concentration to about 70 percent by adding heat to the sludge. This reduces the volume of sludge to be hauled away.

## 60.9 **ADVANTAGES AND DISADVANTAGES OF VARIOUS TREATMENT ALTERNATIVES**

---

All of the techniques described in this chapter have advantages and disadvantages. None of them are appropriate in all situations. Each potential application requires specific analysis and a thorough understanding of the technical and economic issues involved prior to implementation. Table 60.2 presents a summary of the advantages and disadvantages of some of the technologies discussed in this chapter.

# FLEXIBLE CIRCUIT APPLICATIONS AND MATERIALS

---

**Dominique K. Numakura**

*DKN Research, Haverhill, Massachusetts*

---

### 61.1 INTRODUCTION TO FLEXIBLE CIRCUITS

---

Flexible circuits are a form of printed wiring interconnect structure built on thin, flexible substrates. They are also bendable to complete three-dimensional (3-D) wiring that rigid circuit boards cannot achieve. Because of this flexibility, flexible circuits have many advantages over other wiring methods and have many applications in electronic equipment that requires high-density wiring in a small space. As the samples in Fig. 61.1 show, most flexible circuits have cabling functions rather than the mounting functions of electronic components.

Tape-automated bonding (TAB) has not been considered as a type of flexible circuit because of the slightly different manufacturing processes. However, the basic construction and materials of the final products are the same; therefore, TAB is categorized as a type of flexible circuit in this book (see Fig. 61.2).

#### 61.1.1 Advantages and Disadvantages of Flexible Circuits

The basic advantages of the flexible circuits are its thinness and ability to bend. However, a thin flexible circuit generates many supplemental advantages not available with other wiring methods (see Table 61.1). A 3-D wiring with component assembling in a small space and a long-term dynamic flexing with small radius are typical examples of what other wiring materials cannot replace. On the other hand, flexible circuits also have many disadvantages due to unstable thin constructions. It is necessary to consider how to avoid the disadvantages when using a flexible circuit in a packaging system. Otherwise, overall process yield and productivity will be low and the final cost will be relatively very high.

#### 61.1.2 Economics of Flexible Circuits

The largest disadvantage of flexible circuits is that they cost more than rigid circuit boards or flat cables of the same size. Usually, flexible circuits are larger than rigid circuit boards to allow 3-D wiring capability; however, although the total circuit cost increases, using flexible circuits is still often cheaper than using multiple rigid boards and associated connectors.

**FIGURE 61.1** Various examples of flexible circuits.

**FIGURE 61.2** Example of fine TAB circuits.

That is, the cost of using flexible circuits must be compared to the total cost of rigid circuit boards in terms of the following:

- Connectors
- Wires
- Additional assembly costs

**TABLE 61.1** Advantages and Disadvantages of Flexible Circuits

Advantages	Disadvantages
Thin	Fragile
Light	Unstable dimensionally
Bendable	Low reliability—fatigue
Flexible	Difficult to design
Long flexing endurance	Complicated manufacturing process
3-D wiring	Difficult to handle
High-density wiring in a small space	Need special tools for assembling
Avoid connectors and soldering	Low yield in assembling
Avoid missed wiring	Difficult to rework
Low total cost, including all elements	High cost of circuit fabrication

Because the total cost of a flexible circuit is greater than that of an equivalent rigid circuit board alone, designers should not choose flexible circuits over other wiring methods unless three-dimensional advantages are needed, especially for consumer applications that require low-cost wiring. A flexible circuit should be used only when it provides the solution for the application's wiring requirements (for example, when the application requires bendable wiring in a small space, lightweight, long-flex endurance, and so on). The critical question is whether the value of a flexible circuit's performance is greater than its cost.

Miniaturization of electronic products requires extremely lightweight wiring in a small space, and therefore there have been many opportunities for flexible circuits. Figure 61.3

**FIGURE 61.3** Flexible circuits applied for digital camera. (Courtesy of Canon).

shows examples of flexible circuits applied to a digital camera in which their advantages make them the best technical solution, and also the least expensive. In this example, the entire circuit was divided into one multilayer rigid board and more than 10 flexible circuits to optimize the advantages and minimize the total wiring costs.

## 61.2 APPLICATIONS OF FLEXIBLE CIRCUITS

As described, a flexible circuit should be adopted only when other wiring or packaging methods cannot satisfy the application's requirements. Table 61.2 shows how features of flexible circuits relate to appropriate applications. The table shows typical examples of flexible circuit applications in electronic products. Portable electronic products such as cellular phones, digital cameras, automobile instrument panels, and handheld calculators require reliable 3-D wiring in a small space. In some cameras, more than 10 flexible circuits are squeezed into a small space. Flexible circuits are used for the hinge wiring in many electronic products that have mechanical moving parts, such as notebook computers, palmtop computers, and personal digital assistants (PDAs). Many new electronic products, such as hard disk drives, small printers, and clamshell type cellular phones, require a long-life dynamic flexible endurance. Multilayer rigid/flexible circuits have been effective in reducing wiring space and increasing wiring reliability in aerospace electronic equipment and small portable electronic products such as cellular phones. Only flexible circuits could satisfy all these wiring requirements. Efforts to minimize the cost of flexible circuit wiring for consumer applications are ongoing. Often, the miniaturization of a consumer electronic product assumes a wiring system with multiple flexible circuits, especially if the equipment has mechanical moving portions.

**TABLE 61.2** Features and Applications of Flexible Circuits

Features	Applications
High-density wiring in a small space	Digital camera, cellular phone, flat panel display, video camera, facsimile, ultrasound probe
Lightweight 3-D wiring	Calculator Automobile instrument panel, cellular phone, camera, notebook computer
Reliable wiring	Aerospace applications, industrial applications
Long flexing endurance	Printer, hard disk drive, floppy disk drive, CD drive, VCR

## 61.3 HIGH-DENSITY FLEXIBLE CIRCUITS

Serious progress in the density of flexible circuits was made during the second half of the 1990s, owing to the extreme miniaturization of electronic products. These products incorporate a new technical concept in the design of the circuits. They have a much higher density than traditional flexible circuits, with dimensions for traces, spaces, and via holes equivalent to those of rigid high-density interconnect (HDI) boards. (Details are described in the Chapter on Special Construction of Flexible Circuits.) They also have supplemental constructions on the circuit to allow higher termination capabilities. This type of construction is called an *HDI flexible circuit* (that is, a flexible circuit for high-density interconnects).

### 61.3.1 Specifications

Table 61.3 shows typical requirements for interconnection in the end product, and the preferred specification of circuit parameters for the use of high-density flexible circuits.

**TABLE 61.3** Common New Requirements for High-Density Flexible Circuits

Requirements for end use	Preferred specification for flexible circuits
High-density wiring	Pitches smaller than 150 $\mu\text{m}$ , via holes smaller than 150 $\mu\text{m}$ in diameter
Thin and light	Base 25 $\mu\text{m}$ or thinner, conductor thinner than 12 $\mu\text{m}$
High-density SMT	Small opening on coverlay, tin or lead-free plating
High-density connection	High dimensional accuracy (<0.3 mm diameter)
Direct bonding	High-density flying lead, pitch <100 $\mu\text{m}$
Chip-on-flex, flip-chip	High-density microbump array, pitch <100 $\mu\text{m}$
High reliability for vibration	High bond strength of conductors
For mechanical shock	High bond strength between layers
For wide-range heat cycle	High heat resistance
For salty moistures	High insulation resistance

Portable electronic products are exposed to more severe conditions than ever before. As a result, they need higher reliability for the circuits as listed in Table 61.3. In the case of portable telephones, they are often carried in the owner’s pocket, where they may be exposed to a variety of conditions, including continuous vibration, mechanical shock, temperature, humidity, pocket lint, and even perspiration. Other portable electronic products, such as digital cameras, PDAs, and notebook computers, could be exposed to similar conditions.

### 61.3.2 Applications

Due to usage and assembly technologies, many applications require increased performance for high-density flexible circuits. The manufacturing processes for these circuits must adapt to new requirements imposed by additional process conditions. Table 61.4 lists major applications and the associated advantages of using high-density flexible circuits for a given purpose.

**TABLE 61.4** Major Applications of High-Density Flexible Circuits

Applications	Reasons to use high-density flexible circuits
Wireless suspension of disk drives	High-density wiring in a small space Flexible, thin, light, 3-D wiring Direct connection to magnetic heads
Interconnections of disk drive actuators	High-density wiring in a small space Flexible, thin, light, 3-D wiring Repeated reparability
Interposer of CSP	High-density wiring in a small space Thin, light, 3-D wiring
Flat-panel displays	High-density wiring in a small space Flexible, thin, light, 3-D wiring Chip-on-flex capability High-density connection
Ultrasound probes	High-density wiring in a small space Flexible, thin, light, 3-D wiring Direct connection to ultrasound device
Cellular phones	High-density wiring in a small space Flexible, thin, light, 3-D wiring surface-mount technology (SMT) and COF capability
Inkjet printers	High-density wiring in a small space Flexible, thin, 3-D wiring Direct connection to printer head device

Without high-density flexible circuits, these applications could not achieve miniaturization or support valuable new functions. For example, specially developed high-density flexible circuits can provide highly reliable connections at a low cost for new tiny magnetic heads of hard disk drives with a vertical recording system. Chip-scale package (CSP) technologies can be developed with high-density flexible circuits. Driver integrated circuits (ICs) for flat panel displays in personal computers and large flat panel TVs are assembled with a set of chip-on-flex (COF) substrates. Due to the limited space within the camera bodies, small liquid crystal display (LCD) monitors for video cameras and digital cameras are assembled using long-tailed high-density flexible circuits. The wiring of the “next generation” of portable electronics cannot be completed without high-density flexible circuits.

## 61.4 MATERIALS FOR FLEXIBLE CIRCUITS

The basic difference between flexible circuits and rigid circuit boards is the thin and flexible materials used in the substrates of flexible circuits. Furthermore, because the flexible circuits have complicated constructions, supplemental materials other than copper-clad materials have been required to build a whole circuit.

### 61.4.1 Traditional Flexible Circuit Materials

Table 61.5 shows traditional major materials and typical examples of flexible circuits. A broad variety of the materials are employed to build traditional flexible circuits. Film materials, such as polyimide (PI) films and polyester (PET) films are the specially adapted for use in flexible circuits. For greater flexibility, rolled annealed (RA) copper foil is used as the major conductor material.

Coverlays and stiffeners are typical examples of the special components needed to build flexible circuits. Many types of materials have been introduced to accommodate the designs of the end applications.

**TABLE 61.5** Traditional Major Materials Used to Build Flexible Circuits

Application	Typical materials
Base substrates	Polyimide film (PI), polyester film (PET), polyester telephthalate
Conductors	Thin glass-epoxy, fluorinated ethylene propylene (FEP), resin-coated paper Electrodeposited (ED) copper foil, RA copper foil, stainless steel foil, aluminum foil, etc.
Copper-clad laminates	Epoxy-based, acrylic-based, phenol-based (adhesive-based)
Coverlay	PI film, PET film, flexible solder mask
Adhesive layer	Acrylic resin, epoxy resin, phenol resin, pressure-sensitive adhesives (PSAs)
Stiffener	PI film, PET film, glass-epoxy, metal boards, etc.

### 61.4.2 HDI-Oriented Flexible Circuit Materials

Since 1990, many new materials for flexible circuits have been developed in conjunction with design and manufacturing processes to satisfy new requirements in HDI applications. These include:

- High-performance films
- Adhesiveless laminates
- Direct cast processes of liquid polyimide resins
- Photoimageable coverlay

**TABLE 61.6** Materials for High-Density Flexible Circuits

Application areas	New materials for high-density flexible circuits
Base dielectrics	Polyimide films (Kapton K, E, EN, KJ; Apical NP, FP; Upilex S) Liquid polyimide resin, PEN film, LCP films
Conductor materials	Ultra-thin copper foils, sputtered copper, copper alloys, stainless steel foil
Copper-clad laminates	Adhesiveless laminates (cast type, sputtered/plated type, laminated type)
Coverlay	Photoimageable coverlay (PIC) (dry film type, liquid ink type)
Adhesive sheets	Hot-melt polyimide film

See Table 61.6 for a list of new materials for HDI flexible circuits. There is a significant difference between traditional flexible circuits and HDI flexible circuits. For example, more than 80 percent of traditional flexible circuits were covered by adhesive-based copper-clad laminates that use the traditional polyimide films, Kapton H™ or Apical AV™. Conversely, the majority of high-density flexible circuits used in large-volume applications utilize all new materials.

HDI applications require finer traces and microvia holes in severe manufacturing and application conditions. For manufacturing convenience, flexible circuit producers prefer thinner conductors and substrates. However, physical performances of thinner materials may not be optimal. Thinner materials impact both the performance and manufacturing yield of the final flexible circuit.

Dimensional stability of the materials in high-density flexible circuits during manufacturing is a key to good process yields. To produce reliable high-density flexible circuits, conflicts between materials, constructions, and manufacturing processes must be resolved. Measures to accomplish this objective have been undertaken. For example, new construction designs and manufacturing technologies now require use of the materials shown in Table 61.6.

## 61.5 SUBSTRATE MATERIAL PROPERTIES

Many kinds of materials have been developed as the major dielectric layers of flexible circuits; however, polyimide films and polyester films have been the major core material for both substrate films and coverlay films with adhesive for traditional flexible circuits. The polyimide films have been the major substrate material for the soldering process and other high-temperature terminations processes, such as wirebonding and flip-chip, because of their high-temperature resistance and good balance of physical properties. Polyester films are not available for standard soldering, but they are a low-cost solution for large circuits such as those used in automobile instrument panels and long cable circuits of printers.

### 61.5.1 Comparison of Substrate Materials

There have been examples of other materials, such as thin glass-epoxy, that have not been widely used. To satisfy the new concept of HDI flexible circuits, innovative uses of raw materials such as polyethylene naphthalate (PEN) film, liquid crystal polymer (LCP) film, and poly ether ether ketone (PEEK) film have been introduced. Comparisons are shown in Table 61.7.

### 61.5.2 Polyimide Film

Polyimide film continues to be the major substrate material for flexible circuits because only it can support high-temperature processes such as soldering and wirebonding. Both Kapton H film by Du Pont and Apical AV by Kaneka have been used in the flexible circuit industry for

material of the flexible circuits. High moisture levels in the films cause a lot of supplemental problems, mostly in increased temperature processes. Higher-performance polyimide films are required as the substrate material of HDI flexible circuits.

The primary materials used in industry to optimize cost and performance have been 50 micron thick polyimide film, used for industrial and avionics applications, and 25 micron thick films, used for consumer applications. However, since late 1990s, films as thin as 12.5 micron have been specified to reduce thickness and increase flexibility.

**61.5.2.2 High-Performance Polyimide Film.** Various manufacturers have made several aggressive measures to commercialize high-performance polyimide films. Upilex S by Ube Industry has excellent chemical stability, and it is a barrier for chemical processes such as adhesion with the other materials or chemical etching. Strong chemicals, such as hidrasine, are required to do the chemical etching. Upilex-S could be the major material as the substrate of TAB, which requires very high dimensional stability at high heat resistance. Newly developed polyimide films such as Kapton E, EN, and Kaneka's Apical NP and FP have higher dimensional stability and lower moisture absorption rates. It is possible to etch these films using mild alkaline chemistry. Basic properties of the materials are summarized in Table 61.8.

Hot-melt-type (thermoplastic) polyimide films have been developed as high-heat-resistant adhesive materials. Mitsui Chemical's TPI, DuPont's Kapton KJ, Ube's Upicel, and Kaneka's Pixeo are typical examples. These are coated on dimensionally stable polyimide films to ensure good physical performance.

**61.5.2.3 Liquid Polyimide Resin (Photoimageable).** Many new HDI applications require special capabilities and properties on the substrates that are not provided by commercial polyimide films. In these cases, circuit manufacturers initiate production by manufacturing polyimide substrates. Sometimes manufacturers have to start from the synthesis of polyimide resins.

Several liquid polyimide resins have been developed as the base materials of high-density flexible circuits. Some of these liquid polyimide resins can be photoimaged, and have been used in high volume as the dielectric layer and coverlay in the wireless suspension of hard disk drives.

These liquid polyimide resins could be the major dielectric materials of special high-density flexible circuits that demand extremely high density, down to 5 micron pitches with 10 micron via holes. The cost of these materials is higher than that of polyimide film. However, they have broader capability for meeting nonstandard requirements such as ultrathin substrates with microvia holes. The properties are very dependent on the manufacturer.

### 61.5.3 Polyester Film

PET film (polyester film or polyethylene telephthalate) has been produced as a common film for general use, for the following reasons:

- It can provide a low-cost solution.
- It has excellent mechanical performance at room temperature.
- It has low moisture absorption and its dimensional stability is excellent.

Unfortunately, PET film cannot keep its high performance at higher temperatures than 70°C, and it is available for only nonsoldering applications. (Several soldering technologies have been developed for PET-based flexible circuits, but they are very specialized.) Also, PET films are flammable and it is difficult to achieve UL flame class certification. Not many available PET films can satisfy the flammability requirements of UL-94. Typical properties are shown in Table 61.9.

**TABLE 61.9** Basic Properties of PET Films (Nonflammable Grade)

Test Items	Properties	
	MD	TD
Tensile strength (kgf/mm <sup>2</sup> )	16	16
Elongation	110%	100%
Edge tear resistance (kgf/mm)	51	58
Folding endurance	37,000 times	39,000 times
Heat shrinkage	1.4%	-0.2%
CTE	30 ppm	
CHE	10 ppm	
Water absorption	0.7%	
Volume resistivity	4 × exp 15 Ω*cm	
Dielectric constant	3.0 for 1 MHz	
Dielectric loss	0.03 for 1 MHz	
Breakdown voltage	13.6 kV	
Light transmission	46%	
Chemical resistance	Stable in weak acid and alkaline solution	
	Stable in organic solvent	
Flammability	UL-94-VTM-0

#### 61.5.4 Other Materials Used for Flexible Circuits

Thin glass-epoxy sheets less than 200 μm thick can be flexible and can be used as a base substrate of low-cost flexible circuits. Their physical properties are basically the same as those of rigid circuit boards, and standard manufacturing processes and assembling processes for rigid circuit boards are available for these materials. Standard soldering processes are applicable. But glass-epoxy sheets do not have high flexibility, and they are not available for repeated flexing use. The basic properties of these materials are listed in Table 61.10.

**TABLE 61.10** Properties of Thin Glass/Epoxy Substrate

Items	Risho industrial		Matsushita electric
	MD	TD	(R-5766 series)
Tensile strength (kg/mm <sup>2</sup> )	24.5	17.0	—
Elongation (%)	3.2	1.6	—
Thickness (μm)	120		50, 70, 100, 130, 150, 180, 200
Dimension change by heat (%)	-0.05		—
Dimension change by humidity (%)	0.03		—
Surface resistance (Ω)	1 × exp 12-13		5.2 × exp 14
Volume resistivity (Ω*cm)	1 × exp 12-13		
Dielectric constant	—		4.7
Dissipation factor (at 1 MHz)	—		0.015
Water absorption (%)	1.0		0.18
Breakdown voltage (kV/0.1 mm)	3.6		—
Bond strength (kg/cm)	—		1.39
Soldering resistance	—		260°C × 120 s
Flammability	—		UL-94-V-0

These materials are supplied as copper-clad laminates.

Fluorized carbon polymer films have been applied as a low-loss substrate material for flexible circuits. However, they do not have good dimensional stability or adhesion characteristics. High cost of the materials is the major reason that they cannot be standard in flexible circuits. In the last 20 years, several heat-resistant films, such as polypalalabic acid film and polysulfon film, have been developed as alternative substrate materials in flexible circuits instead of polyimide films. Unfortunately, there was no successful material from a business standpoint. LCP films and PEEK have been considered as the new materials of high-speed flexible circuits based on the low dielectric constant and loss tangents.

## 61.6 CONDUCTOR MATERIALS

As flexible circuits have various mechanical stresses, their conductors also have requirements for more flexibility and toughness than traditional ED copper foils of standard rigid circuit boards. An RA copper foil is the solution for high flexing endurance. It is necessary for dynamic flexing use. RA copper foils are more expensive than ED copper, especially at thicknesses of less than 18 micron. Therefore, high-ductility electrodeposited (HD-ED) copper foils have been developed that have greater flexibility than ED copper foils and a lower cost than RA copper foils. The differences between the copper foils are shown in Table 61.11.

**TABLE 61.11** Basic Properties of Copper Conductors

	ED foil	HD-ED foil	RA foil
Manufacturer	Furukawa Electric	Furukawa Electric	Japan Energy
Grade	STD foil	HD foil	RA
Thickness ( $\mu\text{m}$ )	9, 12, 18, 35, 70	18, 35	12, 18, 35, 70
Tensile strength ( $\text{kg}/\text{mm}^2$ )	TD 34	TD 32	MD 21.5 TD 18.9
Elongation (%)	TD 9	TD 23	MD 12.8 TD 9.5
Surface roughness ( $\mu\text{m}$ )	8	10	<3.5
Cost	Low	Middle	High

(Data measured for 35  $\mu\text{m}$  Thick Foils).

Due to the stringent requirements of fine-line etching, thinner copper foils have been developed with small surface profiles. RA copper foil 12  $\mu\text{m}$  thick is a standard product. Low-profile 12  $\mu\text{m}$  thick ED copper foils have also been commercialized for fine-line etching. A special treatment has been developed to ensure reliable bond strength with each adhesive material. In the next five years, these materials will be standard and utilized in large volume. RA copper foils thinner than 10  $\mu\text{m}$  are available; however, processing and high material costs need to be addressed before large-volume production can commence.

Copper foils thinner than 5 micron will be demanded for the semi-additive process to generate 10 micron wide traces or finer since the beginning of 2000s. Two types of technologies have been developed to have ultrathin copper foils. The first one is the “etch-down” process used to reduce the copper thickness from standard thick RA copper foils. Through this process, foils 3–5 micron thick can be obtained from 12 micron RA copper foils. The second is the use of ultrathin foils. ED copper foils 1–5 micron thick have been commercialized with the carrier copper foils. Ultrathin copper layers have been built on the smooth surface of other copper foils with standard thickness. The carrier copper foils are removed mechanically after the lamination with the base layers. Ultra thin copper foils have been applied to adhesiveless laminates through casting or lamination processes.

In addition, sputtering and plating technologies have achieved conductors thinner than 5  $\mu\text{m}$  with semi-additive processes. Among others, these processes can generate copper, nickel,

and gold conductors. Also, they can produce fine traces at less than 10  $\mu\text{m}$  pitch on flexible substrates. Plating baths and chemicals have been developed for these technologies.

Special metal and alloy foils other than copper ones have been developed for specific applications.

Aluminum conductors have been developed as the low-cost solution. They have been applied for volume production of the keyboards of calculators, antennas of wireless devices, and so on. But they could not be universal conductor materials of standard flexible circuits because of difficulty in soldering and the special chemistries needed for etching. The wireless suspension of disk drives has consumed a large volume of special stainless steel and copper alloy foils because of the special mechanical performance of the circuits. A high-resolution printer head has also utilized thin tungsten foils as the conductor of thermal printer head circuits. Nickel-chromium alloy foils have been developed as the conductor materials of flexible heater circuits.

## 61.7 COPPER-CLAD LAMINATES

The majority of flexible circuit manufacturers start the process with copper-clad materials. The properties of these materials depend on the capabilities of laminate manufacturers, even though the same base films and copper foils are used. To choose the right materials, manufacturers must carefully consider the basic properties of each laminate material.

### 61.7.1 Adhesive-Based Laminates

Historically, copper-clad laminates with acrylic or epoxy adhesives have been the major materials for flexible circuits. Each manufacturer has developed a special resin grade or special additives to ensure reliable flexibility and bond strength. Other adhesive materials such as phenol resin or silicon resin have been developed; however, they have not become standard adhesive materials in flexible circuits.

The adhesive-based copper-clad laminates still represent more than 50 percent of the traditional flexible circuit market. The major properties of the materials are shown in Table 61.12.

The manufacturing process is illustrated in Fig. 61.4. Mostly, these films are processed and supplied in roll form. The surfaces of polyester films and polyimide films undergo special processes such as sandblasting and plasma treatment to achieve a reliable bond strength. A specially blended adhesive resin is coated on the film and dried. Then a copper foil is laminated continuously under appropriate temperature and pressure. The surfaces of the copper foils receive a specific treatment according to the requirements of each laminate's manufacturer.

**TABLE 61.12** Basic Properties of Adhesive-Based Copper-Clad Laminates (Polyimide-Based)

Items	Properties		
Manufacturer	DuPont	Nikkan	Shin-Etsu
Grade	Pyralux LF	Nikaflex	RAR Series
Adhesive layer	Acrylic	Epoxy	Epoxy
Peel strength (kgf/ccm)	1.4	1.3	1.8
Dimensional stability MD	-0.08	-0.09	-0.09
(%) TD	-0.07	+0.03	-0.04
Flexing endurance MD	N/A	3200	2650
(MIT, 2.0R) TD		2950	2850
Insulation resistance ( $\Omega$ )	$1.0 \times \text{exp } 11$	$2.5 \times \text{exp } 13$	$1.0 \times \text{exp } 13$
Surface resistivity ( $\Omega$ )	$1.0 \times \text{exp } 13$	$2.7 \times \text{exp } 14$	$1.0 \times \text{exp } 14$
Volume resistivity (cm)	$1.0 \times \text{exp } 14$	$2.0 \times \text{exp } 16$	$1.0 \times \text{exp } 16$
Soldering resistance	$288^\circ\text{C} \times 5 \text{ min}$	$280^\circ\text{C} \times 10 \text{ sec.}$	$280^\circ\text{C} \times 10 \text{ sec.}$
Flammability	No	UL-94-VTM-0	UL-94-VTM-0

**FIGURE 61.4** Manufacturing process for adhesive type laminate, showing a polyimide-based film combined with an adhesive layer coat and laminated to copper foils.

The same process is repeated for double-sided copper-clad laminates. (Some laminate manufacturers, however, have developed simplified manufacturing processes that can make the double-sided laminate in one single process to reduce manufacturing cost.) A well-conditioned aging process is important to achieving reliable bond strength and flexible characteristics of the laminates as the raw material of flexible circuits.

Most of the adhesive resins have lower heat resistances than polyimide films, and are the bottleneck for high-temperature processing of flexible circuits (e.g., lead-free soldering and wirebonding).

The flame-retardant properties of the laminates depend on the composition of the adhesive materials used by each manufacturer. Usually, a normal flame-retardant component in an adhesive resin has a negative effect on bonding. Several adhesive resins contain organic bromine molecules as the flame-retardant components, and will be eliminated for the ecological concerns. (For a discussion of this issue, see Chap. 6.) As soldering temperatures increase, heat-resistant adhesives or adhesiveless laminates systems are required.

### 61.7.2 Adhesiveless-Based Laminates

Several laminates without adhesive layers have been developed as the advanced materials for the next generation of flexible circuits. Lamination technology using epoxy resin or acrylic resin has been almost eliminated from HDI flexible circuits even though it uses new high-performance polyimide films as the substrates. Three types of adhesiveless copper-clad laminates have been developed (see Fig. 61.5):

- Cast
- Sputtering/plating
- Lamination

Each has different manufacturing processes and advantages as the major materials of HDI flexible circuits. Table 61.13 shows basic performances of typical adhesiveless laminate materials.

Currently, there is no perfect solution that satisfies all requirements including cost. Suitable adhesiveless laminate materials should be chosen according to the specifications of the final flexible circuits and the convenience of manufacturing processes.

**61.7.2.1 Cast-Type Adhesiveless Laminates.** The cast-type adhesiveless laminates have a good cost/performance balance. They have a high bond strength between substrate layers and conductor foils. They can also use special conductors such as copper alloy, nickel, stainless

**FIGURE 61.5** (a) Manufacturing process of adhesiveless laminate using the cast process, (b) Manufacturing process of adhesiveless laminate using plating process, (c) Manufacturing process of adhesiveless laminate using lamination process

**TABLE 61.13** Comparison of Adhesiveless Copper-Clad Laminates

Items	Sputtering/plating process	Cast process	Lamination process
Manufacturer	Gould Electronics	Nippon Steel Chemical	DuPont
Grade	GouldFlex	Espanex	Pyralux AP
Choice of dielectric	Wide	Small	Small
Base etchability	Fair	Difficult	Difficult
Dielectric thickness ( $\mu\text{m}$ )	12.5–125	12.5–50	12.5–150
Choice of conductors	Small	Wide	Wide
Conductor thickness ( $\mu\text{m}$ )	~35	12–70	12–70
Bond strength	1.2	1.5	1.4
Double-sided	Available	Available	Available
Flexing endurance	N/A	180 (MIT 0.8R)	N/A
Dimensional change after etching	MD: -0.05%	MD: -0.02%	MD: -0.05%
	TD: 0.03%	TD: -0.02%	TD: -0.05%
Insulation resistance ( $\Omega$ )	$>1 \times \text{exp } 10$	$>1 \times \text{exp } 13$	$>1 \times \text{exp } 14$
Volume resistivity ( $\Omega\text{cm}$ )	$>1 \times \text{exp } 14$	$>1 \times \text{exp } 15$	$>1 \times \text{exp } 17$
Flammability	UL-94-VTM-0	UL-94-VTM-0	UL-94-VTM-0
Roll clad	Standard	Standard	Not available

steel, etc. In addition, they have good flexibility to generate very thin substrate layers down to 12 micron thick. They can have a wide range of copper thicknesses because of the process. There is no difficulty in making 70 or 105  $\mu\text{m}$  copper laminates. Because it has been around longer, the cast-type laminate has a relatively broader availability than other adhesiveless laminates. The process can produce both single-sided and double-sided laminates.

The liquid polyimide resins are coated on a metal foil, directly controlling mechanical stress on the materials. Air-floating conveyors have been employed to reduce the stress. A thermal treatment process is the key to ensuring good physical performance of the laminates. Generally, two or more polyimide layers are coated on the metal foil to ensure both good dimensional stability and high bond strength. Usually, it is difficult to apply the chemical etching process to adhesive polyimide resins using standard alkaline solutions.

Producing double-side laminates through casting requires a special process because the chemical imidation reaction generates a lot of moisture and results in delamination during the lamination process. One special process is to coat hot-melt-type polyimide on the top of the substrate layer, and another is to laminate another copper foil at high temperature and pressure. Physical performance varies depending on the combination of the polyimide resins and lamination conditions. Usually, higher temperatures than 300°C are required.

**61.7.2.2 Sputtering/Plating-Type Adhesiveless Laminates.** A two-step process is required to produce sputtering/plating-type adhesiveless laminates. The first step is a kind of sputtering process to produce seed layers on substrate films. The seed layers have two functions: to generate conductive layers on the nonconductive plastic films, and to increase the bonding strength between base films and conductor layers. Generally, the sputtered layers are thinner than 100 nm. Therefore, the second step builds the thick conductor layers by electrical plating. To produce double-sided laminates, the process is usually repeated twice.

Sputtering/plating-type adhesiveless laminates can generate the thin conductors required for high-density circuits. Theoretically, these laminates provide stable conductor layers thinner than 10  $\mu\text{m}$  at low cost. Technically, it is very possible to have 0.1–1.0  $\mu\text{m}$  thick conductors. Although plating-type laminates provide more substrate material choices, their basic physical properties depend heavily on substrates. The majority of manufacturers introduced the sputtering process to generate a seed layer for good bond strength between the substrate and the conductor. Two or three steps of sputtering processes with nickel, chromium, and their alloys are employed to strike a good balance of chemical, physical, and electrical performance. Sometimes seed layers cannot be etched.

Few choices are available for conductor materials. Thick conductors are not optimal because they require a longer plating process. Micron-size pinholes in the conductor layer are the biggest issue with this material. Several manufacturers have introduced additional chemical processes to eliminate these pinholes. Generally, the bond strength of the laminate is lower than that of other types.

**61.7.2.3 Lamination-Type Adhesiveless Laminates.** Thermoplastic-type polyimide resins with high-temperature melting points have been developed to serve as the hot-melt adhesives between copper foils and dimensionally stable polyimide films. The adhesiveless flexible laminates are produced by a heat lamination of the copper foils and base polyimide films that have thin hot-melt polyimide layers coated on the surface of the core polyimide films. The polyimide films, with hot-melt polyimide layers, are supplied by the major polyimide film suppliers. Temperatures higher than 330°C are required to produce reliable laminates. Materials processed at temperatures lower than 200°C are available for several hot-melt polyimide resins; however, their physical properties are inferior to those of standard laminates.

Producing double-sided laminates is not tremendously difficult. A conventional vacuum heat press with a higher processing temperature than 350°C is available to produce the laminate for small-volume production. A high-temperature roll laminator or belt laminator is used for high volume production.

Lamination-type adhesiveless laminates have advantages in small-volume production. Special polyimide films that have hot-melt polyimide resin on the surface of dimensionally stable polyimide film are available commercially. If a manufacturer has high-temperature heat press equipment, it is not difficult to produce the laminates. A compact roll-type heat laminator was developed to produce the rolled laminates.

Many choices of conductor materials are available for lamination-type adhesiveless laminates. Due to the special combination of conductor materials with stainless steel and copper alloy foils, this material has a variety of uses in multilayer rigid/flexible aerospace applications and in wireless suspension of disk drives. Generally, the adhesive polyimide is difficult to etch using standard alkaline etching solutions, so strong chemistry or a physical process such as plasma etching is required for the process.

Figure 61.6 shows the thickness ranges available for the substrates and conductors for each type material. All of the laminates have expanded their capabilities, and several thicknesses are overlapped. Therefore, circuit manufacturers have more choices for specific thicknesses and can consider other performance variables, including cost.

**FIGURE 61.6** Thickness range of the copper clad laminates.

## 61.8 COVERLAY MATERIALS

One of the major differences between flexible circuits and rigid circuit boards is coverlay. In addition to the solder mask used for assembly, coverlay is the mechanical protector for the fragile conductors on flexible circuits. Film-based coverlay and flexible solder mask have been standard materials for traditional flexible circuits. Several types of photoimageable coverlay materials have been developed to satisfy the fine-resolution requirements of HDI flexible circuits:

- Film coverlay
- Screen-printable coverlay (flexible soldermask)
- Photoimageable coverlay (dry-film type and liquid type)

Several types of the materials are available for each coverlay type.

### 61.8.1 Film Coverlay

Usually the same films are chosen for the coverlay films as are used for the substrate layers. The films are coated with semicured acrylic or epoxy resin, which is used as an adhesive layer. The surfaces of the adhesive layers are covered with release films when the materials are delivered to circuit manufacturers. Semicured adhesive resins are unstable at room temperature, so film coverlay must be kept in refrigerators. The adhesive resins of the coverlay usually have only weeks of pot life even when they are kept in low-temperature environments, and exact conditioning is required for processing.

The process of manufacturing with film coverlay is very complicated, which makes process automation difficult and increases the cost. The manual registration process and the use of unstable film material are major issues when considering film coverlay for HDI flexible circuits due to small hole capability and lower dimensional accuracy. Basic properties of the typical materials are shown in Table 61.14.

**TABLE 61.14** Basic Properties of Film Coverlay (Polyimide Film Base)

Manufacturer	DuPont	Nikkan Industry
Grade	Pyralux LF	CISV
Adhesive	Acrylic	Epoxy
Lamination temperature	180°C	160°C
Storage condition	Room temperature	Refrigerator
Bond strength (kg/cm)	1.3	1.0
Surface resistivity ( $\Omega$ )	$1.0 \times \text{exp } 13$	$3.0 \times \text{exp } 14$
Volume resistivity ( $\Omega \cdot \text{cm}$ )	$1.0 \times \text{exp } 14$	$1.2 \times \text{exp } 16$
Soldering resistance	288°C $\times$ 5 min	280°C $\times$ 10 s
Flammability	No	UL-94-V-0

### 61.8.2 Screen-Printable Coverlay Ink (Flexible Solder Mask)

A screen-printing process similar to that used for rigid circuit boards is available for flexible circuits as the low-cost coverlay process. However, specially conditioned liquid solder mask materials are required to produce appropriate flexibility for the circuits. Standard solder mask materials designed for the rigid boards have small cracks and de-laminations when bending.

**TABLE 61.15** Basic Properties of Screen-Printable Coverlay

Manufacturer	Taiyo Ink	Nippon Polytech
Grade	S-222	NPR-5
Base resin	Epoxy	Epoxy
Color	Green	Green
Hardness	5H	H
Peel strength	100/100 (crosshatch)	100/100 (crosshatch)
Flexibility	N/A	0.5 mm diameter
Soldering resistance	260°C × 20 sec.	260°C × 20 sec.
Insulation resistance ( $\Omega$ )	>1 × exp 13	>1 × exp 12
Flammability	UL-94-V-0	UL-94-V-0

Generally, because of poor resolution, a screen-printing process does not satisfy the requirements of high-density SMT assembling on flexible circuits. Also, such as process does not provide good mechanical performance for dynamic flexing. Typical property examples are shown in Table 61.15.

### 61.8.3 Dry-Film-Type Photoimageable Coverlay

The basic idea of the photoimageable coverlay is to satisfy both of fine resolutions of the opening and physical flexibility by one single material. Also, its simple manufacturing process should reduce costs.

From a processing standpoint, there are two types of PIC materials: dry film and liquid. The dry-film type is easily processed when manufactured with vacuum laminators, which provide good encapsulation with the fine conductors. A vacuum press is also available for a small-volume production. However, the cost per unit area is higher for the dry-film type than for liquid materials.

Dry-film-type and liquid ink-type photoimageable coverlay materials have been developed with different resin matrixes to satisfy different technical requirements of HDI flexible circuits. A comparison of the materials is given in Table 61.16. Properties of the materials are shown in Tables 61.17 and 61.18.

**TABLE 61.16** Comparison of Photoimageable Coverlay Materials

	Dry film type		Liquid ink type	
	Acrylic-base/epoxy-base	Polyimide-base	Epoxy-base	Polyimide-base
Applicator	Vacuum laminator	Roll laminator	Screen print Spray coat Curtain coat	Screen print Spray coat Roll coat
Thickness range ( $\mu\text{m}$ )	25–50	25–50	10–25	10–20
Minimum opening ( $\mu\text{m}$ )	70	70	70	50
Flexibility	*	Good	*	Good

Developer	Sodium carbonate	Sodium carbonate	Sodium carbonate	Sodium carbonate

**61.8.3.1 Acrylic or Epoxy/Dry-Film Type.** Acrylic or epoxy/dry-film types were the first materials developed to act as the flexible photoimageable coverlay for HDI flexible circuits. They have the same product concept as the photoimageable solder mask of rigid circuit boards. The same vacuum laminators and imaging equipment are available for these materials.

Managing the conditioning of the process is not difficult. Acrylic or epoxy/dry-film types are good for small-volume production because of the flexible manufacturing process. They may need some more improvements in electrical performance and chemical resistance if they are to be used in the general application of high-density flexible circuits. The present version

The materials were developed assuming different applications; therefore measured data are not exactly equivalent.

of the materials, however, yields a good balance of performances for both high-density soldering and flexing endurance.

**61.8.3.2 Polyimide/Dry-Film Type.** The physical performance of the polyimide/dry-film type is excellent. When applied to polyimide-based adhesiveless laminates, it provides very high heat resistance and good dimensional stability. Also, it has high electrical properties. It has been applied in high-density wiring of interconnection in the head suspension of disk drives. The major issues with this material are the complicated pattern-generation process and high material cost. It requires multiple chemical processes using special chemical solutions. A high-temperature baking of over 250°C is another difficulty. This is required to complete the standard manufacturing process of flexible circuits.

#### 61.8.4 Liquid-Based Photoimageable Coverlay

Eventually, photoimageable coverlay could be the practical solution for HDI flexible circuits in large-volume production. It is similar to the solder mask of rigid circuit boards; however, the materials for flexible circuits must have high flexibility. None of the materials developed as solder masks for rigid boards are available for flexible circuits, even though dynamic flexing is not required. The liquid PIC requires special coating equipment such as a screen printer or sprayer. It can, however, provide a low-cost coverlay for large-volume production.

**61.8.4.1 Epoxy/Liquid Ink.** This material combination has been providing the best cost/performance combination for large-volume applications. Many manufacturers have tried to develop a good photoimageable coverlay with this combination, and Table 61.17 shows several successful examples. They provide good performance balances in mechanical, electrical, and chemical properties. A specialty is that these materials yield higher flexibility, without serious curling during the thermal processing, than other materials offer.

These materials are available by screen printing, spray coating, and other coating methods. UL-certified grades are available for commercial use. The flexibility of the materials allows several cycles of bending; however, the materials are not available for the long-term flexing that applications such as hard disk drives and printers require.

**61.8.4.2 Polyimide/Liquid Ink.** This material concept was generated as the reliable thin dielectric layer of flexible circuits for both substrates and coverlay. Polyimide/liquid ink is highly reliable for a wide range of thicknesses. A 10  $\mu\text{m}$  thick layer could have sufficient performance to be a coverlay of a high-density flexible circuit. An appropriate combination with an adhesiveless copper laminate allows long-term dynamic flexing. The major issues are short pot life and high cost. Some of the ink materials must be stored at a temperature lower than 0°C. The materials require severe process conditions, especially for the final curing, where they require a temperature higher than 300°C. The cost of polyimide-based photoimageable materials is 5 to 10 times higher than for epoxy-based materials.

### 61.9 STIFFENER MATERIALS

---

All kinds of sheet or board material could be used as stiffener materials for the flexible circuits; however, several materials are commonly used. Typical stiffener materials for the traditional flexible circuits are listed in Table 61.19. Paper phenol boards and glass-epoxy boards are employed for relatively thick requirements. Polyimide films and polyester films are employed for relatively thin requirements. Aluminum plates and stainless steel plates are commonly used as the stiffener materials of flexible circuits. A specialty of the metal stiffeners is their forming capabilities after they are bonded on flexible circuits. Paper phenol and polyester are not available for thermo setting adhesives because of the low heat resistance.

**TABLE 61.19** Comparison of Stiffener Materials

	Paper/phenol	Glass-epoxy	Polyimide	Polyester	Metal
Thickness range ( $\mu\text{m}$ )	500–2,500	100–2,000	25–125	25–250	Very wide
Soldering	Possible	Possible	Possible	No	Possible
Adhesion by thermoset resin	No	Possible	Possible	No	Possible
Cost	Low	High	Medium	Low	Medium

## 61.10 ADHESIVE MATERIALS

Several different types of adhesive materials can be used in flexible circuits depending on the application, except for the adhesive layer of copper laminates and film coverlays. The major applications are the bonding of stiffeners and multilayer constructions.

Table 61.20 compares the materials. Pressure-sensitive adhesives (PSAs) provide a low-cost solution due to their simple application process. A problem of PSA is creep characteristics under mechanical stress, as PSA cannot maintain the exact positions of the stiffener boards under the stress. Thermosetting adhesives provide a reliable bonding between the layers, but they require a long processing time in a heat press with suitable press pad materials and impose a higher processing cost.

Usually, the adhesive materials are supplied on or between separation sheets by rolled form. They should be kept in the refrigerators. The mechanical pretreatments are conducted with the separation sheets.

**TABLE 61.20** Comparison of Adhesive Materials for Flexible Circuits

	Thermosetting epoxy and acrylic resin	Hot-melt-type polyimide resin	Pressure-sensitive adhesives (PSAs)
Reliability	High	High	Acceptable
Bond strength	High	High	Acceptable
Creep	Small	Small	Large
Soldering	OK	OK	OK
Application process	Complicated	Complicated	Simple
Process temperature	160–180°C	>330°C	Room temperature
Material cost	Low	High	Low
Total cost	High	Very high	Low

## 61.11 RESTRICTION OF HAZARDOUS SUBSTANCES (ROHS) ISSUES

Two issues have arisen regarding RoHS requirements for the flexible circuit materials: flame-retardant molecules with bromine in adhesive resins, and heat resistance for high-temperature processing with lead-free soldering. Although the issue of bromine is not actually a part of the RoHS requirement, it has been linked to the general environmental issues of printed circuit materials and processes.

Adhesiveless copper laminates can be the solution for the both of these problems because they do not use adhesive layers and have much higher heat resistance than adhesive-based

laminates. However, because some of the applications need adhesive-based copper laminates, manufacturers of flexible laminates have been developing alternative materials without bromine-based flame-retardant reagents.

There have been technical barriers to developing new materials with a good balance of performances for coverlay eliminating bromine compounds. Film coverlay have to have an adhesive layer with some flame-retardant reagent. Few new epoxy resins have good balance for all of the physical performances without bromine compounds.

New materials of photoimageable coverlay have been developed without bromine molecules. Not many choices offer a balanced performance, especially high flexibilities for dynamic flexing. Polyimide-based photoimageable coverlays are the solution to satisfy the all of the physical requirements, but these polyimide materials are remarkably more expensive.

## DESIGN OF FLEXIBLE CIRCUITS

---

**Dominique K. Numakura**

*DKN Research, Haverhill, Massachusetts*

---

### 62.1 INTRODUCTION

---

Because of the broad wiring capabilities now available, it is possible to cover all 3-D wiring of an electronic product by one flex circuit, or by a set of multilayer rigid/flex circuits, without the need for connectors, extra cables, and soldering. However, to achieve this, the shape of the flex circuit may be very complicated and the size may be large. As a result, the final cost could be extremely high. If so, the use of flexible circuits is not an acceptable solution, especially for large-volume consumer applications. It may be better to divide the wiring into two or more parts to make each circuit simpler. A combination of simple circuits can be less expensive than one flex circuit, even though it mandates several connections between different circuits. A circuit designer should also consider the manufacturing convenience of flex circuits. There are serious differences among rigid circuit boards. A small design modification can sometimes reduce the total cost significantly.

---

### 62.2 DESIGN PROCEDURE

---

To achieve the best cost-performance combination for a wiring design with flex circuits, an appropriate design procedure is recommended, as illustrated in Fig. 62.1. The steps in the process are as follows:

1. A design concept for an electronic product is determined according to the basic specifications for the final product.
2. A logical circuit design and electronic circuit design are formulated.
3. A design for the equipment housing is made according to the final product concept. (This should sometimes be done independently in the case of consumer applications, especially for portable electronic products.)
4. The circuit design is formulated. Appropriate circuit selection is conducted depending on total conditions such as allowed space, sizes of components, operating temperature, possible assembling process, required reliability, and so on.

**FIGURE 62.1** Design procedure for flexible circuits.

5. A flex circuit or a combination with a flex circuit is considered to be the solution for a small wiring space.
6. If the first circuit design does not satisfy the original specifications, the previous design steps are repeated to solve the conflicts.
7. A suitable value analysis is done to minimize the total wiring cost.
8. Conductor trace patterns and coverlay opening patterns are designed to minimize the mechanical stress.
9. Numerical data for photo plotter, NC drilling, punching dies, and other tooling is generated.

### 62.3 TYPES OF FLEXIBLE CIRCUITS

Flexible circuits allow for more variety in their basic structures and supplemental structures than do rigid circuit boards, as shown in Table 62.1. Flexible circuits have single-side or double-side constructions with through holes similar to rigid boards. However, multi-layer construction has significant differences from rigid boards; this is because the flexibility of the composite board will be very low when the circuit has more than two conductor layers. Therefore, the flexing parts of the circuit have to have special layer constructions to keep flexibility. The construction is called rigid/flex when the rigid part includes rigid board materials such as glass/epoxy. A simple single-side or double-side flexible circuit is mechanically fragile, so coverlay and stiffener boards are generally added as the supplemental structures of the flexible circuits. Further special constructions, such as flying leads and dimples, are used for specific applications.

**TABLE 62.1** Construction Types of Flex Circuits

Classification	Structure types
Basic structure includes	<ul style="list-style-type: none"> <li>• Single-sided flexible circuits</li> <li>• Double-sided flexible circuits with or without through-holes</li> <li>• Multilayer flexible circuits with through-holes</li> <li>• Multilayer rigid/flexible circuits with through-holes</li> <li>• Blind via holes, inner via holes</li> <li>• Flying-lead structure</li> </ul>
Supplemental structure includes	<ul style="list-style-type: none"> <li>• Coverlay structure</li> <li>• Stiffener structure</li> <li>• Dimple structure</li> <li>• Micro bump structure</li> </ul>

An appropriate combination of a basic structure and supplemental structures should be chosen according to the requirements of the application. Also, appropriate termination technologies and suitable circuit constructions must be considered together.

### 62.3.1 HDI (High-Density Interconnect) Flexible Circuits

There are significant differences in design, materials, and manufacturing technologies between traditional flexible circuits and new high-density flexible circuits developed for high-density interconnect (HDI). Figure 62.2 shows one way of defining the areas of high-density flexible circuits by using the technical hurdles of manufacturing for both trace densities and via hole sizes. Advanced etching technology is needed to give the high-density flexible circuits fine traces. Also needed are new micro via hole generation technologies other than traditional mechanical drilling, such as laser, plasma, and chemical etching.

Ultra-high-density flexible circuits have been developed for special applications. They have extremely fine circuits that are smaller than 20  $\mu\text{m}$  in pitch, as well as micro via hole connections

**FIGURE 64.2** Definition of HDI flexible circuits.

smaller than 25  $\mu\text{m}$  in diameter. Product concepts for ultra-high-density flexible circuits are very different from those for traditional flexible circuits in construction and manufacturing technologies. They need completely new concepts for the manufacturing processes, such as an additive process with new materials and new equipment. (See Chaps. 22 and 23 for detailed discussions of HDI design and fabrication.)

New high-density flexible circuits have supplemental structures such as flying leads and micro bump arrays to complete high-density terminations. As volume production is limited, the designers should consider the manufacturers' process capabilities seriously.

### 62.3.2 Single-Sided Circuits

A bare single-sided flex circuit has a construction very similar to those of the single-sided rigid circuit boards, except for the thickness of the substrate layers. On the other hand, the protection of the conductors of the flexible circuits is very different from the rigid boards. A film coverlay system is introduced for the flexible circuits instead of solder masks (see Fig. 62.3). As introduced in Chap. 61, there are several choices of substrate (see Table 62.2). A 25- $\mu\text{m}$ -thick polyimide film substrate is the most common material for consumer applications, with large volume due to its low cost. For higher reliability thicker film should be chosen, while for lower reliability, a thinner film can be used.

FIGURE 62.3 Basic structure of single-sided flexible circuit.

The thickness of the adhesive layers must be counted when total thickness is considered.

TABLE 62.2 Thickness of Base Substrates

	Base film ( $\mu\text{m}$ )	Adhesive ( $\mu\text{m}$ )
Polyester base/adhesive type	25, 38, 50, 75, 100, 125, 188	25–50
Polyimide base/adhesive type	12.5, 25, 38, 50, 75, 125	25–50
Polyimide base/adhesiveless type	12.5, 25, 30, 35, 40, 50	No
Glass-epoxy	100, 200	–0

Adhesive layer thickness is doubled for double-sided laminates.

Possible fine-line capability is illustrated for each copper thickness in Fig. 62.4. Currently 18- and 35- $\mu\text{m}$  copper foils are standard. Copper foils 12  $\mu\text{m}$  and 9  $\mu\text{m}$  thick are becoming the new standard to enable finer pattern etching. Thinner copper foils are available in sputtered/plated adhesiveless laminate materials. The fine-trace etching capability depends very much on the manufacturer, especially the exposure process and etching process.

### 62.3.3 Coverlay System of Flexible Circuits

The coverlay system of flexible circuits is one of the big differences from rigid printed circuit boards, as shown in Fig. 62.3. A coverlay has to have more functions than the solder mask of rigid boards. It should not only have solder dam capability, but also mechanical protection capability for the fragile conductors of flexible circuits. Also it is required to have high toughness to survive long flex endurance and to optimize the major advantage of flexible circuits.

Appropriate coverlay material and thickness including adhesive layers have to be chosen to have the best balance between the layers. Generally, the same film material laminated with appropriate adhesive as base substrate is selected as the coverlay materials. Polyimide film coverlay should be selected for the high temperature assembling processes such as soldering.

**FIGURE 62.4** Fine line capabilities. Potential line pitch is noted for copper thickness alternatives along with whether a given thickness leads itself to high-volume production or requires too a high level of technical interaction.

The manufacturing process for the film coverlay is very complicated compared to the solder masks of the rigid boards, so the final cost of the circuits cannot be low. Flexible, screen-printable inks are a low-cost solution; however, most of the ink materials made of epoxy resins do not have good mechanical properties and cannot be applied for dynamic flexing usage. A combination of polyimide-based screen-printable coverlay on adhesiveless copper-clad laminate provides the smallest total thickness with very long flexing endurance life. A comparison of cross sections is shown in Fig. 62.5.

(a)

(b)

**FIGURE 62.5** Cross section of a single-sided flexible circuit showing (a) adhesives-based laminate and film overlay; (b) adhesiveless laminate with liquid coverlay.

**TABLE 62.3** Varieties of Coverlay

	Material selection	Thickness ( $\mu\text{m}$ )	Dimensional accuracy (minimum opening)	Reliability (flexing endurance)
Traditional film coverlay	PI, PET	30–100	$\pm 0.3$ mm (800 $\mu\text{m}$ )	High (long)
Film coverlay + laser drilling	PI, PET	30–100	$\pm 50$ $\mu\text{m}$ (50 $\mu\text{m}$ )	High (long)
Screen print liquid ink	Epoxy, PI	10–20	$\pm 0.3$ mm (600 $\mu\text{m}$ )	Acceptable (short)
Photoimageable (dry film type)	Epoxy, PI, acrylic	25–50	$\pm 50$ $\mu\text{m}$ (80 $\mu\text{m}$ )	Acceptable (short)
Photoimageable (liquid ink type)	Epoxy, PI	10–20	$\pm 50$ $\mu\text{m}$ (80 $\mu\text{m}$ )	Acceptable (short)

High-density flexible circuits that have been developed since 1990 need a small pitch opening with high accuracy on the coverlay. Because traditional coverlay technologies have no capabilities to meet these requirements, new technologies were required. Many new technologies and new materials have been developed to satisfy the new requirements of high-density flexible circuits. The capabilities of the major technologies are shown in Table 62.3.

For example, laser drilling is capable of generating openings smaller than 100 microns on the traditional film coverlay; therefore it satisfies the requirements of physical performance and high density SMT assembling. However, the processing costs of the laser abrasion are much higher than other coverlay processes, and it is difficult to apply for the high volume production of consumer applications. A screen-printing process provides a slightly higher resolution than traditional pre-punching process of the film coverlay, but the process can not satisfy the recent requirement for high density SMT assembly. A practical solution is the combination of film coverlay for the flexing areas and solder mask for the SMT areas. It needs supplemental processing to complete the construction, accordingly the total process yield will be lower and the final cost of the circuits could be higher.

The idea of the photo-imageable coverlay could be the final solution to solve the all requirements, including the processing cost. The photo-imageable solder mask materials developed for rigid boards are too brittle, however, and a lot of cracks can be created easily by small radius bending—requiring flexible materials. Several types of flexible photo-imageable coverlay materials have been developed with different base resin systems. Most of the photo-imageable coverlay materials provide finer resolutions than 200 micron pitches, but the physical performances very depend on the base resin systems. Suitable material should be chosen for the applications.

Appropriate surface treatments for the bare conductors after the coverlay construction should be chosen according to termination technologies. Several examples are listed in Table 62.4. Details are explained in Chap. 64.

**TABLE 62.4** Surface Treatments and Termination Technologies

Surface treatment	Termination technologies
Solder and lead-free solder	Lead-free soldering, FFC connector
Lead-free Hot-air leveling	Lead-free soldering
OSP (pre-flux)	Lead-free soldering
Hard Ni/Au plating	Connector, pressure contact
Soft Ni/Au plating	Wire bonding, direct bonding
Tin	Lead-free soldering

### 62.3.4 Surface Treatment Alternatives Stiffener boards

Thinness and bendability are the major advantages of flexible circuits. However, flexible circuits can lose mechanical strength when it is necessary as part of a composite assembly. The addition of stiffeners on flexible circuits is a practical solution to solve the conflicts, but appropriate stiffener board materials and adhesive materials have to be chosen based on the applications purposes.

Figure 62.6 illustrates typical examples of the stiffener systems. The first one shows a stiffener construction for an insertion part into a connector. A stiffener adjusts the total thickness of the insertion part. Heat resistant materials, such as polyimide films, are not required for the construction. PET films with PSA (pressure-sensitive adhesive) could provide the low cost combination. A second example shows a case of the assembling of the traditional lead components. A relatively thick stiffener board, such as glass/epoxy, is bonded on the component side to support heavy parts. The soldering for the leads is conducted at the other side. Heat resistant materials including adhesives have to be chosen to survive the high temperature soldering process. Thermo-setting type adhesives should be chosen instead of PSA for the high reliability requirements. The third example indicates the case of SMT assembling. A thin heat resistant stiffener material such as polyimide film is bonded on the other side of SMT assembling.

FIGURE 62.6 Stiffener systems for flexible circuits.

### 62.3.5 Double-Sided Circuits with Via-Holes

A double-sided flexible circuit can have the same through-hole structures for the traditional designs as rigid circuit boards. However, there are several critical differences in micro via holes on flexible circuits. Most of the differences come from a thin-film base substrate such as

**FIGURE 62.7** Blind via structure of double sided flexible circuits.

polyimide film. Electrically plated copper conductors are much more brittle than rolled-annealed copper foils; therefore, thin copper plating is preferred to maintain the flexibility of the circuits. Generally, sufficient through-hole reliability is established with 15- $\mu\text{m}$ -thick copper plating. Copper plating should be eliminated from the dynamic flexing area by using a suitable masking method.

Adhesiveless, copper-clad laminates that have simple and uniform substrate layers and smooth copper surfaces have become popular in high-density flex circuits. Because of thin film materials, there are several choices in small hole generation and copper plating processes. Flex circuits can contain both through-holes and blind via holes for double-sided circuits as shown in Fig. 62.7. Micro-size blind via holes on double-sided flex circuits confer the ability to make SMT assembly density much higher.

The micro via hole capability depends on the process used by the manufacturer; however, general ideas are introduced in Chap. 61. Certainly the smaller via holes are available for the thinner substrates. Using the latest technology, such as excimer laser drilling, micro via holes smaller than 40  $\mu\text{m}$  are available for 25- $\mu\text{m}$ -thick adhesiveless polyimide base substrates.

Microvia hole capabilities for polyimide substrates are shown in Fig. 62.8.

**FIGURE 62.8** Microvia capabilities shown by base thickness and hole diameter. Also shown is the range of technologies from HDI to mechanical drilling required to create the vias.

**FIGURE 62.9** Multilayer rigid flex construction.

Basically, the same construction systems of coverlay, stiffeners, and surface treatments as single-side flexible circuits could be available for double-side flexible circuits.

### 62.3.6 Multilayer Rigid/Flex (Multilayer Flex)

A simple, multilayer, flexible circuit does not make sense other than for its small thickness, because these circuits will not have any more flexibility. Therefore, rigid/flexible constructions that contain both rigid parts and flexible parts have been developed. A typical layer construction is illustrated in Fig. 62.9. It is not a simple combination of flexible circuits and rigid circuits. Generally, there are common flexible layers that are separated in the flexible parts. A flexible layer of the flexible parts can have only one or two conductor layers to keep high flexibility. At the rigid parts, the flexible inner layers are sandwiched by cap layers that consist of rigid circuit materials such as glass epoxy or glass polyimide. The constructions of rigid parts are very similar to those of rigid multilayer circuits except for the thin polyimide dielectric layer inside. Thin polyimide films were used as the cap layer at the rigid part to reduce the total thickness required in portable electronics such as cellular phones. The multilayer construction in these cases, the circuits are called multilayer flex.

Through-hole and blind via hole constructions similar to those of multilayer rigid circuit boards are available using coated copper foil or photo-via processes for multilayer flexible and rigid/flexible circuits. However, there are more varieties from which to choose in both materials and manufacturing processes. Basically, the same assembly technologies are available on the rigid parts. The latest portable electronic equipment, such as palmtop computers, requires high-density SMT assembling on the rigid parts.

There are no limits to the number of flex layers. More than 30 layers are built into one rigid/flex circuit for aerospace applications. However, the circuits require very complicated manufacturing processes—more so than the standard rigid multilayer circuits—and therefore their costs are much higher than costs for rigid boards of the same size. Design should be considered seriously prior to manufacturing to reduce the total cost based on the capability of the manufacturer. A higher circuit density can reduce the layer counts and the total manufacturing cost.

### 62.3.7 Flying-Lead Construction (Double access construction)

A specialty construction for flexible circuits is the double-electrical access capability on even single conductor layer circuits, achieved by removing the base insulation layer under the conductors as shown in Fig. 62.10. It can be an alternative construction instead of double-side circuits with through holes for the low cost 3-D wiring. When the insulation layers are removed from both sides of the conductors, they can then be partially free from the organic materials. Unsupported conductors, also known as flying leads or flying fingers, are not a new idea in the construction of flexible printed circuitry. (Fig. 62.10) The biggest advantage of flying-lead technology is its extremely high heat resistance and thermal conductivity when compared to standard conductors insulated by dielectric substrate materials. Based on the lack of insulation, flying leads can be treated as a bare conductor material similar to bare wire. There are many high-density flexible circuit applications that require flying-lead terminations. Details are discussed in Chap. 64.

**FIGURE 62.10** Flying lead construction (Double sided construction).

Consideration must be given to specific surface treatments required on the flying leads to make each of the various application terminations. Previously, tin/lead plating was the most common treatment for various soldering processes; however, it is expected to be replaced by lead-free technologies, which need higher temperatures for the soldering. Soft gold plating with a nickel under-plating is the standard surface treatment for the wire bonding and direct bonding to the other devices. The purity and the thickness of the plated gold, along with the bond strength of the plated layer, are important factors in bond performance.

Copper thickness is a key consideration when developing a new circuit design involving flying leads. Although it is easier to manufacture high-density circuits utilizing thinner copper, the resultant flying lead may be extremely fragile and will not have the mechanical strength of the thicker copper circuits (see Fig. 62.11). Manufacturing yield plays an important role in the overall circuit costs, and thinner copper foils typically result in more damage during processing. It is important to understand this correlation as poor circuit design can affect manufacturing yields.

Because the flying leads are basically bare conductors, suitable surface treatments should be conducted according to termination technologies.

**FIGURE 62.11** "Flying lead capability of copper foil, showing potential line width versus thickness of the copper foil."

### 62.3.8 Micro Bumps and Dimples

Many kinds of micro bump arrays and dimple arrays have been developed for high-density terminations of flexible circuits other than solder ball grid arrays. Recent technologies allow for a wide variety of shapes, materials, sizes, and pitches; down to 50 microns. The solder ball arrays are built by similar processes of the rigid BGA substrates. The combinations of the electrical and electroless-plating process provide a lot of choice for the shapes and sizes of the micro bump arrays on flexible circuits. The double-access capabilities of flexible circuits provide more choices for the locations of the micro bumps, as shown in Fig. 62.12, other than through coverlay. The micro bumps can be built on the bottom side of the conductors through base layers. They can be also built on both sides of the flying leads. An appropriate design should be chosen according to the requirements of the terminations. Whether it's a permanent connection or non-permanent connection is one of the key points needed for designing the basic constructions of the micro bumps. Bump density and reliability are other factors needed to design the micro bump structures. Details of the manufacturing processes are described in Chaps. 64 and 67.

**FIGURE 62.12** Locations of microbumps.

Dimple structure of flexible circuits is a low cost solution for the non-permanent termination. Multiple dimple arrays can be formed on the polyimide base or PET base flexible circuits by simple pressing processes. (Details are shown in Fig. 62.13) A typical example of the dimple termination is the connection of the disposable cartridges of ink jet printers. Over 60 dimples with hard gold plating are formed at the end of flexible circuit for the connection with the ink cartridge. The dimple arrays can make reliable connections over one thousand times.

**FIGURE 62.13** Dimple structures (Ink jet printer).

## 62.4 CIRCUIT DESIGNS FOR FLEXIBILITY

One of the major features of flexible circuits is their long flexing endurance. A suitable layer construction and materials survives over billion times of flexing with a small radius. A basic idea of the mechanical stress during the bending is illustrated in Fig. 62.14(a). To have the longest flexing life, the conductor layer should be the center of the layer construction. It should have symmetrical layer constructions for both sides of the conductor layer. The flexing life will be remarkably shorter when the conductor layer is out side of the bending center as shown in Fig. 62.14(b). A rolled annealed copper foil should be used instead of ED copper foil for a longer flexing life. But there is no exact relation between roll direction and flexing

**FIGURE 62.14** (a) and (b) Mechanical stress at bending, (a) Symmetrical, (b) Nonsymmetrical.

**FIGURE 62.15** “Layer construction for dynamic flexing, (a) Standard layer construction, (b) Dynamic flexing construction with thin adhesive layers, (c) Dynamic flexing construction without adhesive layer.”

endurance; the exact performance should be evaluated for each material. Generally, 35 microns thick RA copper is more expensive than the same thick ED copper foil. The cost difference between RA copper foil and ED copper foil will be larger at thinner thickness. A high ductility ED copper foil could be alternative choice for middle class dynamic flexing. Its flexing life is shorter than RA copper foil, but it is less expensive and it can survive one million flexing instances with an appropriate layer construction and flexing radius.

Another principle is that for dynamic flexing, the thinner the layer, the better. An 18- $\mu\text{m}$ -thick copper foil has a longer flexing life than a 35- $\mu\text{m}$ -thick copper foil. A 12.5- $\mu\text{m}$ -thick polyimide film provides a longer flexing life than a 25- $\mu\text{m}$ -thick polyimide film (Fig. 62.15). Adhesive layers should be as thin as possible for dynamic flexing. But thin adhesive layers do not have good bond strength and good encapsulation for traces, and therefore a suitable thickness should be determined based on experimental data. Generally, polyimide films have a longer life than polyester films. The combination of a thin, adhesiveless, polyimide base laminate and a thin coverlay of liquid polyimide resin could be the best solution to have the longest flexing life.

Many kinds of bending modes on flexible circuits could be practical, but in IPC-TM-650 it is recommended to evaluate the flexing life using the movement shown in Fig. 62.16.

The larger flexing radius provides a longer flexing life, as shown in Fig. 62.17.

There are several ideas for reducing the risks of flexing failures in actual cases for electronic products; Fig. 62.18 shows some examples.

Basically, double-sided flexible circuits with through holes are not available for dynamic flexing. The flexibility depends on the configuration of conductors in both sides of the base substrate, as shown in Fig. 62.19 shows examples. Bending the circuit with thin copper circuits on the outside of the flexible circuits may cause them to break, because the mechanical stresses are concentrated on the small traces.

A dynamic flexing area of a double-sided flexible circuit should have only one conductor layer. Coverlay on the other side of conductor should also be eliminated to enable symmetrical layer constructions. Copper plating for the through-holes of double-sided flexible circuits should be eliminated from dynamic flexing areas using a plating mask.

FIGURE 62.16 “Typical dynamic flexing mode of flexible circuit specified by IPC-TM-650.”

FIGURE 62.19 (Continued)

## 62.5 ELECTRICAL DESIGN OF THE CIRCUITS

There is no significant difference between the electrical performance of flexible circuits and that of rigid circuit boards. But there are small differences in conductivity and insulation resistance depending on the materials. Also, there are small differences in dielectric constant and tangent delta. Therefore, similar calculations can be applied to determine electrical performances for a flexible circuit. However, flexible circuits have a relatively long parallel circuit for cabling capability, and impedance should be managed carefully, especially for high-speed circuits with high frequencies.

**62.6 CIRCUIT DESIGNS FOR HIGHER RELIABILITY**

Because of the thin and fragile materials used, flexible circuits have lower mechanical reliability than rigid circuit boards. They have a low conductor bond strength and low base substrate tear strength. Nevertheless, most of the flexible circuits are subjected to more mechanical stresses due to movement. This means that special care is required in the circuit design to gain higher circuit reliability.

There are several ways to make the reliability higher. Figures 62.20 and 62.21 show several common ideas for increasing the reliability of flexible circuits by modifying conductor patterns.

The trace patterns should be smooth slopes between different widths. The pad size should be as large as possible. Figure 62.22 shows an example applied for automobile instrument panels. The conductors are designed to be as wide as possible, and the spaces between conductors are

**FIGURE 62.20** Reliability design for flexible circuits (a) Unacceptable, (b) Preferred.

kept in the safety range. A suitable coverlay opening could increase the reliability, as shown in Fig. 62.23. The amount of squeeze-out of coverlay adhesives should be minimized, however. The edge areas of stiffener boards are dangerous places in which mechanical stresses are concentrated. Figure 62.24 shows ways of reducing these risks.

## 62.7 CIRCUIT DESIGNS FOR ROHS COMPLIANCE

As it was described in Chap. 61.11, there are two issues involved in satisfying RoHS compliance and Halogen-free requirements. They are the eliminations of bromine molecules and lead components. A suitable material combination should be selected to survive during the high temperature process of lead-free soldering. The adhesiveless copper laminates could be the suitable materials for this purpose. OSP (Organic Surface Protection) treatment or Tin-Copper plating could be the alternative solution for the surface finishing of the bare conductors instead of the eutectic solder and hot air leveling.

## 63.1 INTRODUCTION

---

Basically, it is possible to produce the standard constructions of single- and double-sided flexible circuits and multilayer rigid/flex for small volume—if there is a set of manufacturing facilities for multilayer rigid circuit boards. However, it is not easy to achieve high productivity, with high process yield, for volume production of flexible circuits using these facilities, as they are not designed to deal with the unique issues of flexible circuits, such as their thin, flexible material. Therefore, manufacturing facilities for high volume flexible circuits must be designed to take advantage of these differences, including specific equipment and process conditions, as discussed in this chapter.

Table 63.1 shows the specialties for processing the flexible circuit materials. Most of the issues are caused by their complicated structures and fragile materials. The coverlay structures and the stiffener constructions require supplemental manufacturing processes, making process yields lower. The varieties of outer shapes make material yields and productivity lower. Thin, fragile materials can easily incur serious mechanical damage due to rough handling. Thin materials can also undergo significant dimensional changes in the manufacturing processes. They cause a pattern shift between the processes and make the process yields lower. High-level automation has basic barriers, discussed later, when applied to the manufacturing process for flexible circuits, because of its unstable materials. Many processes must be conducted by manual methods, which are, of course, labor intensive.

Process elements particular to flexible circuits are required to achieve a high manufacturing yield. Also, an appropriate total process design is required to achieve high productivity with high yield.

A roll-to-roll (RTR) manufacturing system is a high-productivity solution for volume production of flexible circuits. However, the RTR lines are not flexible for a non-standard construction, and they are available for only the early steps of the long manufacturing processes. Also, RTR processes have many limitations to apply.

---

## 63.2 SPECIAL ISSUES WITH HDI FLEXIBLE CIRCUITS

---

High-density flexible circuits, which have been developed since the mid-1990s, have special constructions and therefore require supplemental processes. In addition, high-grade manufacturing technologies are required to generate finer circuits. Sometimes, they are called HDI

**TABLE 63.1** List of Specialties for Processing Flexible Circuits

Areas	Issues for processing flexible materials
Special constructions	Coverlay, stiffeners, and so on Complicated shapes
Materials	Thin, low stiffness Low dimensional stability Fragile for mechanical forces
Automation	Difficult for automation RTR available only for beginning

**TABLE 63.2** New Manufacturing Technologies for High-Density Flexible Circuits

Processes	New technologies
Raw materials	Stable polyimide film (~20 ppm CTE) Thin copper foil (9, 12 $\mu\text{m}$ ) Adhesiveless copper-clad laminates
Microvia hole drilling	Laser (excimer, UV:YAG, carbon dioxide) Microhole punching High-accuracy $x$ - $y$ table Plasma etching, chemical etching
Copper plating	Direct plating Seed layer sputtering
Surface cleaning	New cleaning reagent
Etching resist	Thin dry film (~15 $\mu\text{m}$ ) Liquid resist
Exposure	Collimated light source, auto aligner Laser direct imaging
Etching	High-resolution etchant
Coverlay	Laser drilling Photoimageable coverlay (dry film type and liquid type)
Surface finishing	Electroless plating for Ni, Au, solder High-speed plating
Flying leads	Laser/chemical etching Chemical etching
Guide holes	Automatic high-accuracy punching machine
Inspection	Universal AOI Noncontact electrical tests
Roll-to-roll system	Low-tension EPC system Automatic aligner with CCD camera

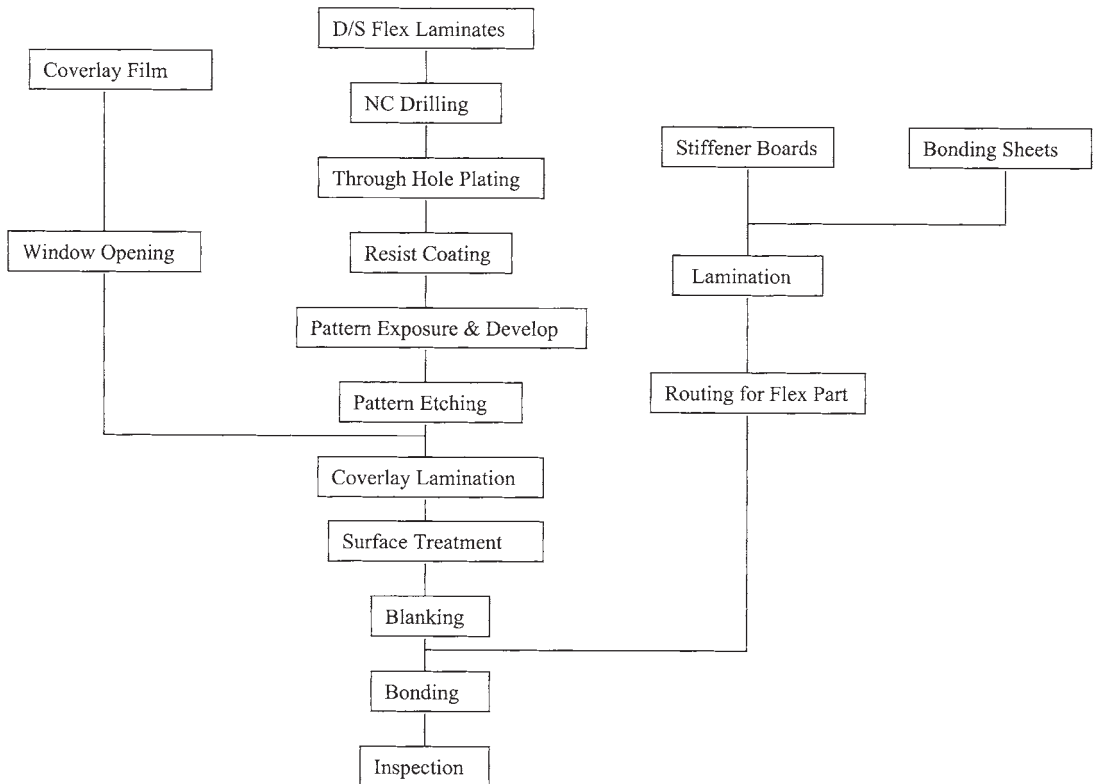

flexible circuits because of new termination technologies. Major items are listed in Table 63.2. Details of the processes are described in each section.

Furthermore, ultra high-density flexible circuits have been considered recently as the necessary substrate materials for the next generation electronics packaging. Their circuit densities will be under 20 micron pitches with 20 micron diameter via holes. They need completely new manufacturing technologies, such as an additive process instead of traditional subtractive process. Ultra high-density flexible circuits will be considered separately.

### 63.3 BASIC PROCESS ELEMENTS

Figure 63.1 shows the basic idea of the standard manufacturing process flow for double-sided flexible circuits, with both through-holes and stiffener boards. Basically, most of the manufacturing processes for single-sided flexible circuits are included in these processes. The first half of the manufacturing process (through pattern etching) has few choices, and the automation of the processes are relatively easy. However, the second half has many options, depending on the design of the construction. The second half consumes more labors because of the difficulties of the automation, and its manufacturing cost per unit area is much higher than that of the first half. An appropriate consideration of process design should be conducted to increase the productivity and reduce the total cost. Good process design can reduce the total cost significantly, especially for complicated constructions. Typical ideas are introduced in the following sections.

**FIGURE 63.1** Standard manufacturing flow for double-sided flexible circuits.

#### 63.3.1 Preparation of Materials

Most of the major materials for flexible circuits, such as copper laminates and coverlay films, are supplied in rolled form. The first process of manufacturing is to slit and cut the rolled materials into workable sizes. It is possible to cut with a manual shearing tool; however, an automatic machine is recommended to get an exact size without handling damage.

Cleaning processes for the copper foil surfaces of single-sided circuits should be conducted prior to cutting if roll-to-roll processing is available. A chemical etching system and soft brushing systems are recommended to use to reduce the scratches on the copper foils and mechanical stress on the thin substrate films. This could reduce handling damage and increase the manufacturing yield significantly.

### 63.3.2 Direct Cast Processes

For special substrate constructions such as ultra thin substrates or ultra-high-density flexible circuits, a direct casting process of polyimide resin has been developed instead of polyimide films. A photosensitive polyimide varnish is sometimes coated on a carrier stainless foil. Then an electroless and an electro copper layer are plated as the thin conductor layer. The casting process with photo-sensitive polyimide varnish is also available as a reliable coverlay of the HDI flexible circuits. The technology of the direct casting is valuable to build multi-layer constructions by semi-additive process. (See Sec. 63.4.2.) A special surface treatment on the polyimide is required for good bond strength. The thin copper layer is then etched to generate fine traces. Finally, the carrier tape is removed for flexibility. Sometimes the carrier tape is partially etched and kept as a stiffener.

### 63.3.3 Mechanical Generation of Through-Holes

There may be several different processes for each via hole construction in the case of flexible circuits. Suitable processes, including material combination, should be designed according to final requirements (for example, construction, circuit density, reliability, manufacturing volume, available equipment, urgency, and so on)

Figure 63.2 shows standard manufacturing processes of the through holes for the double-sided flexible circuits. A mechanical numerically controlled (NC) drilling process on double-sided flexible circuits can be done similarly to that used for rigid double-sided printed circuit boards. More laminates can be stacked up in the setup because of the thin materials.

**FIGURE 63.2** Standard manufacturing process for microvia holes in double-sided flexible circuits starting with copper clad laminate (CCL). The hole is created by drilling and then copper plated.

However, appropriate backing boards and drilling conditions should be determined to achieve good hole quality. A suitable combination of the NC drilling machine and drilling bit can generate smaller holes than 100 microns diameter.

A punching process with a suitable die set is available for the thin, flexible copper laminate.

It can provide a low-cost solution, but it needs a large-volume production to compensate for the high-cost die. A small-diameter punching process controlled by an NC system is available for thin, flexible copper-clad laminates instead of using the NC drilling process. A sharp punching die set can generate smaller holes than 100 microns on thin flexible copper laminates with high through-put. Another advantage of the punching process is that it has a relatively easy applicability to RTR process. These mechanical hole-generation processes cannot make blind via holes on double-sided flex circuits.

### 63.3.4 Through-Hole Plating

Through-hole plating processes similar to those used in rigid board fabrication are available for thin, flexible circuits. Usually, a mild cleaning process is applied prior to the chemical plating process because of thin base layers and relatively small smear amounts. Both standard electroless (chemical), copper-plating processes, and direct copper-plating processes with conductive carbon paste have been established for the seed layer in the holes. Then, suitable thickness copper is plated electrically for whole surface of the panels. Generally, a thinner plated copper conductor than a typical 20 micron version is recommended to maintain the flexibility of the circuits. A thicker copper plating than 25 micron is recommended to have good reliability. Selective copper plating with suitable masking is required for dynamic flexing circuits. Precise thickness control of the through-hole copper is required, because the electrically plated copper does not deposit uniformly on the surface of the original copper foil if the raw material sheet is not fixed exactly on a fixture. Good design of fixtures and electrodes in the plating process is critical for achieving uniform copper thickness, because a thin, flexible sheet flops by agitation in the plating bath. As a result, it is not easy to achieve very uniform copper thickness for large panels. Non-uniform plated copper will cause a lower etching yield and reduce through-hole reliability, especially for small pitch traces.

As an adhesiveless copper-clad laminate does not have low-heat-resistant layers such as epoxy or acrylic resin, it provides excellent through-shapes without de-smearing processes.

Figure 63.3 shows a comparison of a hole plated with an adhesive-based laminate and a hole plated with adhesiveless laminate. The adhesiveless laminate provides a sharp through hole shape compared to the traditional laminate with adhesives.

**FIGURE 63.3** (a) Cross section of through-hole of a double-sided circuit with adhesive-based laminate. (b) Cross section of through-hole of a double-sided circuit with adhesiveless base laminate.

### 63.3.5 Microvia Hole Processes

Micro via hole generation can be one of the critical items in the building of high-density flexible circuits. Figure 63.4 shows standard manufacturing processes for micro via holes, including blind via holes for double-sided flexible circuits. Several new technologies have been developed for micro hole generation on thin polyimide dielectric layers, as shown in Table 63.3.

**63.3.5.1 Mechanical Microvia Hole Creation.** The newly developed NC drilling machine can generate micro via holes smaller than  $100\ \mu\text{m}$  in diameter using special drill bits. Technically, the newest NC drilling system can generate  $50\text{-}\mu\text{m}$ -diameter holes on  $50\text{-}\mu\text{m}$ -thick flexible copper laminates. However, it can drill fewer sheets in a stack than larger holes with slower speeds, and its productivity becomes smaller with smaller hole sizes. An NC micro hole-punching system can also generate micro holes smaller than  $70\ \mu\text{m}$  in diameter on  $25\text{-}\mu\text{m}$ -thick polyimide base flexible copper laminates. It has lower productivity issues to the NC drilling machines; however, multiple punch die systems can increase productivity significantly. A roll-to-roll (RTR) capability is another benefit of the NC micro hole punching.

**FIGURE 63.4** Basic high density circuit generation process by subtractive process.

**TABLE 63.3** Comparison of Technologies for Hole Generation on Dielectric Layers

	Drilling	Punching	Laser drilling	Plasma etching	Chemical etching	Photo polymer process
Hole diameter ( $\mu\text{m}$ )	~50	~70	~10	~70	~70	~70

TH for multilayer	Yes	No	Possible	No	No	No
Blind via hole	No	No	Yes	Yes	Yes	Yes
Material choice	Wide	Wide	Wide	Fair	Small	Small
Technical flexibility	Small	Small	High	Fair	Small	Small
Chemical waste	No	No	Small	Small	Serious	Fair
RTR availability	No	Possible	Possible	Difficult	Possible	Possible

**63.3.5.2 Laser Microvia Hole Creation.** Several laser systems have been developed to generate microvia holes for flexible circuits. The excimer laser has a wide capability to generate small holes on most organic substrates. It can generate holes 10  $\mu\text{m}$  in diameter on 25- $\mu\text{m}$  thick polyimide film, as shown in Fig. 63.5. The largest issue with the excimer laser is its slow speed. Appropriate process design is necessary to achieve a good productivity.

**FIGURE 63.5** Micro-blind vias drilled by different lasers. (a) Excimer laser, plated hole diameter 25 ‘micrometer’ (b) YAG laser, plated hole diameter 20 micrometer, (c) Carbon dioxide laser, plated hole diameter 100 micrometer. (Source: *Photo Machining*.)

The UV:YAG laser is another choice for generating microvia holes smaller than 50  $\mu\text{m}$  in diameter on flexible materials. It has a higher productivity rate than the excimer laser. It can drill through both copper foil and flexible substrates. An issue with the UV:YAG laser is that it takes a long time to generate large holes.

The carbon dioxide laser has greater productivity than the excimer laser or the UV:YAG laser when used to generate via holes larger than 60  $\mu\text{m}$  in diameter; however, it cannot drill through copper foil directly. As a result, a black surface treatment is required on the thin copper foils before the laser operation. (See Fig. 63.6) Comparisons of the technical capabilities of these micro via processes of the laser systems are shown in Table 63.4.

Another major advantage of the laser via generation systems is RTR capability compared to the traditional mechanical NC drilling systems for the volume production of the double-side flexible circuits. It needs some modifications and loader and un-loader for the RTR systems for the standard laser equipment. Several laser systems are available for RTR process.

**FIGURE 63.6** Microvia holes 50 micrometer in diameter created by carbon dioxide laser. (a) through hole, (b) blind via. (Source: Photo Machining.)

**TABLE 63.4** Technical Capabilities of Microvia Hole Technologies for Double-Sided Flex Circuits

	Excimer	UV:YAG	Carbon dioxide	Plasma etch	Chemical etch
Hole size ( $\mu\text{m}$ )					
For small volume	~10	~15	~50	~70	~50
For large volume	25–150	25–75	75–250	~100	~75

Technical hurdles	Low	Low	Fair	High	High
Cost	High	High	Fair	Low	Low

For only specific polyimide resins.

**63.3.5.3 Conformal masks for Microvia Generation.**

Mostly, the laser systems are capable for the drilling for both of base films and copper foils of the flexible laminates. It is possible to make microvia holes through copper foils by the same machine in one process. However, the drilling speeds on the copper foils by lasers are remarkably lower compared to organic base films. Therefore, the conformal mask systems with copper foils are recommended to use for the volume productions with a large numbers of the holes in a unit area. The basic process is illustrated in Fig. 63.7. Firstly, small holes are generated on the copper foils by standard photolithography and etching process. The holes generated on the copper foils work as the masks for the laser drilling process. A slightly larger laser beam is irradiated on each opening of the copper foil, and the organic layers under the opening are engraved effectively.

**FIGURE 63.7** Conformal mask system for laser drilling.

To optimize the productivity of the laser drilling process, blind via hole structures are recommended for the high density flexible circuits.

**FIGURE 63.8** Microvia generated by plasma etching. The hole diameter is 200 micrometers.

The basic idea of the conformal mask is applicable for the plasma and chemical etching introduced in the following section.

**63.3.5.4 Plasma and Chemical Microvia Hole Creation.** Plasma etching and chemical etching are the unique processes used to generate micro via holes on flexible circuit materials (see Figs. 63.8 and 63.9). Both can generate micro via holes smaller than  $100\ \mu\text{m}$  in diameter on  $50\text{-}\mu\text{m}$ -thick polyimide substrates. Plasma processes can etch all kinds of organic materials, but standard alkaline etching can etch only specific polyimide materials such as Kapton™ or Apical™. Special strong chemicals are needed to etch Upilex™-type chemically stable polyimide substrates, which have high dimensional stability. Processing costs of plasma processes and chemical processes do not depend on the number of holes or sizes in a unit area.

**FIGURE 63.9** Microvia holes made by chemical etching. The hole diameter is 40 micrometers. (Source: Asahi Fine Technology.)

They have a remarkably lower cost than laser processes, if there are many holes in the same area. On the other hand, they have several disadvantages. Generally, there are many parameters that affect process capabilities. An exact process conditioning is required for each construction of the flexible circuit.

Chemical etching is a convenient technology to apply to a reel-to-reel manufacturing system. It takes a large investment to introduce a reel-to-reel system for plasma etching system.

Waste treatment is another issue, especially in the case of wet chemical etching. The used etching solution for this process should be treated separately from the other chemical waste used for the wet process in the manufacturing lines.

Capabilities to process materials of each technology are shown in Fig. 63.10 and Table 63.5.

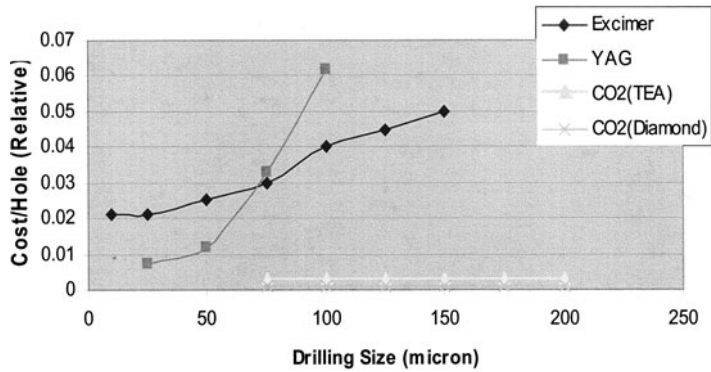

FIGURE 63.10 Microvia hole capabilities of the technologies.

TABLE 63.5 Material Availability

	Punching and drilling	Excimer laser	UV:YAG laser	Carbon dioxide laser	Plasma etching	Chemical etching
Copper	Yes	Slow	Slow	No	No	Yes

Espanex	Yes	Yes	Yes	Yes	Yes	Difficult
NeoFlex	Yes	Yes	Yes	Yes	Yes	Difficult

Figure 63.11 shows examples of the cost comparison of the technologies for micro-through holes on 50- $\mu\text{m}$  polyimide substrates. Figure 63.11(a) shows cost comparison of micro-size NC drilling versus the excimer laser and UV:YAG laser. NC drilling cost is inversely proportional to hole size. A conventional NC drilling process has small advantages over laser processes for holes smaller than 200  $\mu\text{m}$  in diameter. Figure 63.11(b) shows a cost comparison of different laser systems. The UV:YAG laser is cost-advantageous in the 25- to 75- $\mu\text{m}$  hole diameter range. However, its cost increases exponentially with hole size, especially for holes larger than 75- $\mu\text{m}$  in diameter. The cost of the excimer laser process is more stable. It is proportional to

**FIGURE 63.11** Relative cost comparison by hole creation technology, (a): Comparison of NC drilling cost in Excimer and YAG lasers, (b): Comparison of alternative laser processes (c): Comparison of NC laser, plasma, and chemical etch.

hole sizes in the 20- to 200- $\mu\text{m}$  diameter range. Carbon dioxide lasers show extremely lower drilling cost than the excimer laser and UV:YAG laser for the holes larger than 75  $\mu\text{m}$  in diameter. It is very possible to generate more than 10,000 holes, 100  $\mu\text{m}$  in diameter, in 1 min with the Galvano mirror. This is a Diamond Carbon Dioxide Laser System™ that has higher productivity than a traditional carbon dioxide TEA laser system.

Figure 63.11(c) shows a drilling cost analysis of a plasma etching system and a chemical etching system as compared to a laser system or an NC drilling system. A unique cost feature of the etching procedure is that it does not depend on the number of holes or shapes, but on area sizes. Therefore, there are big cost advantages for circuits that have a large number of holes in a small area.

### 63.3.6 Wet Processes for the Flexible Materials

The conveyer systems of the wet processes designed for rigid circuit boards do not work properly for thin flexible materials. They can't make a high process yield generating a lot of wrinkles or scratches, even though the flexible sheet is fixed on a leader board or carrier frame. Appropriated conveyer system should be introduced for the volume production lines of the thin flexible circuits.

Several new ideas have been introduced to convey the thin flexible materials in the wet manufacturing processes. Large diameter conveyer rings with smooth surface have been employed to reduce the scratches on the soft thin copper foil surface. Smaller ring pitches, for both line direction and transverse direction, results in an overlapped conveyer system, which avoids the drop down between the rings and winding of the thin materials on conveyer rolls. Strings and thin bars between the conveyer rings are not recommended to use. These devices make small scratches on the soft thin copper surface, as shown in Fig. 63.12.

**FIGURE 63.12** Special wheel conveyor system for thin, flexible materials showing high density and smooth wheels. (Source: Camellia.)

It looks like a conflict to have a stable conveyor and an effective spray of the liquids, therefore synchronized spray array with mild pressure are required to optimize the condition. A high spray pressure makes fluttering and partial distortion for the thin materials especially after etching.

Standard wet processing machines are designed to process both single side and double side circuits. Well-controlled soft rubber rolls are recommended for the conveyers of the RTR wet manufacturing process to avoid damage to the circuit surface.

### 63.3.7 Surface Cleaning

A pre-cleaning process is required to remove the stains and oxidations on the surface of the copper foils prior to the coating of photo resist materials. Several adhesiveless laminates have extremely shiny copper surface, therefore the chemical cleaning has an important function in making a better affinity with the etching resist, especially for the fine trace etching.

A mild chemical cleaning process, such as organic acid solution, should be applied for thin flexible materials for eliminating serious mechanical damages. Soft scrubbing or soft brushing must be used when a mechanical process is necessary to remove tough stains or oxidation on the copper surface. A severe mechanical brushing will produce mechanical stress on the thin materials and will cause the loss of dimensional uniformity. A soft brushing process on a belt conveyor has been developed to minimize mechanical damage to flexible materials. This process works only for one side of the laminates, therefore a two-step process is required for the double-side laminates.

### 63.3.8 Resist Coating

The same etching resist inks used for rigid circuit boards and screen printers are available for flexible circuits. These inks allow for relatively rough pattern etching with large volume. Also, similar dry films and laminators, designed for rigid boards, could be used for flexible circuits. RTR is can be available adding rolled loader and unloader. However, flexible dry films with a high etching yield should be selected. A tenting method with relatively thick dry films is used for the double-side circuits with standard size through holes.

A thinner dry film is recommended for the single-side circuits, especially for fine patterns. Dry films 15 or 20  $\mu\text{m}$  thick can generate 30- to 40- $\mu\text{m}$  lines/spaces on 12- $\mu\text{m}$ -thick copper foils with a high yield. A liquid photo resist should be used for very-high-density traces with pitches smaller than 40  $\mu\text{m}$ .

### 63.3.9 Pattern Generation

Similar exposure equipment is available for flexible circuits. A collimated light source machine is recommended for high-density traces with pitches smaller than 50  $\mu\text{m}$  to achieve a high yield.

An appropriate matching tool for flexible materials should be developed in order to achieve good pattern alignment with high productivity. Suitable auto alignment systems with CCD cameras have been introduced to minimize the pattern shift from the via holes generated previously. Because of the dimensional changes in the previous mechanical and wet processes, appropriate dimensional corrections are required for the photo masks. A glass mask is required for tracers finer than 50 microns pitches instead of polyester base film masks. A set of reliable mask holder is required to keep the heavy glass masks in the machines. An exact alignment between top mask and bottom mask is required for the high density double-side flexible circuits.

Sometimes, partial dimensional corrections are required to adjust the distortions of the thin flexible materials. A higher alignment accuracy than  $\pm 10$  microns is required for the finer pitched than 50 microns. The easiest way for the dimensional correction is to reduce the panel sizes. But it reduces the process productivity. An alternative method is a step-and-repeat imaging with a small exposure area on a large panel.

It is possible to make a corrected photo mask for the imaging process in order to minimize the misalignment. Unfortunately, the distortion of the flexible laminate is unstable, sometimes, it needs to generate the corrected masks for each job lot. It asks the material to stay beside the exposure machine until the right mask is ready.

Laser direct imaging equipment (LDI) is capable of making the dimensional corrections for the serious distortions of the unstable flexible materials promptly. It provides a high productivity for the prototype or middle volume productions. On the other hand, it is not very capable for traces finer than 25 microns lines and spaces. Lower throughput compared to traditional exposure machines, especially for double-side imaging, is the barrier for the volume productions.

### 63.3.10 Etching

Ferric chloride or cupric chloride solution is recommended for use as the etching chemicals for flexible circuits, especially for high-density circuits. An alkaline solution has a higher process speed, but is not good on fine circuits because of unstable etching rates. As an alkaline solution makes some chemical attacks on polyimide surfaces, it should not be used for fine line requirements.

There are appropriate correction factors for the etching rates of each combination. Between conductors, patterns, thickness, and etching, solutions should be introduced for the photo masks, based on the actual trials, especially for the multiple parallel fine lines very common to high density flexible circuits. Usually, there are remarkable differences in etching factors between middle conductors and edge conductors, as shown in Fig. 63.13.

A set of dummy conductor patterns helps to minimize the difference of the etching factors.

**FIGURE 63.13** Pattern correction for the etching factors (a) Unacceptable (b) Preferred.

## 63.4 NEW PROCESSES FOR FINE TRACES

The generation of fine lines is the most basic process in building high-density flexible circuits. Three basic manufacturing concepts have been developed:

1. Advanced subtractive
2. Semi-additive
3. Full-additive

These methods have many variations to cover different construction concepts and specifications.

Innovative technologies have been developed for each unit process, such as the collimated light source exposure machine and the laser direct imaging system.

### 63.4.1 Advanced Subtractive Process

The subtractive (etching) process is the most common technology for generating copper-based circuitry on flexible film substrates. It is basically the same method used for rigid boards, but there are several differences in the process. An example is that it may be automated for use with a roll-to-roll process.

Subtractive technology with traditional equipment and materials cannot produce high-density traces with pitches smaller than 150 μm. However, many new technologies have been introduced for each key item, as shown in Table 63.6. The most advanced subtractive process with adhesiveless laminates can generate 30-μm-pitch traces on 9-μm copper foil for the single-side circuits using roll-to-roll manufacturing systems. A 50 micron pitch trace circuit is shown in Fig. 63.14 .

**TABLE 63.6** New Technologies Needed to Generate Fine-Line Traces on Flexible Substrates

Processes	New technologies
Surface treatment	New soft etching chemicals (organic) Sputtering of seed layer
Resist coating	High-resolution liquid etching resist and plating resist (spray coater, dipping coater, etc.) Thin dry film (~15 μm) High-sensitivity dry film with high resolution (10 mJ/cm <sup>2</sup> ) Wet laminator
Exposure	Collimated light source with glass mask (~15-μm line/space) Autoalignment system for double-sided circuits (with accurate dimension compensation system, ~5 μm) Roll-to-roll conveyor system with low tension Laser direct imaging system (30–40 μm line/space)
Etching	High-resolution etchant (cupric chloride, ferric chloride)

It is possible to produce 20-μm-pitch traces by subtractive process (as shown in Fig. 63.15), but the process will have relatively low yields.. The advanced subtractive process can produce 60-μm-pitch traces on double-sided flexible circuits with thin copper foil plated to 20-μm-thick.

Processes New technologies Surface treatment New soft etching chemicals (organic) Sputtering of seed layer Resist coating High-resolution liquid etching resist and plating resist (spray coater, dipping coater, etc.)

**FIGURE 63.15** Twenty micron pitch traces made by advanced subtractive process. (*DKN Research.*)

### 63.4.2 Semi-Additive Processes

The first candidate to produce fine traces instead of subtractive process could be the semi-additive process. Several kinds of semi-additive processes—including thin copper laminates and sputtering—were developed to generate fine-line traces on specific polyimide substrate materials. An advantage of these processes is that the conductor layers can have

varying thicknesses. Both processes create suitable electroless plating processes to achieve reliable bond strength on the substrates.

The first idea of the semi-additive process is that the chemical and electrical deposition makes the copper layers after the drilling on the plain base film followed by traditional imaging and etching process as illustrated in Fig. 63.16.

**FIGURE 63.16** Basic high density circuit generation process flow for semi-additive method, (a) Plain film substrate, (b) Drilling via holes and plating of copper layers, (c) Etching of copper layer.

The thin copper laminate process does not need special technology such as sputtering, therefore it is relatively easy to design the manufacturing process. Figure 63.17 illustrates a typical manufacturing process for the double-side circuits.

1. It starts from double-side laminates with very thin copper layers.
2. The first step is drilling to form the via holes. Most of the drilling technologies are available to generate the small holes. Mechanical process including micro punching works for larger holes than 60 microns diameters. Chemical etching and plasma etching could be the low cost solutions for the high hole counts designs. But they need supplemental photolithography and copper etching process. Excimer laser and UV YAG laser are capable to generate smaller holes than 50 micron diameters for both through holes and blind via holes.
3. Copper layers are plated on the whole surface to build the conductive layer in the via holes, by both electroless and electrolytic processes, using, standard copper plating process. It is important that the processes are controlled well enough to make the thin copper layers with uniform thickness.
4. A negative pattern of conductor traces for the plating resist is formed on the copper surface by a high-resolution photolithography process.
5. Further electro plating is conducted to build the required copper thickness. The plating conditions should be well controlled to have a uniform thickness for whole circuits. A smaller panel size is recommended for an easy control of the plating conditions.
6. The plating resist is removed by standard stripping process.
7. As the final process, the seed layers between the conductor traces are removed by appropriate etching process. A supplemental metal plating is conducted as the protection layer for the process, prior to the stripping process of the plating resist.

**FIGURE 63.17** Semi-additive process with thin copper laminates.

**FIGURE 63.18** Twenty micron traces on double sided flexible circuits made by semi-additive process.

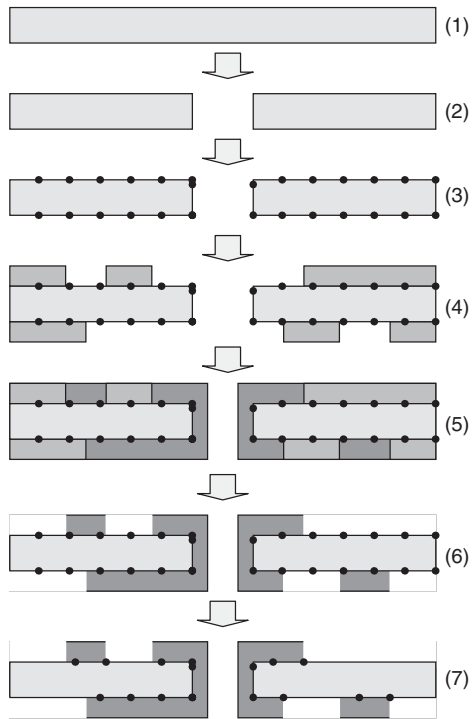

Figure 63.18 and Fig. 63.19 show examples made by the semi-additive process.

The sputtering process has been developed to have thin seed layer for the semi-additive process with finer trace densities as shown in Fig. 63.20.

**FIGURE 63.19** Fifteen micron traces with 20 micron holes for 10 layer circuits. (Source: MicroCommex.)

**FIGURE 63.20** Semi-additive process with sputtering.

1. Because it's a plain plastic film, polyimide film is typically the starting material for the manufacturing process.
2. The small size holes are generated by mechanical processes or laser process. It needs supplemental photolithography process to use chemical etching and plasma etching for this process.
3. A set of sputtering processes is employed to form the electrically conductive thin seed layer, typically thinner than one micron. To have a reliable bond strength between organic layers and conductors, appropriate conditioning including surface treatment should be conducted.

The following processes are used for plating resist formation:

- Electro-forming of the copper conductors
- Stripping of the plating resist
- Etching of the seed layers
- A process that is basically the same as the previous semi-additive process, but is able to provide finer pitches with higher aspect ratios because of extremely thin seed layers. An optimized condition of the process can produce smaller than 5 micron pitches and larger aspect ratios than 1:5.

Figure 63.21 shows two examples of fine trace produced by sputtering/electro-forming process.

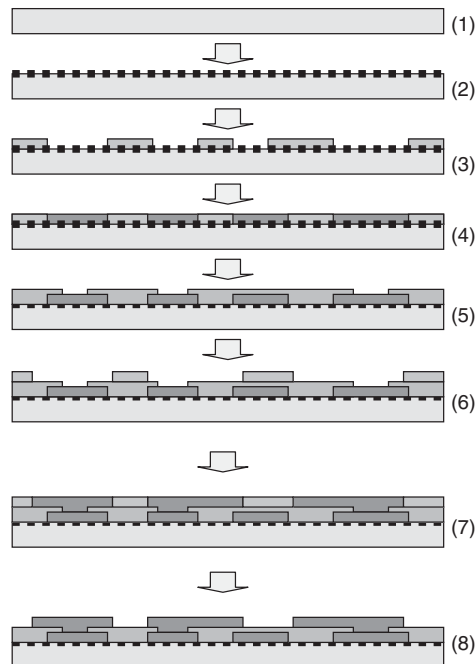

**FIGURE 63.21** Ultra thin patterns made by semi-additive process with sputtering, (a) Ten micron pitch traces with one micron thick trace, (b) Ten micron wide traces with 25 micron thick traces. (*Dynamic Research.*)

A combination of the semi-additive process with a casting technology of the polyimide resin provides a capability to build multi-layer constructions with ultra fine traces and micro via holes. But the layer constructions and the manufacturing process could be very different from the traditional flex circuits. The manufacturing process starts from the preparation of the base layer. A commercialized polyimide film is available as the starting material for the process.

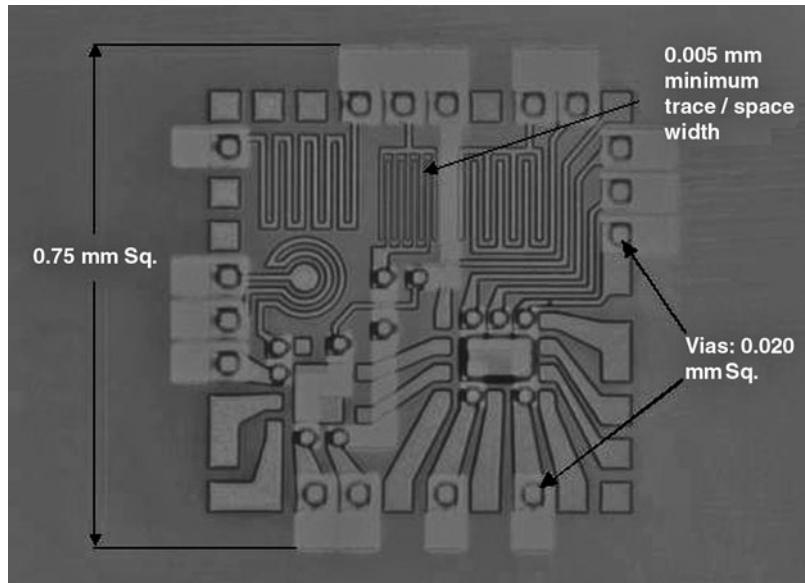

A casting of the liquid polyimide on a suitable carrier plate is another choice to have a thinner base layer than 12 microns. A glass or a stainless steel plate is recommended to use to manage the dimensions stable.

1. A seed layer is formed on the base layer by a series of sputtering processes.
2. A negative pattern of conductor traces is formed with plating resist by a high resolution photolithography process. The selection of the photo resist could be the key of the technology. A spin coating of the liquid photo resist is recommended for the high resolution.
3. An electrical forming of copper or other suitable metals is conducted to generate the fine conductor traces with necessary aspect ratios.
4. A set of process for stripping and etching of the seed layer between conductor traces is conducted to have isolated circuits. A gold plating on the conductors prior to the stripping process is recommended for the chemical protection of the traces.
5. A polyimide resin is coated on the circuits as the insulation layer for the next conductor layer. A photo-sensitive polyimide resin is recommended to coat to generate via holes by photolithography process. A combination of non-photo sensitive polyimide and Excimer laser is another choice. It has a flexible capability to form reliable insulation layers. But its productivity is low and processing cost per unit area is relatively high.
6. The second seed layer is formed by the same sputtering process as shown previously in process 2. A difference is that the thin seed layer have to cover the different surfaces in the via holes.
7. The same processes of photolithography of plating resist, electro forming of the conductors, stripping of the resist and etching of seed layer are conducted to build the second conductor layer.

An example of the processes is illustrated in Fig. 63.22.

**FIGURE 63.22** Semi-additive process with polyimide (PI) casting.

**FIGURE 63.23** Ten micron pitch with 20 micron diameter via holes on the three layer flexible circuits made by semi-additive process with casting. (Source: *Dynamic Reaserch.*)

The same processes can be repeated to form more conductor layers. Figure 63.23 shows an example of ultra high density multi-layer flexible circuits with 10 micron pitch and 20 micron diameter via holes.

### 63.4.3 Fully Additive Processes

Several full-additive processes that can produce extremely fine traces on flexible substrate materials have been developed.

Several combinations of chemical deposition process of the conductor materials and photo-sensitive resists have been tried. Unfortunately, there is no good combination that satisfies the needs for both high-resolutions and physical performances. Further improvement is required to have practical high density flexible circuits.

Screen-printing has had a remarkable progress to generate fine resolutions. An appropriate combination of the screen printer and screen mask can provide smaller pitch traces than 20 microns as shown in Fig. 63.24. It could be the low cost solution for the volume production for the high density flexible circuits. The process is capable for both conductor materials and insulation materials. A screen printable conductive material could be the key of the process.

### 63.4.4 Process Comparison

A comparison of the fine line generation technologies is shown in Fig. 63.25. The advanced subtractive process can provide the best cost-performance solution when building a high-density circuit at pitches larger than 30  $\mu\text{m}$  for single-side circuits and 50  $\mu\text{m}$  for double-side circuits. The process does not need very different technologies from the traditional etching process, therefore the technical hurdles are relatively low and it minimizes the investment for the manufacturing equipment.

**FIGURE 63.24** Twenty micron pitch traces made by advanced screen-printing process. (Source: Micro Tech.)

**FIGURE 63.25** Total high density capabilities of the process.

Semi-additive process with thin copper laminates will provide reliable solutions to produce the fine line generation down to 20 micron pitches with 40 microns via holes for both single and double-side circuits. Technical hurdles are relatively low other than the control of the copper plating. The copper thickness of the original laminate is the key to producing finer traces.

Semi-additive process with sputtered seed layers is able to generate the finest traces, all the way down to 5 micron pitches with 10 micron via holes, on a thinner polyimide layers than 10 microns. A well conditioned sputtering is the key to have reliable bond strength for the fine traces. Additionally, a photolithography process with photo-sensitive polyimide resin provides the multi-layer capability with micro-size via holes for the ultra-fine flexible circuits.

It needs some more technical improvement to make the full-additive process with chemical deposition practical. Another full-additive process with high resolution screen printing will be a low cost solution for the 20 micron pitch single-side circuits when appropriate conductor materials are ready to apply. Combinations with the other technologies will create double-side and multi-layer capabilities.

### 63.5 COVERLAY PROCESSES

The coverlay construction of flexible circuits demands another special process. It is very different from the solder mask used for rigid circuit boards. Furthermore, recent high-density flexible circuits need new coverlay technologies. Table 63.7 summarizes the comparison of traditional coverlay technologies and new technologies. Traditional film coverlay has an excellent balance of physical properties and can provide high reliability, especially for long dynamic flexible endurance.

**TABLE 63.7** Coverlay Process Options

	Accuracy (minimum opening)	Reliability (flexing endurance)	Material selection	Equipment/ tooling	Technical hurdles	Cost
Traditional film coverlay	Low (800 $\mu\text{m}$ )	High (long)	PI, PET	NC drill, heat press	Need long experience	High
Film coverlay + laser drilling	High (50 $\mu\text{m}$ )	High (long)	PI, PET	Heat press, laser	Low	High
Screen print liquid ink	Low (600 $\mu\text{m}$ )	Acceptable (short)	Epoxy, PI	Screen printer	Medium	Low
Photoimageable, dry film type	High (80 $\mu\text{m}$ )	Acceptable (short)	Epoxy, PI, acrylic	Laminator, exposure, developer	Medium	Medium
Photoimageable, liquid type	High (80 $\mu\text{m}$ )	Acceptable (short)	Epoxy, PI	Coater, exposure, developer	Relatively high	Low

Unfortunately, it requires very complicated, labor-intensive processes, and it is difficult to introduce automatic manufacturing systems. Another big issue is that the standard film coverlay process cannot make small openings with high dimensional accuracy because of the manual handling of thin film materials.

Fine openings smaller than 200  $\mu\text{m}$  in diameter with high dimensional accuracy and better than 100  $\mu\text{m}$  positioning have been required for flexible circuits that need high-density interconnect (HDI). Examples include SMT of CSP or chip type passive components. Screen printing of flexible ink can provide a low-cost solution for volume production. However, it cannot provide a better solution for small openings with high dimensional accuracy. The technology of photo-imageable coverlay could be the right solution to the problem of having fine openings with high dimensional accuracy along with keeping the cost down by automation. A suitable photo-sensitive material has been in demand to satisfy all of the requirements.

#### 63.5.1 Film Coverlay

A typical coverlay manufacturing process is shown in Fig. 63.26. Generally the same film materials are chosen for the base film and the coverlay film. A B-stage adhesive such as epoxy

**FIGURE 63.26** Lamination process of film coverlay.

or acrylic resin is coated on one side of the film covered with a release sheet. The epoxy-based coverlay films have a short shelf life in the room temperature and must be kept in a refrigerator. Openings for access windows are made by NC drilling or punching with a release sheet. The surface of traces must be cleaned before coverlay lamination takes place. It is difficult to introduce an automation system for the lamination process because the materials are very unstable after window openings are made. Manual alignment is the solution for this process unless the circuit needs an accurate registration higher than  $\pm 0.5$  mm. After the coverlay film is temporarily fixed on the circuit, the adhesive layer is cured in a heat press or autoclave similar as multi-layer rigid boards. A suitable curing condition should be chosen carefully based on the circuit design and material conditions. Epoxy resins change flow properties significantly by thermal aging, even though they are kept at a low temperature; therefore, a detailed conditioning should be performed based on the flow properties of the adhesives. A high flow of the adhesive resin makes good encapsulation of the conductors, but it also causes a squeeze out of the resin in the openings and makes serious stains on the copper traces. On the other hand, a low resin flow causes a poor encapsulation and results low bond strength and air voids beside the traces. The selection of the press pad materials and separation films is another key factor to have good encapsulation and minimum squeeze out of the glue from the edges. A vacuum press or a vacuum autoclave helps to make good encapsulation of the conductors, eliminating voids or air traps beside the traces, especially for a thick copper foil.

It takes more than one and a half hours for the whole heat press cycle to complete the chemical curing reaction of the adhesive resins, therefore the batch size and the lamination equipment have been becoming larger to make the productivity higher. But it makes the process flexibility lower. A quick press system has been developed to have a better flexibility. One set of coverlay films and an etched flexible circuit panel is hold in a small vacuum press for less than two minutes as the preliminary lamination. After that, several numbers of panels are baked in a thermal oven to complete the chemical curing of the adhesive resin. This process needs a special epoxy resin for the adhesives, but it provides a high flexibility for the small volume and prototype productions.

### 63.5.2 Screen-Printing Coverlay

Basically, the same process and the same screen printer are available for applying liquid coverlay materials as a solder mask on rigid circuit boards. The solder mask materials have to have appropriate flexibility to avoid the cracks during the bending. The only difference in the processes is the

handling of the unstable flexible materials. Any vacuum used to fix the material on the printing table should be set to a low value to make the circuit flat without causing damage. A strong vacuum makes many small spots on the coverlay. The post-baking should be conducted with a suitable carrier that can keep the material flat to avoid supplemental damages.

An appropriate ink material and a suitable baking condition must be chosen to minimize the shrinkage of the material and have a uniform flatness (See Fig. 63.27).

### 63.5.3 Photoimageable Coverlay

As photoimageable solder mask systems for rigid circuit boards were developed in the 1980s, similar ideas were tried for flexible circuits. Ideally, fine openings and high dimensional accuracy were expected. Unfortunately, the materials for rigid circuit boards were too brittle for flexible circuits, and therefore new materials were required. Du Pont developed a dry film-type photoimageable coverlay (Pyrulux PC™) and Nippon PolyTech developed a liquid ink-type photoimageable coverlay (NPR-80™) in the early 1990s. These were practically the first materials available for flexible circuits. They had volume applications in automobiles, disk drives, cameras, and so on. There were several problems with early versions, but there have been remarkable improvements, and application areas have expanded. More material manufacturers have been commercializing different materials, and therefore there are more choices nowadays. Reliability performances depend very much on materials and manufacturers. Material selection should be conducted carefully.

There are significant differences in the manufacturing processes between the dry film type and the liquid ink type, as shown in Fig. 63.28. The dry film-type materials are laminated by a vacuum laminator to ensure good encapsulation of conductors. The same laminators designed for dry film-type solder mask are available. Roll-to-roll vacuum laminators have been developed, but have not gained wide acceptance. Some materials are applicable by a simple heat roll laminator, but supplemental processes are required for good encapsulation. These machines are capable to manage both single sided and double-side in one processing. A range of 15 to 30 minutes holding time are recommended to stabilize the photo-imageable resins.

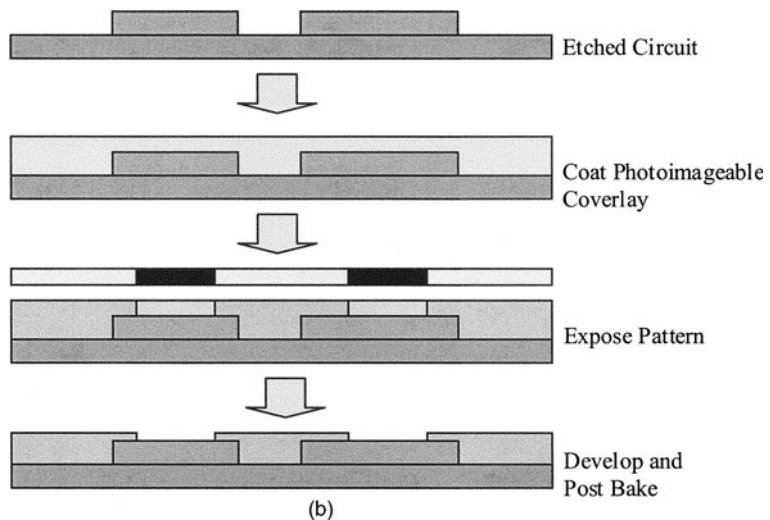

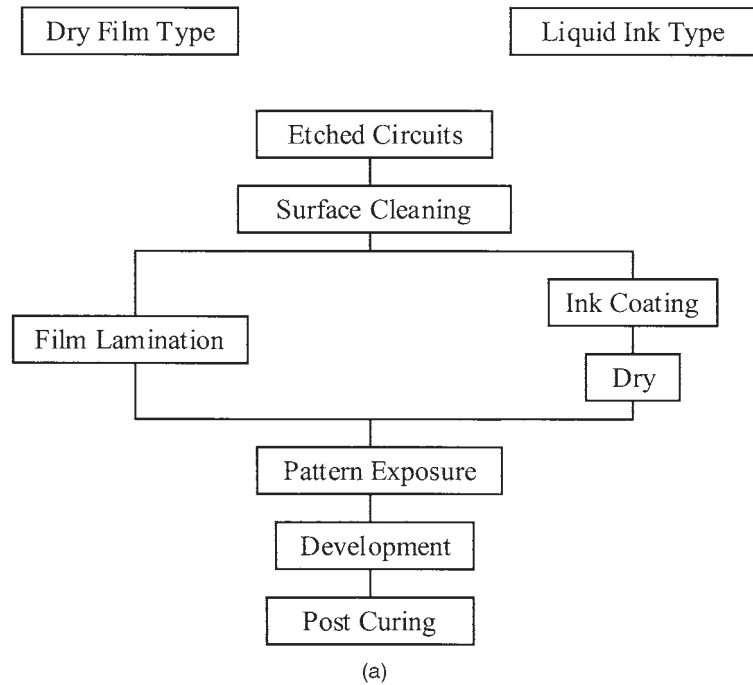

**FIGURE 63.27** Screen print process of liquid ink coverlay.

There are several choices for application processes of liquid ink photoimageable coverlay.

Screen printing could be an easy method for most circuit manufacturers because they have been using the processes and machines for other purposes for a long time. Newly-introduced spray process or curtain coating could be a low-cost solution for volume production. These technologies are relatively easy to apply for RTR process. For pattern imaging, drying is necessary. Therefore, it needs to conduct the process two times for double-side circuits. Several automatic coating machines are designed for the double-side circuits, but they have become very big and have lost the flexibility for the small volume productions.

UV exposure with traditional equipment can be conducted to generate the pattern of window openings. The same chemicals, generally one percent sodium carbonate aqueous

**FIGURE 63.28** An example of a manufacturing process for photoimageable coverlay (a) A schematic flowchart of a generic process using either dry film or liquid resist, (b) A graphic flowchart starting with the etched circuit, showing the manufacturing process for a photoimageable coverlay.

solutions and the same wet lines as etching resist, are available to develop the photo-imageable coverlay.

A half hour post-baking processes for curing is often used for important for good physical performances. Usually, a temperature higher than 150 degrees C is required to achieve 100% curing.

**FIGURE 63.29** Small opening with photoimageable coverlay. Hole diameter is 100 micrometer.

Conventional air ovens or infrared furnaces with appropriate conveyers can be used for the post baking. Figure 63.29 shows a 100 micrometer hole made by photoimageable process.

#### 63.5.4 Laser Drilling on Film Coverlay

Excimer laser drilling of traditional film coverlay can provide a perfect solution for both physical performances and fine openings with high dimensional accuracy. A traditional film coverlay is laminated on the etched traces without pre-punching or drilling. (See Fig. 63.30 for a manufacturing flowchart for laser drilling on film coverlay.) The latest excimer laser system can make sharp 50- $\mu\text{m}$  openings on film coverlay without serious changes of physical

**FIGURE 63.30** Flowchart of process for laser drilling of film coverlay.

**FIGURE 63.31** Small coverlay opening drilled by excimer laser. Hole diameter is 100 micrometer. (Source: Shinozaki.)

properties (Fig. 63.31). It keeps the good mechanical, electrical, and chemical properties of the film coverlay, and the circuits are available for dynamic flexing. The largest issue with this technology is the low productivity and high processing cost. The processing time and cost are proportional to the total size of the opening areas; therefore it could be expensive when there are high-density SMTs. Several new laser systems such as the YAG laser and carbon dioxide laser have been developed to achieve a higher processing speed and higher productivity. A carbon dioxide laser with a Galvano mirror has a speed one order higher than that of an excimer laser, even though engraving quality is worse than that of the excimer laser (Fig. 63.32). It cannot remove organic residue perfectly from copper surfaces, and it requires a supplemental cleaning process such as plasma etching or chemical etching.

**FIGURE 63.32** Small coverlay opening drilled by carbon dioxide laser. Hole diameter is 200 micrometer. (Source: Shinozaki.)

A laser process does not require supplemental tooling such as punching die or photo mask. Also, its initial conditioning is significantly simpler than that for other technologies. Therefore, a laser process could be very valuable for prototype jobs and small-volume quick turnaround jobs.

## 63.6 SURFACE TREATMENT

Electro- and electroless plating of tin, nickel, gold, and solder are common surface treatments for flexible circuits. Solder plating by a hot-air leveler could be a low-cost solution. However, it entails severe high-temperature process conditions, and the poor uniformity of the solder is not acceptable for several applications.

Several new surface finishing technologies have been developed to satisfy the requirements of new termination technologies. A soft nickel/gold plating is the major process for the wire-bonding and flip chip bonding processes. A tin plating is also available for flip chip bonding. A hard nickel/gold plating is applied for the fine pitch pads of ACF termination (Anisotropic Conductive Film) and insertion parts of the FFC connectors. Tin- and lead-free solder plating will be an alternative treatment to traditional solder plating. OSP (Organic Surface Protection) will be a low-cost solution for next-generation soldering eliminating the lead components.

Prior to the surface treatment for the opened conductors, a suitable cleaning process is required to have good plating performances. Sometimes, it needs a strong chemical with mechanical brushing to remove the tough residues and oxidation on the copper surface made by previous processes. Strong alkaline solutions should be eliminated as the cleaning reagents. Several adhesive resins and photo-imageable coverlays have been attacked seriously and they cause de-lamination of the coverlay.

Electro plating is capable to provide a reliable metallic surface treatment controlling the thickness and the surface conditions. It is not difficult to manage the plated metal surface shiny or non-shiny. An issue is the all of the metal pad must be connected to the electrodes. It is not a big issue for the simple cable type flexible circuits, which have mostly parallel lines. But it is an serious issue SMT type circuits what have electrically isolated termination pads. They need supplemental lines for only electro plating, and they should be cut after the process.

Electroless plating has less limitation in its application. The plated metals are deposited uniformly for all bare terminals even though they are electrically isolated. On the other hand, electroless plating process has several limitations to control the thickness and the quality of the plated metals. A long processing time and high cost solutions cause the thick plating expensive. Basically, electroless plating is a kind of chemical reaction in an aqueous solution. Some of the plating solutions are high pH alkaline and they make serious damages for the adhesive layers and coverlay materials.

Micro bump arrays will be constructed by advanced processes. Optimized combinations of plating processes can build many kinds of bump shapes at a reasonable cost (see Table 63.8).

**TABLE 63.8** Surface Treatments of Flexible Circuits

	Materials	Process conditions
Electroplating	Ni, Au, Sn, solder, etc.	Wet process
Electroless plating	Ni, Au, Sn, solder, etc.	Wet process
Hot-air leveling	Solder	>260°C
Solder roll coating	Solder	>260°C
OSP	Organic molecules	Wet process

## 63.7 BLANKING

A punching press similar to those used in the processing of rigid boards could be used for the blanking of flex circuits. Smaller tons are required to cut thin materials. Steel rule dies are the specialty for flex circuits (see Fig. 63.33). They can be prepared in a few days, and their costs are much smaller than those of hard tools. Their weight is also much smaller than that of hard tools and operators can manage them by hand. A typical cross section is shown in Fig. 63.33(a), a finished steel rule die is shown in Fig. 63.33(b), and some limitations on the configurations that can be used are illustrated in Fig. 63.33(c). Steel rule dies have less dimensional accuracy, lower productivity, and a shorter life than hard tools, and they need maintenance more frequently.

They are good at quick-turnaround jobs and small- to medium-volume productions. Table 63.9 shows a comparison.

A hard punching die is recommended for use for high dimensional requirements and large volume production. Zero clearance between the male and female dies is required for thin materials.

**FIGURE 63.33** Steel rule die for blanking flexible circuits (a): A cross section of the configured die, (b): A sample finished die (c): Limitations on shapes that can be designed into a steel rule die.

FIGURE 63.33 Continued.

TABLE 63.9 Comparison of Punching Dies

Items	Steel rule dies	Hard tool dies
Accuracy	~0.2 mm for whole	~0.01 mm for whole
Minimum hole size	3 mm diameter	0.4 mm diameter
Minimum slit width	Zero	0.5 mm
Minimum corner radius	0.5 mm	0.1 mm
Delivery time	2-4 days	More than 3 weeks
Weight	Light, manage by hand	Heavy, need a lift
Tooling cost	Low	High
Processing cost	High	Low

Special technology and periodical maintenance are needed when zero-clearance punching die sets are used.

Combinations of steel rule dies and hard tool dies are the trend for achieving high productivity and high dimensional accuracy at a low cost. Quick-change die systems are the new trend for high productivity for small-volume productions. An NC routing process is also available for the blanking of flex circuits. However, special backing boards and conditions are required to process unstable flexible materials.

It is very important to have accurate punching guide holes to create good perimeters for flex circuits. Unfortunately, a standard NC drilling machine does not provide accurate positions for each hole in a work sheet because of distortions during the previous manufacturing processes. An appropriate compensation for dimensional changes is necessary for each guide hole. Several punching and drilling machines that have self-alignment systems that use CCD cameras are available to ensure accurate positioning with guide holes. The latest machine has a level of accuracy better than  $\pm 50 \mu\text{m}$  and high productivity based on automatic x-y table. Recently, higher perimeter accuracies have been required for specific areas, such as insertion parts for the small pitch FFC connectors. The auto alignment punching machines designed for the guide holes are modified for the trim punching.

Very different ideas are required to achieve a severe perimeter that allows tight spaces from conductors (smaller than  $50 \mu\text{m}$ ). A laser router that has self-alignment capability could be a possible solution. However, the processing speed is slow and expensive. A chemical etching process for the base could be a low-cost solution for volume production; however, the manufacturing process is very different from a standard process and a special process design is required. Its applicable construction and materials are limited, and suitable design changes are recommended.

### 63.8 STIFFENER PROCESSES

---

Flexible circuits have many supplemental constructions other than electrical traces to optimize their capabilities. The stiffener boards are the major one of them. An issue is that it is difficult to apply full automation to the process of making stiffener boards because of the many varieties. Most of the processes are conducted manually and are labor intensive. Sometimes stiffener boards account for a big percentage of the total manufacturing cost.

An adhesive film is laminated on a rigid board with a release sheet first. The boards are then routed by punching or by NC router. It is a very simple process if the adhesive material is pressure-sensitive adhesives (PSAs). Each piece of stiffener is placed on the flex circuits with appropriate pressure, mostly by hand. The process is more complicated when a thermo-set type adhesive material is required. A temperature higher than  $160^\circ\text{C}$  with a pressure higher than  $20 \text{ kg/cm}^2$  is required for more than 30 min. A similar heat press used for multilayer circuit boards or film coverlay is necessary. Dummy boards should be prepared to make the pressure uniform.

A heat press with a vacuum chamber or autoclave could provide uniform adhesion for irregularly shaped stiffener boards.

### 63.9 PACKAGING

---

Many ideas have been introduced for packaging fragile HDI flex circuits. The packaging should provide easy handling capability, including the processing of the assembling side. A reeled tape modified from TAB technology is a valuable solution for volume production. A sheet carrier is another possible solution for medium- and large-scale production. Reusable cartridge or container designed for each circuit is recommended for volume production.

An appropriate packaging design results a lot of benefit for both flex circuit manufacturers and customers.

It needs a total design of the circuits including their manufacturing and assembling to optimize the productivities.

## 63.10 ROLL-TO-ROLL MANUFACTURING

Roll-to-roll (RTR) manufacturing is a specialty developed for rolled materials of flex circuits.

It can reduce manual handling and defects caused by human errors; therefore, when running effectively, it will increase productivity significantly and reduce manufacturing cost. On the other hand, RTR manufacturing has several serious disadvantages and a lot of applied limitations. It requires a large investment and advanced engineering capabilities. It is not appropriate for small-volume production, and can create a lot of scrap when not set up correctly.

Table 63.10 shows advantages and disadvantages of RTR manufacturing systems for flex circuits. Table 63.11 shows available manufacturing processes and typical examples. Most RTR systems are developed for single-sided flex circuits.

**TABLE 63.10** Advantages and Disadvantages of RTR Systems

Advantages	Disadvantages
<ul style="list-style-type: none"> <li>• High productivity</li> <li>• High process yields</li> <li>• Low manufacturing cost</li> </ul>	<ul style="list-style-type: none"> <li>• Small flexibility for small volume</li> <li>• Much scrap caused by small mistakes</li> <li>• Large investment cost</li> <li>• Limited for quick turnaround</li> <li>• Low flexibility for design changes</li> </ul>

**TABLE 63.11** Availability of RTR Processes

Process	Technical difficulty
Surface cleaning	Standard machines available
Via hole generation	Possible, but difficult
Via hole plating	Big investment
Resist coating	Standard machines available
Pattern generation	Standard machines available
Developing	Standard machines available
Etching/strip resist	Standard machines available
Coverlay	Possible, but difficult
Surface treatments	Standard machines available
Blanking	Possible, but difficult
Inspection	Possible, but difficult
Stiffener boards	Difficult

### 63.10.1 RTR Drilling

There have been significant technical barriers to applying the RTR system for double-sided flex circuit with through-holes. The NC drilling process is the bottleneck in introduction of the RTR system. A punching process, which is basically a continuous-flow process element, is an alternative technology to NC drilling of the RTR system to be used for double-sided flex circuits. However, it requires an expensive punching die and is not flexible for a design change.

An RTR base NC drilling machine has been developed, as shown Fig. 63.34. The machine is capable to generate smaller holes than 100 micron diameters processing multiple rolls in a same time.

**FIGURE 63.34** Reel-to-reel base numerical control drilling machine. (Source: Hitachi Via Mechanics.)

The new via hole technologies such as laser drilling and chemical etching are an innovative solution for generating small holes in rolled materials. A blind-via hole design is preferred for these RTR manufacturing processes.

### 63.10.2 RTR Copper Plating

Technically, RTR copper plating is possible. But the line will be very long, and it is not easy to have uniform quality for the wide rolls. There is a difficult choice which is better vertical system or horizontal process.

### 63.10.3 Pattern Generation

The pattern generation processes of resist coating, photo-print, development, etching and resist stripping are well established for single-side circuits. There are several key points such as straightness of the whole line, EPC (Edge Position Control), etc. Stability of loader/un-loader could be an example. Appropriate stabilities are required for the one-side holding systems of the rolled materials, especially for the wide materials.

There are not many technical difficulties with double-side circuits for we processes such as development or etching. On the other hand, special alignment systems are required between top/bottom and holes/traces.

### 63.10.4 RTR Coverlay Process

After etching process, technical hurdles to apply RTR become extremely higher compared to previous processes because of the difficult alignments between the patterns.

The coverlay process could be the typical example. RTR lamination of film coverlay is almost impossible. The screen-printing for RTR processing has developed for relatively rough circuit patterns. The photo-imageable coverlay system could be the right solution for the RTR process of the coverlay of the flexible circuits. However, there have been several limitations to apply.

### 63.10.5 Other Process

The other processes such as blanking and stiffeners are very difficult except special designs with large volume production.

### 63.10.6 Tape Processing

Manufacturing process of TAB (Tape Automated Bonding) has been developed by reel to reel from the beginning for specific applications. The details of the technology will be considered in Chap. 66.

## 63.11 DIMENSION CONTROL

---

Due to increasing density requirements and inherently unstable film substrate characteristics, dimensional control has become a key issue for both circuit fabricators and their end customers.

In order to achieve such densities while maintaining high production yields, careful dimensional consideration in both the design and manufacturing processes is necessary. An exact concept for dimension control of the whole manufacturing processes is required for high-density flex circuits. There are many factors that impact the dimensional stability of high-density flex circuits. These factors can be categorized as follows:

- Materials
- Circuit design
- Manufacturing processes

### 63.11.1 Materials

Substrate material selection may be the most important item to consider for dimensional control of high-density flex circuits. (For a more detailed discussion of flexible circuit materials, see Chap. 61.)

**63.11.1.1 Polyimide.** Kapton H<sup>TM</sup> and Apical AV<sup>TM</sup> are standard substrate materials for traditional flexible circuits. Unfortunately, these films have high moisture absorption rates, which create excessive dimensional instability, making them unsuitable for high-density flexible circuits.

Several newer polyimide films such as Upilex S<sup>TM</sup>, Kapton E<sup>TM</sup>, and Apical NP<sup>TM</sup> and FP<sup>TM</sup> have been commercialized to satisfy the requirements for increased dimensional stability.

A comparison of these base materials is shown in Table 63.8. Although these new polyimide materials have lower moisture absorption and CTEs than traditional polyimide films, their dimensional change is still not zero. In addition, process variations of 0.02 to 0.05 percent are common from batch to batch during film production.

Generally, material manufacturers fabricate polyimide film with a wide web. Special conditioning is necessary to ensure uniform properties for the whole web. Unfortunately, there are usually deviations from one side to another. Because the master roll is slit in halves or thirds according to the customer's convenience, each roll has different mechanical properties depending on its location in the master roll. If the master roll is slit into three rolls, a roll in the middle may have more uniform properties than the others. If the master is slit into two rolls, relatively wide edges will be wasted.

**63.11.1.2 Copper-Clad Laminate.** Most manufacturers of flexible circuits initiate their processes with copper-clad laminates. During production of these laminates, mechanical

stresses are generated (by heat and pressure) that can become locked into the material. These stresses are partially released during the circuit manufacturer's etching operation and a certain amount of dimensional reversion takes place. In actuality, these stresses (or dimensional stability characteristics) differ in the machine direction (MD) vs. the transverse direction (TD). It is therefore important to review all the mechanical stresses in a laminated material and to consider some form of stress relieving prior to circuit fabrication.

IPC-TM-650 recommends a method of testing dimensional stability in a  $9 \times 10$ -in rectangle for both MD and TD. One standard-size test sheet is too small to represent the whole web.

Several samplings are required to evaluate the whole web. Yaw direction changes and local changes of dimensions that cannot be measured by the IPC test method are sometimes critical for high-density flexible circuits. Detailed investigation should be conducted.

**63.11.1.3 Coverlayer Selection.** Coverlayer selection should be considered the second important material factor for controlling dimensional stability. Generally this layer is adhered to the circuitry using heat and pressure, which can induce additional dimensional distortion.

Careful consideration should be taken if effective dimensional stability is to be achieved.

## 63.11.2 Circuit Design

As discussed earlier, most laminate materials undergo mechanical stresses, which generate non-uniform dimensional changes during the etching process. After etching, an etched area with substrate only has different physical properties from a non-etched area with substrate and copper foil. During manufacturing, the laminate materials generate different dimensional changes. A uniform circuit pattern design is necessary to control dimensional stability. A dummy copper pattern in an empty area can help to maintain optimal dimensional stability.

## 63.11.3 Critical Processes for Dimension Control

The critical manufacturing processes for dimensional control of flexible circuits are shown in Tables 63.12 and 63.13. In general, a high temperature or a wet chemical process can alter the dimensions of flexible circuits. Increased mechanical tensions can also impact dimensional control.

The major manufacturing steps for standard double-sided flexible circuits with through-holes are listed here. Each step should be considered carefully to determine its contribution to the overall distortion:

1. *NC drilling* Although NC drilling does not significantly impact the final dimension, certain scale factors based on assumed movements during the following operations may be factored into the drill pattern.
2. *Through-hole plating* Because the electric field in a through-hole plating bath is generally non-uniform, the copper thickness becomes uneven. An extremely thickly plated copper conductor will create mechanical stresses. During the etching process these stresses are released, generating some dimensional changes. In an extreme case, a copper-plated sheet cannot lie flat. An appropriate set of work fixtures and plating electrodes should be designed to create a uniform plating thickness.
3. *Dry film lamination and pattern printing* Due to the relatively low temperature and lack of wet processing (moisture), dry film lamination and pattern printing have little effect on dimensional control. Pattern imaging is, however, an opportunity to apply appropriate dimensional corrections for the following processes.
4. *Etching and stripping of resists* The most critical wet process in flexible circuit manufacturing is etching. Dimensional changes can occur when the by-products of the etching process are combined with the various materials. It is important to identify how to correct

**TABLE 63.12** Key Items for Dimension Control in Flex Circuit Manufacturing

Categories	Key items for dimension control
Materials	Base film, copper, coverlay, bonding material
Design	Layer constructions, circuit density, circuit balance
Manufacturing process	Wet processes, heat processes, mechanically stressed processes

**TABLE 63.13** Critical Processes for Dimensional Control

Process	Category	Importance
NC drilling	Mechanical	Medium
TH plating	Wet and heat	High
Cleaning	Wet and heat	Medium
DF lamination and print	Mechanical	High
Development	Wet and heat	High
Etching and stripping of resist	Wet	High
Coverlay, film lamination	Heat and pressure	High
Coverlay, screen printing	Heat	High
Coverlay, photoimageable	Heat	High
Lamination for multilayer	Heat and pressure	High
Plasma etching	Heat	Medium
HASL	High heat	High
Electro- and electroless plating	Wet and heat	Medium
Baking	Heat	High
RTR process	Mechanical	Medium

Heat means temperatures higher than 80°C.

the various dimensional alterations, particularly as additional factors are incorporated into the process.

5. *Coverlay processes* There are several coverlay processes that have been developed with varying process conditions for different concept materials. Film coverlay undergoes a manufacturing process with a temperature greater than 160°C and a pressure over 20 kg/cm<sup>2</sup>.

Cover coat ink withstands a screen-printing process with a drying temperature higher than 130°C. A newly developed photoimageable coverlay must be baked at over 150°C. The majority of the heat and pressure processes impact dimensional stability significantly. Additional factors, such as press pad heating, make dimensional changes even more complicated. Conditioning should be reviewed in detail for each construction.

6. *Lamination pressing for multilayers* Like the coverlay process, lamination pressing involves high temperature and pressure. Due to the number of layers, however, dimensional changes are more complicated because each level needs to be considered.

## CHAPTER 64

---

# TERMINATION OF FLEXIBLE CIRCUITS

---

**Dominique K. Numakura**

*DKN Research, Haverhill, Massachusetts*

---

### 64.1 INTRODUCTION

---

Major termination technologies for flexible circuits are listed in Table 64.1. Most termination technologies developed for rigid printed circuit boards are available for flex circuits with small modifications. Surface-mount technology (SMT) components can also be assembled through the same processes used for rigid circuit boards, such as standard pick and place and reflow soldering without significant conditioning. The card-edge connectors designed for rigid circuit boards are also available for flex circuits with the addition of suitable stiffener boards. In addition, because of the unique wiring capabilities and special construction of flexible circuits, many specialized termination technologies have been developed for them. These include solder fusing, anisotropic conductive film (ACF) connections, flying-lead direct bonding, dimple contacts, and flat flexible cable (FFC) connectors.

To accommodate the miniaturization of electronic products, many termination technologies have also been developed for high-density interconnect (HDI) flexible circuits. These technologies are key points in the assembly of various electronic components in small spaces, such as cellular phones, miniature liquid crystal displays (LCDs), keypad switches, antennas, connectors, microphones, speakers, battery cases, etc. It is common for several different termination processes to be used in each electronic product. Examples of applications include wireless suspension of disk drives and chip-scale packaging (CSP). These technologies use high-density flexible circuits as the interposers. Multiple special termination capabilities are required for these interposer flexible circuits.

All of the termination technologies of flexible circuits have both advantages and disadvantages.

No technology can satisfy all of the requirements at the same time. In general, flexible circuits have numerous wiring options, and therefore a thorough review of the technologies and the wiring requirements is required to design the appropriate termination.

---

### 64.2 SELECTION OF TERMINATION TECHNOLOGIES

---

To determine the optimal cost-performance combination, one first must establish the requirements from the assembly side and the capability of the termination technologies. Table 64.2 lists the critical items that are required to design a suitable termination.

**TABLE 64.1** Termination Technologies for High-Density Flexible Circuits

Rigid PWB-based	Flexible circuit-based
<ul style="list-style-type: none"> <li>• SMT</li> <li>• COB(chip-on-flex [COF])</li> <li>• Wirebonding</li> <li>• Conductive adhesive</li> <li>• Card-edge connectors</li> <li>• Pair connectors</li> <li>• Flip-chip bonding</li> </ul>	<ul style="list-style-type: none"> <li>• Solder fusing</li> <li>• anisotropic conductive material (ACM) (ACF)</li> <li>• Direct bonding of flying leads</li> <li>• Dimple contact</li> <li>• Microbump contacts</li> <li>• FFC connectors</li> <li>• Nonconductive paste (NCP) bonding</li> <li>• Pressure contact</li> </ul>

**TABLE 64.2** Critical Items in the Design of High-Density Interconnects

Critical Item	Description
Objectives	What kinds of devices?
Termination density	Points per cm or cm <sup>2</sup> Number of connections in the allowed space
Permanent or nonpermanent	Repeated connections or not?
Circumstances used	Temperature, humidity, etc.
Condition processed	Temperature of the application
Reliability	Total performance
Cost	Material and handling

### 64.2.1 Termination Objectives

Several types of electronic components can be attached to flexible circuits. Table 64.3 categorizes these from the termination standpoint, assuming the use of high-density flexible circuits.

**TABLE 64.3** Categories of Electronic Components

Category	Components
SMT devices	Discrete chip components, (BGA), CSP, multichip module (MCM), bare IC chips
Imaging devices	Large flat-panel display (FPD), small FPD, charge coupled device (CCD), linear sensors, 2-D sensors, printers
Wiring devices	Rigid PWB, ceramic-based circuits, flex circuits, cable, wires, connectors
Specialty devices	Keyboards, switches, printer heads, antennas, actuators, sensors, microphones, speakers, chimes

Because of the nature of their use, there are a limited number of locations where imaging devices such as LCDs and CCDs can be placed in electronic products. As a result, there are fewer choices for wiring materials other than flexible circuits. Newer imaging devices have numerous pixels in a limited area, which requires more connections with smaller pitches. In addition, it is often important to place the driver integrated circuit (IC) close to the device. Therefore, a flexible circuit is required for both wiring and chip-on-flex (COF). A large LCD, typically used in a personal computer and flat-panel TV, often needs several tape-automated bonding (TAB) circuits to create the wiring between a rigid board and the LCD device. A flat-panel display can be wired by a single high-density flexible circuit, which reduces the cost of the entire package.

It is common for a flexible circuit to be connected to other circuit boards. However, more traces and a higher density of the connections are then required. The basic design of the end products automatically determines the placement of specialty components such as keyboards, switches, antennas, actuators, printer heads, sensors, microphones, speakers, and buzzers in small electronic applications. Although these components do not require numerous wires, they do need high-density connections due to the extreme miniaturization of portable electronic products.

### 64.2.2 Nonpermanent or Permanent Termination

The permanence of a termination is determined by connection repeatability. For example, if connections are changed regularly, a nonpermanent termination should be utilized. Due to the number of reconnections, inkjet printers and electrical test probes should have nonpermanent terminations. Conversely, if a connection is to remain relatively constant, a permanent termination method should be employed. Termination method capabilities are profiled in Table 64.4.

**TABLE 64.4** Capabilities of Termination

Methods	Permanent or nonpermanent	Termination density
SMT soldering	Permanent	350 $\mu\text{m}$ pitch (2-D)
SMT wire bonding	Permanent	150 $\mu\text{m}$ pitch (4 directions)
Solder fusing	Permanent	150 $\mu\text{m}$ pitch
ACM connection	Permanent	30 $\mu\text{m}$ pitch (100 contacts in 1 $\text{mm}^2$ )
Direct bonding	Permanent	50 $\mu\text{m}$ pitch (1- or 2-D)
Pressure contacts	Non-permanent	20 contacts in 1 $\text{cm}^2$ (1- or 2-D)
Dimple contacts	Non-permanent	20 contacts in 1 $\text{cm}^2$ (1- or 2-D)
FFC connectors	Non-permanent	300 $\mu\text{m}$ pitch (1-D, 1 line)
Pair connectors	Non-permanent	500 $\mu\text{m}$ pitch (1-D, 2 line)
Film connectors	Non-permanent	100 $\mu\text{m}$ pitch (2-D, 100 contacts in 1)

### 64.2.3 Termination Density

To design a suitable termination solution with flexible substrates, one must consider the density and the number of terminations. An overview of each method's termination density is profiled in Table 64.4. Due to higher connection reliability, a contact array can produce more connections than a contact line in the same space with a larger pad pitch. Numerous wires must fit together in a limited space.

#### 64.2.4 Wiring of Imaging Devices

A high-density flex circuit could be the best solution for the wiring of a small imaging device module designed for consumer electronics. In general, these devices have hundreds of pads that need to be connected with COF for the driver IC close to the device. The flex circuit usually requires a long tail to be connected to the other device. Only a high-density flex circuit can satisfy all the requirements as a single circuit. There are several choices in the design of the constructions of the COF area and the bonding area. An adhesiveless clad laminate having a stable substrate with polyimide resin is required to create a high connection yield for a high-resolution device. An anisotropic conductive material (ACM) connection is a low-risk solution because of the low processing temperature. A direct bonding process with fine flying leads can provide reliable connections for COF and wiring with the imaging device. Due to increased temperature, the design requires a higher dimension control.

### 64.3 PERMANENT CONNECTIONS

---

If there is no functional reason to remove the connection during normal operation, a permanent connection is recommended because of the small mounting space and lower costs. Examples of this type of connection include:

- General soldering
- Through-hole leaded components
- General SMT components
- Solder fusing
- Wirebonding
- Direct bonding
- ACM connection
- Flip-chip connection
- NCP connection

#### 64.3.1 Soldering

Soldering is still the most popular and common termination technology for flexible circuits. All kinds of solder and termination materials and equipment are available with suitable tooling guides. Usually, the soldering parts of the flexible circuits have stiffeners on the bottom side of the flexible substrates to make them tough enough to handle high-temperature soldering. However, the other parts of the circuits are still fragile, and appropriate frames or carrier boards have to be prepared to make the flexible circuits stable during the assembling processes, including screen printing, SMT mounting, solder reflow, and cleaning.

If adhesiveless laminates are used as the major materials, high temperatures can be used with lead-free soldering. In the case of SMT assembling, the flexible circuit should be fixed on a carrier frame. This allows it to be processed by the same mounting and soldering equipment as used for rigid boards.

#### 64.3.2 Through-Hole Leaded Components

Often, through-hole leaded electronic components are necessary for specific applications.

Processes similar to those used for single-sided rigid boards are used to attach the components to the flexible material. However, because through-hole leaded components require

**FIGURE 64.1** Examples of direct soldering of flexible circuits (a) Without stiffener, (b) With stiffener.

clinging of the leads and are heavier than SMT components, special fixtures and control are required when placing them on a fragile flexible circuit. This is to minimize mechanical stresses, especially when components are connected by soldering, as shown in Fig. 64.1 (a) and (b). A complicated stiffener system is required for the double-sided assembly of the leaded components on the flexible circuits.

### 64.3.3 SMT General Issues

Most SMT technologies can be used for flexible circuits without significant alteration, as shown in Fig. 64.2. In general, the same circuit design rules can be applied to SMT for a high-density

**FIGURE 64.2** SMT soldering of high density flexible circuits.

**FIGURE 64.3** Mounting of BGA device on flexible circuit.

flexible circuit. A suitable thin stiffener sheet such as 125  $\mu\text{m}$  thick polyimide film should be bonded to support SMT components. Figure 64.3 shows the case of the ball grid array (BGA) component with a thin polyimide stiffener. Adhesiveless copper-clad laminates need to be used as the raw material to withstand the high temperatures of typical lead-free soldering processes. A flexible photoimageable solder mask needs to be applied to cover the fine traces. A special dynamic flexible-grade photoimageable coverlay should be used if the flexible circuit has a portion of repeated flexing. A stiffener of suitable thickness needs to be bonded on the back side

of an SMT area of a thin, single-sided flexible circuit. A thicker substrate layer should be used for double-sided assembly.

An appropriately designed stiffener board can increase assembly productivity without a big cost increase. A larger stiffener board and adhesive sheets are punched beforehand for the preparation of the assembling processes. The stiffener board has extra frame space that contains appropriate guide holes for the convenience of part mounting and soldering. The flexible circuits fixed on the stiffener boards can be managed the same as rigid printed circuit boards in the assembling processes. A standard mounting machine places small SMT components without additional tooling. In addition, the same high-temperature soldering equipment used for reflow soldering in an SMT line can be used here. In-circuit tests are conducted with an aluminum board. As the final process of the assembly, unnecessary parts of the stiffener boards are cut off and the whole circuit is folded to make a part of the module casing. An appropriate seal is made with the other casing parts to protect the module from the outside stress.

### 64.3.4 Solder Fusing

Although solder fusing (Figs. 64.4 and 64.5) is not a new technology for making connections for flex circuits, it is still a low-cost and reliable solution for multi trace connections. There has also been remarkable progress in fine-pitch capability. The newest applicator, coupled with well-controlled solder plating on fine traces of flex circuits, can provide a 150  $\mu\text{m}$  pitch connection

**FIGURE 64.4** Flexible termination by solder fusing.

**FIGURE 64.5** Flexible circuits connected to a rigid board by solder fusing.

with the other circuit pads. A big advantage of the connection is a very low height even though the part is covered with an appropriate protection film. It is also possible to produce 30 connections in a 5 mm square, but high fusing temperatures with lead-free soldering are required. Because traditional adhesive materials such as epoxy or acrylic resin cannot survive the process, adhesiveless laminates need to be used as the major materials.

### 64.3.5 Wirebonding

A wirebonding process similar to COB has been applied for high-density flexible circuits without serious changes. Due to the high heat resistance of new adhesiveless laminates, standard bonding materials and equipment for flexible circuits can be used (see Fig. 64.6).

**FIGURE 64.6** Wire bonding on and HDI board.

**FIGURE 64.7** Direct bonding of flying leads.

Relatively thick soft gold plating with nickel base is required on the copper pads of the flexible circuits. The best combination of the bonding machine and bonding wire with a suitable process condition can make a 40 micron pitch connection between the high-density flexible circuits and the chip device. A relatively thick polyimide film is recommended to attach on the bottom side of the wirebonding area to make it stiff. The wirebonding process could be one of the standard assembly technologies for the COF system. Numerous driver ICs for LCD devices have been assembled by these methods.

### 64.3.6 Direct Bonding

Although flying-lead construction is not a new technology, fine-line traces created direct bonding. When a flying lead has a fine line smaller than  $100\ \mu\text{m}$  wide with nickel-gold plating on it, it can be processed using processes similar to wirebonding of the semiconductors. This can produce high-density, reliable connections between a flexible circuit and another circuit or device. (See Fig. 64.7). The basic idea was developed with TAB, but flexible circuits expand the capabilities and applicable areas. The small pitch direct bonding is used to assemble specific devices such as the magnetic heads of the hard disk drives and the semiconductor chip of inkjet printers (see Fig. 64.8).

The thickness of the soft gold plating on the nickel base is specified carefully based on the trials.

**FIGURE 64.8** Direct bonding of fine flying leads. (*Ink cartridge of H.P.*)

**FIGURE 64.9** Flex interconnection through bump array.

### 64.3.7 Bump Connections

The microbump constructions are valuable for making reliable connections of the high-density flexible circuits with high-pin counts. Several ideas have been created to make practical termination technologies. Figure 64.9 shows an idea modified from the Bit<sup>2</sup> process developed by Toshiba. The copper bump arrays are formed by an etching process of the two-layer copper laminates on the heat-resistant polyimide film, and they have suitable plating such as nickel and gold. The microbump array is placed on the other circuit or devices through an adhesive layer of the insulation resin. A suitable combination of temperature and pressure makes a reliable metal-to-metal connection between the microbumps and the metal pad of the other printed circuits.

Supplemental etching processes after the heat press provide a special practice for building a low-cost rigid/flex construction.

### 64.3.8 Flip-Chip Bonding

The flip-chip connection is one of the termination methods with microbump arrays. The technology consumes a very small space for the package because all of the connections are conducted under the IC chips, as shown in Fig. 64.10. Arrayed gold bumps make reliable metal-to-metal connections with the tin- or gold-plated pad on the other devices through the combined process of the pressure and heat with ultrasound vibration. The process can provide smaller-pitch connections than 200 micron for large pin counts. Flip-chip mounting of bare IC chips is becoming more common in the memory devices of the portable electronics. The same technologies as used in rigid circuit boards are available for flexible circuits. Adhesiveless copper-clad laminate should be used when high-temperature processes are applied. Cast-type or lamination-type adhesiveless laminates could provide high-reliability because of high bond strength.

Applying underfill materials between the bare chip and the flexible substrate is recommended for higher reliability.

### 64.3.9 Anisotropic Conductive Material (ACM)

The connection of flexible circuits with anisotropic conductive materials is not new idea. An organic adhesive material that has conductive particles becomes conductive only in the z direction when sandwiched between a flexible circuit and the other device under a pressure

**FIGURE 64.10** Flip chip mounting of bare chip.

**FIGURE 64.11** ACF (M) connection on HDI flex 30 micron pitch.

(see Fig. 64.11). The connection technology was widely applied for the simple displays of low-cost products such as calculators and clocks. Usually the conductors of the flexible circuits are built by screen printing of the carbon paste or silver paste, so the connection can be applied only for pitches larger than 1 mm with small currents.

Newly developed anisotropic conductive resins have generated several new termination technologies for high-density flexible circuits. Film-type and paste-type anisotropic materials are developed with suitable applicators. The film-type material, called anisotropic conductive film (ACF), has been widely used for the mounting of driver IC chips on the flexible substrate and connections

between the flexible substrates and the glass substrates of the LCD devices. The latest material has 30  $\mu\text{m}$  pitch connections in one direction for the IC chips on the gold-plated pads of the flexible circuits. Examples of the basic properties are provided in Table 64.5

The connections have relatively high resistance with a high noise level. The low-heat resistance resulting from the organic matrix of the anisotropic conductive materials is another barrier to apply as a reliable termination under sever operating temperatures.

**TABLE 64.5** Basic Properties of the ACF Connection (*Source: Sony Chemical*)

Grade	CP9631SB	CP9221FS	CP7652K
Applications	FOG, TCP	FOG, COF	FOB, TCP

Process temp.	170 degree C	190 degree C	170 degree C
Process time	15 sec.	10 sec.	20 sec.
Repair	Possible	Good	Possible

FOG: Film on glass, FOB: Film on Board, TCP: Tape Career Package  
COF: Chip on Film

### 64.3.10 Nonconductive Paste (NCP) Connection

An NCP connection looks similar to the flip-chip connection described in Section 64.3.7. The NCP connections do not need such severe conditions for both temperature and pressure. The

nonconductive paste filled between the bare chip and flexible substrate works as an adhesive resin (see Fig. 64.12). It has good bond strength for both the bare chip and the substrate. The adhesive resin shrinks under a thermal treatment and generates negative pressure between the chip and flexible substrate. The negative pressure is remarkably strong at the contact points of the microbumps, so the metal-to-metal bonding is made between the microbumps and the pads of the flexible substrates (see Fig. 64.12.). A smaller contact of the microbump is recommended to generate a higher pressure at the bonding points. The gold bumps or soft gold-plated copper bumps and tin-plated copper pads usually are

**FIGURE 64.12** NCP bare chip packaging.

**FIGURE 64.13** Cross section of NCP packaging, (a) Stud bump made by wire bonding machine. (b) Flat bump made by plating process.

used for this bonding. Stud bumps made by the similar machines as gold wirebonding provide needle shapes at the top of the bumps to make good bonding (see Fig. 66.13).

NCP connection provides a higher reliability than ACM connections with a pitch smaller than 100 micron. The density of an NCP connection looks lower than that of an ACM connection, but it covers more pin counts in a small space, utilizing the area connection capability.

#### 64.3.11 Automatic Equipment for the Permanent Connections

Many kinds of equipment have been developed for the high-density permanent terminations of flexible circuits. However, the basic process and equipment look similar. A mounting machine places the devices on the reeled flexible circuit with accurate alignment by CCD cameras. The bonding head adds pressure and heat from the top of the electronic devices. An ultrasonic vibration of the bonding head could help to increase the reliability of the connections.

### 64.4 SEMIPERMANENT CONNECTIONS

Semipermanent connections have been required for rework, replacement of components and modules, and repeated connections. Realistic assembly processes for most electronic products are not perfect, so semipermanent terminations are required for rework and replacement of electronic components or modules in standard assembly processes to increase final manufacturing yields. Also, temporary connections are required for testing and adjusting electronic products and modules. These often need 5 to 10 reconnections, with as many as 100 reconnections required in extreme cases. Basic data on typical semipermanent termination technologies are summarized in Tables 64.6 through 64.8.

**TABLE 64.6** Semipermanent Interconnects with Flexible Circuits

	Objectives	Application examples
Pressure contacts	Flex/rigid boards	Facsimile
Anisotropic conductive rubber	Flex/flex or rigid boards	Flat panel displays
Dimple contacts	Flex/rigid parts (flex-flex)	Inkjet printers
Microbump array	Flex/rigid boards and parts	Board testers

**TABLE 64.7** Performance of Semipermanent Technologies

	Connection density	Repeatability	Trace density of flex circuits
Pressure contacts	150- $\mu\text{m}$ pitch	$\sim 20$	150- $\mu\text{m}$ pitch
Anisotropic conductive rubber	100- $\mu\text{m}$ pitch, 200 contacts per $\text{cm}^2$	$\sim 50$	100- $\mu\text{m}$ pitch

**TABLE 64.8** Items to Be Considered in Semipermanent Termination Technologies

	Supplemental parts	Applicators	Remarks
Pressure contacts	Rubber strip and fixture	Simple tooling	Good dimensional control required
Anisotropic conductive rubber	Fixture and ACR strip	Simple tooling	Not available for high currents High contact resistance High noise level

#### 64.4.1 Pressure Contact Termination

The basic idea of pressure contact termination technology is very simple and is not new. Pad patterns of the same pitch plated with gold are generated on a flexible circuit and opposite circuits, and they are attached to each other with uniform pressure using a suitable rubber strip (see Fig. 64.14). There is no high-temperature process to complete the connection; polyester base materials are available. The maximum connection number and density depend on the capability of dimension control and uniformity of the circuits. It is possible to make 200 connections with 150  $\mu\text{m}$  pitch because of the processes all take place at room temperature. Neither special application equipment nor special constructions on flexible circuits are

**FIGURE 64.14** Pressure contact of flexible circuits.

required except simple tooling, so pressure contact termination can be a low-cost solution. Unfortunately, connection and disconnection take time, which makes this technology unsuitable for multiple repeated connections.

#### 64.4.2 Anisotropic Conductive Elastic Materials

Newly developed anisotropic conductive rubber has generated several new termination technologies for high-density flexible circuits (see Fig. 64.15). The latest material has  $200\ \mu\text{m}$  pitch resolution in one direction. Another type of sheet rubber can have more than 200 contacts in  $1\ \text{cm}^2$ . These types of rubber can make more varieties for traditional pressure contacts. A disadvantage of the technology is high contact resistance, which makes it unavailable for large-current circuits. Also, it generally has a relatively high noise level. Table 64.8 gives the basic properties.

FIGURE 64.15 Pressure contact with anisotropic conductive rubber.

### 64.5 NONPERMANENT CONNECTIONS

Many repeated connections are required for replacement of disposable components such as inkjet printer cartridges and biological sensor devices. These require more than 1,000 repeated connections for a flexible circuit cable. More than 1 million repeated reliable contacts on flexible

circuits are required for switching circuits and test probe circuits. Flat-panel switches and electrical test probe fixtures for microcircuits are typical examples. As flex circuits have high-density cabling capabilities other than the mounting capabilities of electronic components, there have been serious requirements for high-density nonpermanent termination.

There have been two kinds of approaches to realizing high-density nonpermanent flex circuits. The first is improvement in connection densities of traditional termination technologies. Crimp tabs, pressure contacts, key contacts, and FFC connectors could be categorized in this group.

Another approach is a new concept. Anisotropic conductive rubber, dimple contacts, and bump contacts are typical examples. The technologies are compared in Tables 64.9 through 64.11.

**TABLE 64.9** Nonpermanent Interconnects with Flexible Circuits

	Objectives	Application examples
Crimp tabs	Flex-flex	Tach panel switches
Key pad contacts	Flex internal	Keyboards
FFC connectors	Flex-flex or rigid boards	Computer peripherals
Area array connectors	Flex-rigid boards	Industrial equipment
Dimple contacts	Flex-rigid parts (flex-flex)	Inkjet printers
Microbump arrays	Flex-rigid boards and parts	Board testers

**TABLE 64.10** Performance of Nonpermanent Technologies

	Connection density	Repeatability	Trace density of flex circuits
Crimp tabs	1.27 mm pitch	~100	1.27 mm pitch
Keypad contacts	10 in 1 cm <sup>2</sup>	10 million	200 $\mu$ m pitch
FFC connectors	0.3 mm pitch	~100	150 $\mu$ m pitch
Area array connectors	100 contacts per cm <sup>2</sup>	~500	100 $\mu$ m pitch
Dimple contacts	20 contacts per cm <sup>2</sup>	~1000	0.5 mm pitch (150 $\mu$ m pitch)
Microbump arrays	400 contacts per cm <sup>2</sup>	~1 million	60 $\mu$ m pitch

**TABLE 64.11** Items to Be Considered for Nonpermanent Termination Technologies

	Supplemental parts	Applicators	Remarks
Crimp tabs	Tab and housing	Applicator	Low connection density.
Keypad contacts	Conductive keypads or a sheet	No	Density depends on mechanical key sizes.
FFC connectors	ZIF connectors	SMT soldering	Soldering on the other circuit.
Area array connectors	Male and female connectors	Special soldering	High-density traces are required on flex circuits.
Dimple contacts	(Housing)	Simple tooling	Suitable forming process shall be developed.
Microbump arrays	(Housing)	Special fixtures	Suitable processes to build microbumps must be developed.

FIGURE 64.16 Examples of soldering lead-type connection in flexible circuits.

### 64.5.1 General Connectors

Most of the general connectors designed for other wiring technologies are applicable without serious changes. (Figure 64.16 shows a set of alternative designs.)

**64.5.1.1 Card-Edge Connectors.** All kinds of connectors designed for rigid circuit boards are available for flexible circuits. They can be mounted and soldered on flexible circuits supported with stiffener boards of suitable thickness. Card-edge connectors designed for rigid circuit boards are also available. A flexible circuit with a suitable stiffener board on the bottom can be inserted into the connector. However, the newest FFC connectors designed specifically for flexible circuits have a much higher density in a smaller housing and should be replaced by FFC connectors for large volume.

**FIGURE 64.17** High-pin-count area array connectors available for high density flexible circuits.

**64.5.1.2 Area Array Connectors.** Density higher than  $150\ \mu\text{m}$  pitch on double-sided flexible circuits with through holes is required for high-pin-count connections. All kinds of connectors designed for rigid printed circuit boards are available for flexible circuits with some modification on flexible construction. A newly designed array connector for high-density flexible circuits can make 300 connections in a  $10 \times 15\ \text{mm}$  area (see Fig. 64.17). Special constructions are not necessary, other than  $0.5\ \text{mm}$  pitch array soldering. However, traces with pitches smaller than  $150\ \mu\text{m}$  are required for high pin counts. They can survive 1,000 repeated contacts.

**64.5.1.3 Crimp Tabs.** Crimp tabs were originally developed for connections of flat conductor cables; however, they are also applied for flexible circuits because of the similar construction.

An applicator firmly staples female tabs mechanically through dielectric layers (see Fig. 64.18). Male tabs are stapled on the other cable. Both are covered with plastic housings. Because there is no soldering process, polyester-based materials are available. For a long

**FIGURE 64.18** Clamp type connector for flexible circuits.

time, the standard pitch was 2.54 mm. A 1.25 mm system was introduced recently, doubling the connection density. The connectors can make reliable repeated connections more than 100 times. Total cost per connection is relatively high.

### 64.5.2 FFC Connectors for Flexible Circuits

Originally, FFC connectors were developed for laminated cable with flat conductors to connect to another circuit board. A similar construction of flexible circuits was developed to attach the connector. At this time, the standard pitch of the connectors was 2.54 mm. Due to increased trace densities of flexible circuits, small-pitch FFC connectors are now required. The newest connector can make 0.3 mm pitch connections for 30 traces. Zero in force (ZIF) mechanisms were introduced for easier handling. Due to limited height requirements for thin board assembly, a 1.0 mm high connector from the board surface is now available.

### 64.5.3 Pair Connectors for Flexible Circuits

Originally, the board-to-board connectors were designed for the connection between rigid circuit boards, and they have been also used for the connection of flexible circuits to rigid circuit boards. However, portable electronic products demand thin connectors with small pitches for the flexible circuit connections, so connector manufacturers have developed special connectors called *pair connectors* specifically for connecting high-density flexible circuits. Basically, they are a pair of male and female connectors separately mounted on the flexible circuit and rigid board by SMT soldering (see Fig. 64.19).

The smallest pitch of the pair connector is 0.5 mm. It is larger than the smallest pitches of FFC connectors; however, because the pair connectors have dual line contacts and soldering leads, they can manage more pin numbers in a limited space. A higher reliability for the repeated connections is another advantage of the pair connectors. Accordingly, they have been used as the standard methods for connecting high-density flexible circuits in portable electronics such as cellular phones and digital cameras (see Fig. 64.19).

**FIGURE 64.19** Pair connectors for flexible circuits. Example shown is for connection in cellular phone.

**64.5.4 Bump and Dimple Array Contacts**

Small bump arrays are valuable for the nonpermanent connections of high-density flexible circuits. Various bump constructions on flexible circuits have been developed through different manufacturing processes that are driven by the needs of specific applications.

**64.5.4.1 Dimple Contacts.** Dimpled pads of flexible circuits can be a low-cost solution for high-density connection of flexible circuits. One hundred contacts in 12.5 mm square between flexible circuits and the other circuit boards are possible. Appropriately shaped dimples are formed by pressure and temperature for a gold-plated pad. Dimpled pads with hard gold plating have enough life for several thousand connections and disconnections (see Fig. 64.20). The dimples are supported with bumped rubber to create long and reliable contacts. The pitches of the dimples cannot be smaller than 1.5 mm, but high-density termination can be realized with the area dimple array.

**FIGURE 64.20** Dimple contacts for flexible circuits.

The dimpled connection was adopted for the disposable ink cartridges of the inkjet printers, and huge numbers of flexible circuits are consumed as the partner of the dimpled flexible circuits (see Fig. 67.21).

**FIGURE 64.21** Dimple connections for ink jet printer. (Source: LexMark.)

**FIGURE 64.22** Flat disk-shaped microbump array on flexible circuit fir area contacts. Contact metal is copper-nickle-gold at 0.5 mm pitch. (Source: Asahi Fine Technology.)

**FIGURE 64.23** Column shape Cu/Ni/Au bump array on a flexible circuit substrate.

**64.5.4.2 Microbump Array.** Because of thin substrates, various constructions of microbump arrays have been developed on flexible substrates. A plating combination of nickel and hard gold on a copper bump provides reliable contact performances. A microbump array built on flexible circuits by a plating process enables high-density contacts with the other circuit boards. The process has a range of wide flexibility to generate various shapes of microbumps. It is possible to build more than 1,000 microbumps in  $10 \text{ mm}^2$  if  $30 \mu\text{m}$  line/space circuits are available. A mushroom-head copper bump plated with hard nickel and hard gold has enough life for millions of contacts (see Fig. 64.22).

**64.5.4.3 Film Connectors.** High height bumps built on the flexible substrates as shown in Fig. 64.23 enable various repeatable interconnections between flexible circuits and the other devices. A flexible circuit with a microbump array makes a connection thinner than 0.3 mm from the surface of the other circuits. Over 100 connections could be made in 5 mm square by a microbump array. The column-shaped microbumps work as the male parts of the connection. An appropriated design of the female parts of the flexible circuits enables over 1,000 repeated connections for the high-pin-count circuits.

Figure 64.24 shows the concept of a film connector made with bumped flexible circuits. The column-shaped microbump array is built on both sides of a thin, flexible substrate, and it works as the film connector between two flexible circuits. The film connector could generally be used with standard designs because it manages high-pin-count connections of flexible circuits without special constructions. Many varieties for the constructions could be possible depending on the combinations of flexible circuits and other devices.

## 64.5.5 Keypad Contacts

There are several different constructions for keypads on flexible circuits. Thick-film circuits on polyester film called *membrane switch* could be a low-cost solution with many millions of reliable contacts. The basic mechanism of the switching is illustrated in Fig. 64.25. Generally, the membrane switches are connected through FFC connectors to the main circuit board. Polyimide-based circuits are necessary with soldering of components.

**FIGURE 64.24** Thin connection by film connector.

**FIGURE 64.25** Membrane switch mechanisms.

The membrane switches built on polyester film are widely used as the standard keyboard circuits of personal computers. They are also used as the switching components of touch panel boards for home appliances such as microwave ovens and office machines such as copy machines. They are also used with the touch screens of display devices.

## 64.6 HIGH-DENSITY FLEXIBLE CIRCUIT TERMINATION

No perfect termination technology can satisfy all requirements, especially for high-density connections with high pin counts. On the other hand, higher performances are required for the new portable electronics to complete reliable terminations in limited spaces. Accordingly, many new termination technologies with flexible circuits have been developed to satisfy many requirements. Nevertheless, it is still difficult to use one termination technology to satisfy

**TABLE 64.12** New Termination Technologies for High-Density Flexible Circuits

Termination technology	Termination density ( $\mu\text{m}$ pitch)	Repeatability	Requirement for flex circuits
Lead-free reflow	300	~2	Higher heat resistance (260°C for 30 sec.)
Lead-free hot bar reflow	150	~2	High heat resistance (400°C for 10 sec.) High dimensional accuracy (~0.02%)
Wire bonding	150	1	High heat resistance (450°C for 3 sec.)
Direct bonding	50	1	Flying-lead construction (50 $\mu\text{m}$ pitch)
High-density BGA for flip-chip	200	1	Microbump array (200 $\mu\text{m}$ pitch)
Anisotropic conductive materials	60	~5	High dimensional accuracy (~0.01%)
Small-pitch ZIF connectors	300	100	High dimensional accuracy (~0.05%) uniform tin plating
Contact probe array	200	~1000	Microbump array hard gold plating on nickel

all requirements. Therefore, suitable combinations are recommended to complete all terminations in an electronic product or module. Table 64.12 shows several examples of the major termination technologies used for high-density flexible circuits.

# CHAPTER 65

---

# MULTILAYER FLEX AND RIGID/FLEX

---

**Dominique K. Numakura**

*DKN Research, Haverhill, Massachusetts*

---

## 65.1 INTRODUCTION

---

Originally, the basic design concepts and manufacturing processes for the multilayer rigid/flex had been developed for aerospace equipment because of the need to manage reliable wiring in limited space. More than 30 conductor layers were built on a rigid/flex for complicated applications. On the other hand, consumer portable products such as cellular phones and digital cameras have long been demanding high-density, low-cost wiring technologies and new design concepts and new manufacturing processes have been developed for this task.

A combination of rigid and flexible circuits can be called *rigid/flex, flex/rigid, or rigid/flexible*. However, they are called *multilayer flex* when flexible materials are used instead of glass/epoxy. The term *rigid/flex* is used throughout this chapter.

---

## 65.2 MULTILAYER RIGID/FLEX

---

Multilayer rigid/flex is basically a combination of rigid multilayer and flexible circuit processes.

However, the successful accomplishment of this combination requires a high level of skill in both areas, and it is important to have a clear understanding of the abilities and limitations of the chosen fabricator before designing this type of circuit for a product.

### 65.2.1 Basic Constructions

There are many different concepts in the construction design of multilayer rigid/flexible circuits.

Figure 65.1 shows the basic construction of a multilayer rigid/flex, both from a plane view and in cross section. Figure 65.2 shows an example of this construction with air gaps between the flexible layers, in order to have high flexibility. More than 30 layers are built in extreme cases, such as for aerospace applications. Because of the requirement for high-reliability, fine pattern designs with micro via holes cannot be used. In addition, leaded components are

FIGURE 65.1 Basic construction of multilayer circuits (a) Plane view, (b) Cross section.

FIGURE 65.2 Air gap structure of multilayer rigid-flex board.

FIGURE 65.3 Folding type rigid/flexible circuit.

FIGURE 65.4 Flying tail type rigid/flexible circuit.

specified instead of SMT components. The design usually calls for relatively large lines/spaces and large-diameter through-holes with thick copper plating. There are several types, designated the folding type (Fig. 65.3), the flying tail type (Fig. 65.4), the bookbinder type, and so on, according to their shapes.

**65.2.2 Materials**

Several supplemental materials are necessary for building a multi-layer rigid/flex, as shown in Table 65.1. It should be noted that there has been significant technical progress in the development of these high-performance materials.

**TABLE 65.1** Materials for Multilayer Rigid/Flexible Circuits

Materials required	Traditional materials	High-performance materials
Flexible substrates	Traditional polyimide films (Kapton H™, Apical AV™)	New polyimide films (Kapton E™, Apical HP™, Upilex S™)
Copper-clad laminates (double-sided)	Polyimide film substrate Acrylic adhesive (epoxy adhesive)	Polyimide film substrate Adhesiveless laminate (cast materials or laminated materials)
Coverlay	Traditional polyimide films coated with acrylic or epoxy adhesives	New polyimide films coated with hot-melt polyimide adhesives
Bonding sheets	Acrylic resin films Epoxy resin films Polyimide films coated with acrylic adhesives on both sides	New polyimide films coated with hot-melt polyimide resin on both sides
Rigid substrates	Glass/epoxy boards	Glass–BT resin boards Glass-polyimide boards

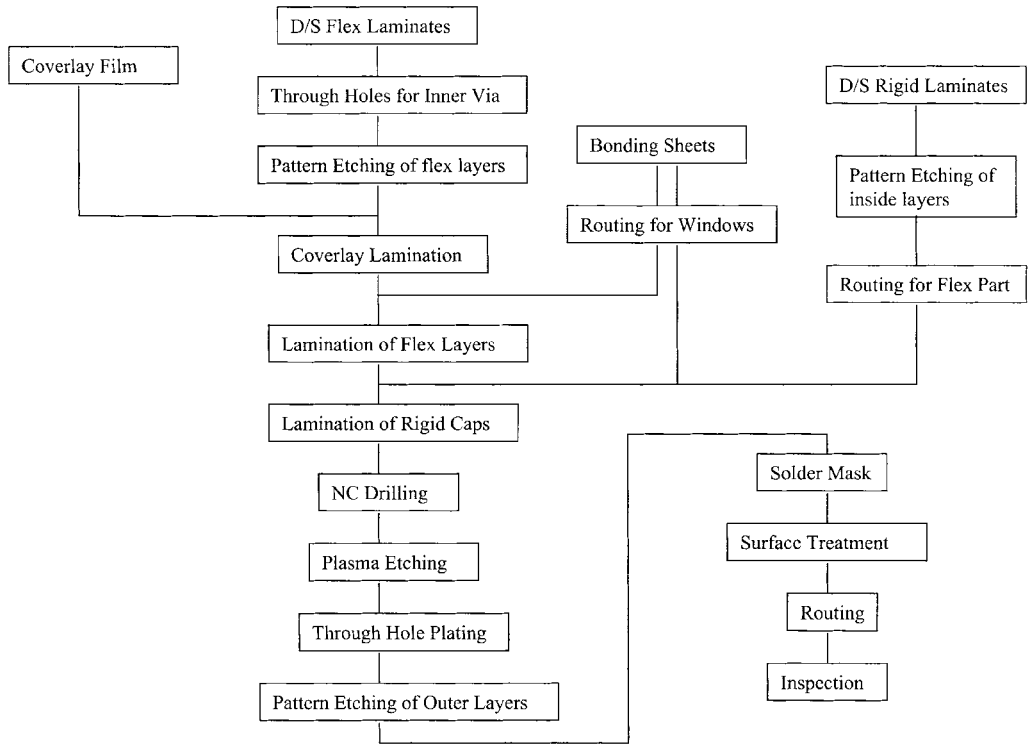

The materials must have high heat resistance and high dimensional stability to survive during several high-temperature processes. Thicker polyimide films (50 μm thick or thicker) are recommended because the basic dielectric materials are required to have good stability in the manufacturing processes. An acrylic adhesive system in copper-clad laminates, as well as coverlay film and bonding sheets that have higher heat resistance than epoxy systems, are also recommended for use in manufacturing. Adhesiveless, copper-clad laminates, made by casting or lamination processes, usually perform better in high-temperature processes. They are also valuable because they reduce the total thickness of the finished board. Hot, melt-type, polyimide adhesive systems, including coverlay films and bonding sheets, have been developed to have very high reliability and smaller thicknesses. They can reduce smear level in drilled holes significantly. But they must be processed at temperatures higher than 300°C, and therefore require special facilities and conditioning.

**65.2.3 Manufacturing Process Flow**

There are many varieties of manufacturing processes for multilayer rigid/flexible circuits because of their complicated structures. Figures 65.5 shows a typical layer construction using

**FIGURE 65.5** Standard manufacturing flow for multilayer rigid/flexible circuits.

**FIGURE 65.6** Material construction for multilayer rigid/flexible circuits.

the standard manufacturing process for multilayer rigid/flexible circuits shown in Fig. 65.6. As seen in Fig. 65.6, the process starts with flexible, double-sided copper-clad laminates.

The conductive patterns are generated by the traditional etching process without through holes. All traces are covered with plain coverlay films, which have no openings. The multiple covered flexible circuits are bonded with bonding sheets, which are already routed to make openings for nonbonding flexible areas.

Caps (the outside layers of rigid parts) are made with rigid double-sided copper-clad laminates.

Traces are printed and etched only on the inside surfaces of the laminates as the first process. Flexible parts of the boards are removed through NC routing or punching. Both flexible layers and caps are bonded with bonding sheets that have been routed for flexible parts.

Appropriate dummy boards are prepared for the flexible part during the bonding process. A vacuum press is preferred for good bonding quality. An autoclave system is recommended for complicated circuit constructions, because the autoclave can create uniform pressure on the entire circuit. Suitable baking should be done prior to lamination or bonding processes.

As the laminated board can be handled in the same way as multilayer rigid boards, the same through-hole processes are available, except desmearing, which is dependent on the combination of materials used (see later). The drilling process is conducted after enough baking in basically the same way as for rigid boards. A plasma etching process should be applied to remove smears of acrylic resins in the holes. The etchback conditions should be determined carefully. The same through-hole plating process is available; however, detailed conditions must be determined based on reliability test data.

**FIGURE 65.7** Example of typical multilayer rigid/flexible circuit with via holes. (Source: Toshiba.)

The rest of the processes are very similar to those used for multilayer rigid boards. Outer layer etching, coverlay (solder mask), and surface treatment are conducted in the same way.

When the dummy boards are removed after routing, the circuit becomes a rigid/flexible circuit.

#### 65.2.4 Through-Hole Process

When inner via holes are required in flexible layers, the same through-hole process should be conducted prior to etching of inner-layers as for rigid board inner-layers. Figure 65.7 shows an example of inner via holes in flexible parts of a multilayer rigid/flex, and Fig. 65.8 shows a cross section of a multilayer rigid/flex plated through-hole. The through hole drilling can be accomplished by the same machine as used for rigid multilayer boards. However, the drilling conditions should be determined carefully for each material's construction.

Baking conditions prior to drilling could be critical in creating reliable through-holes.

Desmearing of the rigid/flex is different from that of standard rigid multilayer boards. The acrylic adhesive materials will undergo serious swelling during standard permanganate desmearing processes, lowering through-hole reliability. A plasma etching process is recommended to remove the smears of acrylic adhesive materials in the drilled holes. Use of a polyimide adhesive system can reduce the smear level significantly, but this also requires a high-temperature process in special press equipment.

**FIGURE 65.8** Cross section of a through-hole in a multilayer rigid/flexible circuit.

### 65.2.5 Reliable Through-Holes

Aerospace and industrial equipment require a higher reliability for the through holes than consumer electronic products. Copper plating thicker than 25 microns is recommended.

**FIGURE 65.9** Etchback of through-hole in multilayer flexible circuit.

Several adhesive resins, especially acrylic-based adhesives developed for flexible circuits are not stable with the permanganate solution that is common for rigid multilayer boards, which means that a very narrow window is allowed for the desmearing of the rigid/flex process. If the materials are dipped too long in the solution, the adhesive layers swell and the reliability of the through hole will be damaged.

A plasma etching process has been introduced to remove the smear inside of the drilled holes as a substitute for using potassium permanganate solution for the polyimide base multilayer rigid/flex. The plasma gas removes the smear in the holes effectively without chemical damages on the adhesive resins.

The use of supplemental plasma etching, called the Etch Back Process, is recommended to achieve high reliability of through-hole multilayer rigid/flexible circuits. The plasma gas provides further etching on both of polyimide films and adhesive layer in the drilled holes. The plasma gas does not etch metal materials and it clears the surface of the copper foils for reliable copper plating as shown in Fig. 65.9.

### 65.2.6 Bookbinder Construction

A multilayer rigid/flex that has multiple conductor layers in its flexible (parts fixed by rigid caps at both sides) will not bend effectively if all the layers are of the same length. Special designs are not required while the flex areas have long distance and they use thin films and copper foils. They are sometimes called Air Gap Construction.

The Bookbinder Construction is recommended for the reliable interconnects of the multiple flexible layers in a rigid/flex with a short distance. A longer length of the flexible layer should be provided at the outer side of the flexible area. When they are bent, the flexible layers have uniform gaps between the flexible layers as shown in Fig. 65.10.

Special tooling and equipment are required to build the bookbinder construction, and the productivity is comparatively extremely low. As a result, this process is not used for consumer or other applications that require low cost.

**FIGURE 65.10** Design of bookbinder construction of multilayer rigid/flex circuit.

### 65.2.7 High Density Multi-layer Rigid/Flex for Industrial Use

High-density designs with fine traces and micro via holes for rigid/flex are not recommended for use in aerospace applications because they are not reliable enough under extreme conditions. Only traditional soldering processes are used for the terminations of the rigid/flex.

On the other hand, recent designs for industrial and medical applications have been using both high density and high reliabilities, therefore, new design concepts and termination technologies have been designed to meet this need.

Smaller trace pitches than 100 microns and smaller via-hole diameters than 100 microns have been introduced for the high density multilayer rigid/flex. To achieve the new design concepts, 25 micron or thinner polyimide films were introduced without adhesive layers for the thin copper laminates, mostly 18 microns or less. Several laser processes are used to generate small via holes, especially with blind via holes of the build-up process. (Fig. 65.11)

Several high density, but reliable termination technologies such as Ball Grid Array (BGA) and Flip Chip Bonding have been introduced for the high density rigid/flex.

**FIGURE 65.11** Micro blind via hole on a multilayer rigid/flexible circuit made by a build-up process using resin-coated foil. The hole diameter is 150 micrometer. (Source: Photo Machining.)

### 65.2.8 Build-Up Process and Blind Via Holes

To build the high-density rigid/flex, the build-up process with blind via holes has been introduced as the new standard manufacturing process. Similar build-up processes are used with multilayer rigid and rigid/flex circuits; however, instead of the traditional manufacturing process used for multilayer rigid/flex circuits, more layers are built on the rigid part with resin-coated foils. Figure 65.12 shows a cross section of a blind micro via hole in a multilayer rigid/flexible circuit made by a buildup process with adhesiveless copper laminate and prepreg sheet. Holes smaller than 100 micron diameters were drilled by carbon dioxide laser and a thin copper plating was plated in the via hole conductors. Figure 65.13 also shows a

**FIGURE 65.12** Micro-blind via hole on a multi-layer rigid/flexible circuit made by a build-up process using adhesiveless laminate prepreg. (Source: Photo Machining.)

**FIGURE 65.13** Micro blind vias on two sides of a multilayer rigid/flexible circuit.

micro-blind via hole in a multilayer rigid/flexible circuit, made by a build-up process using an adhesiveless laminate, but with prepreg sheet and with hole diameter of  $150\ \mu\text{m}$

### 65.2.9 High-Density Multilayer Rigid/Flex for Consumer Use

Consumer applications, such as digital cameras and cellular phones, often require high-density rigid/flex to complete complicated wiring and packaging in small spaces. They often use traces finer than  $75\ \mu\text{m}$  and blind via holes smaller than  $150\ \mu\text{m}$  in diameter with high-density SMT. Many small chip components are mounted on the rigid part of the circuits and the traces are connected to other circuits by soldering to have relatively large current capacities (See Fig. 65.14 for example of multilayer flexible circuit used in cellular phones.

Figure 65.15 shows another examples of rigid/flex applied for an LCD display module of a cellular phone. High density SMT including flip chip mounting of controller IC and small CMOS camera were conducted on a small rigid part of the rigid/flex. One of the flex parts was connected to the glass substrate of the LCD by ACF (Anisotropic Conductive Film) connection with 150 microns pitch. Another side of the flexible parts was to be inserted to the FFC connectors with 0.5 mm pitch.

**FIGURE 65.14** Multilayer flexible board for cellular phone application.

**FIGURE 65.15** Rigid/flexible circuit for LCD driver.

Many technologies have been developed to satisfy these requirements. The use of a build-up process technology could be one of the solutions. The specialty of the consumer application is the large volume with extremely low cost, therefore a new design concept and manufacturing processes have been required.

### 65.2.10 Design Concept of Rigid/Flex for Consumer Use

To eliminate the conflicts of the requirements between high density and low cost, new design concepts for the consumer rigid/flex have been developed. The basic design concepts are listed in Table 65.2. Generally, thinner materials have been selected compared to those for aerospace and industrial use in order to reduce the total thickness significantly. Copper plating for the via hole connections should be less than 15 microns, but the high reliabilities should be kept.

Polyimide films or adhesiveless copper laminates can be used as the cap layer instead of thick glass epoxy materials for reducing the thickness of the rigid/area that is sometimes called multi-layer flex. The total thickness of the 6 layer rigid part for SMT can be less than 400 microns.

The numbers of the conductor layers should be 10 or fewer microns to keep total thickness small and reduce the manufacturing cost. Finer traces than 100 microns pitches should be

**TABLE 65.2** Design Concepts of Rigid/Flex for Consumer Use

Base film	Polyimide, 25 micron thick or thinner
Laminate	Adhesiveless type by cast or lamination process
Conductors	Copper foil, 18 micron thick or thinner less than 10 layers
Type of via hole	Through hole, inner via hole, blind via hole
Min. via hole size	Down to 50 micron diameter
Trace density	Inner layer: down to 25 microns line/space Outer layer: down to 50 microns line/space
Copper plating	15 micron or thinner
Cover film	Polyimide, 25 micron or 12.5 micron
Bonding material	Epoxy or acrylic resin, 50 micron or thinner
Cap materials	Glass Epoxy, thinner than 250 micron Polyimide Film, 50 micron thick or thinner
Solder mask	Photo-imageable
Surface treatment	Ni/Au, lead-free solder or OSP
Shape	As smaller as possible

used instead of additional conductor layers. Figure 65.14 shows an example of multilayer flex designed for the display control module with hinge cables connected to key pad module in a cellular phone. It does not use glass epoxy for the cap layers and could minimize the thickness of SMT assembling ar.

The shape of the rigid/flex is a key to minimizing the cost. The whole rigid/flex should be in a small square or rectangular to maximize the material efficiencies and processing efficiencies. The size of the rigid/flex should be minimized as much as possible to minimize the manufacturing costs.

### 65.2.11 Manufacturing of High Density Multi-Layer Rigid/Flex

To satisfy the requirements for high density with low cost for the consumer rigid/flex, several new manufacturing technologies have been introduced.

The buried, or inner, via hole system has been introduced to optimize the space factors of the inner conductor layers as shown in Fig. 65.16. The inner layer circuits with via holes can be produced as the same process of the double-sided flexible circuits. Adhesiveless copper laminates made by the cast process or lamination process are recommended for use in minimizing the smear during the drilling and optimizing the heat resistance during the multiple high temperature processes.

The build-up system with blind via holes has been introduced to generate fine outer layers and utilize the spaces for the via holes as shown in Fig. 65.16. The adhesiveless copper laminates with heat resistant epoxy bonding sheets are also recommended to use for the build-up layers.

**FIGURE 65.16** Micro inner vias in multilayer rigid/flexible circuit construction.

Carbon dioxide lasers are used to generate micro blind via holes for the build-up layers. The conformal mask system is effective for optimizing the drillings speed and efficiencies of the laser system. The optimized condition with carbon dioxide laser can generate more than ten-thousand blind via holes per minute. Appropriate cleaning process such as plasma etching should be introduced before the copper plating to ensure high via hole reliability.

The roll-to-roll process could be available for high productivities in the inner layers if there are no inner via holes. However, it needs sever dimension control to use RTR process for inner layers with via holes.

The similar semi-automatic machines, such as guide hole punchers and punching presses used single- and double-sided, should be used because they have high productivities for the finishing processes. Steel rule dies are effective, and have higher productivity compared to NC routing machines, for the partial and whole blanking, especially for the half cutting of flexible parts of the thin multilayer flex. But the shape of the steel rule dies should be well designed to avoid the cracks or nicks at the boarders of the flexible parts.

Dimensional control is one of the major keys to have a high process yields. Even though dimensional stable laminates are selected, the thin flexible materials will have remarkable shrinkages during the multi-layer rigid/flex's multiple thermal processes of the. The correction factors for the each thermal or chemical process should be measured carefully. Appropriate work sizes should be chosen carefully to optimize the process yields.

# CHAPTER 66

---

# SPECIAL CONSTRUCTIONS OF FLEXIBLE CIRCUITS

---

**Dominique K. Numakura**

*DKN Research, Haverhill, Massachusetts*

---

## 66.1 INTRODUCTION

---

Because of thin base layers, the flexible circuits can have many special constructions that are impossible to build by traditional manufacturing processes of the rigid circuit boards. These special constructions generate further functional values for the flexible circuits. This chapter introduces the major constructions in use, along with their manufacturing processes.

---

## 66.2 FLYING-LEAD CONSTRUCTION

---

Flying-lead construction is a special case of the double access flexible circuit. The base layer under the traces are removed and the conductors are completely free from the organic materials. New HDI flexible circuit applications have arisen involving flying-lead constructions. Applications such as wireless suspension of hard disk drives, interposers for chip-scale packaging, and ultrasound probes depend on the reliability of this high-density interconnect. In competitive markets such as these, it is imperative that flying-lead applications offer low cost and high volume. The TAB (Tape Automated Bonding) is one of the major application of the flying lead constructions.

Traditional manufacturing processes used to create flying leads, such as pre-punching or pre-drilling, are not conducive to the quality levels and manufacturing yields required to achieve low cost, and alternative processes are needed, as described later.

### 66.2.1 Basic Design

A flying-lead structure is composed of a single layer of high-density-pitch copper conductors accessed from both sides of the substrate. Generally, the substrate side of a conductor on a circuit board is not electrically accessible because the conductive foil is typically laminated to the substrate board in sheet form. In the case of a flex circuit, however, the substrate can be

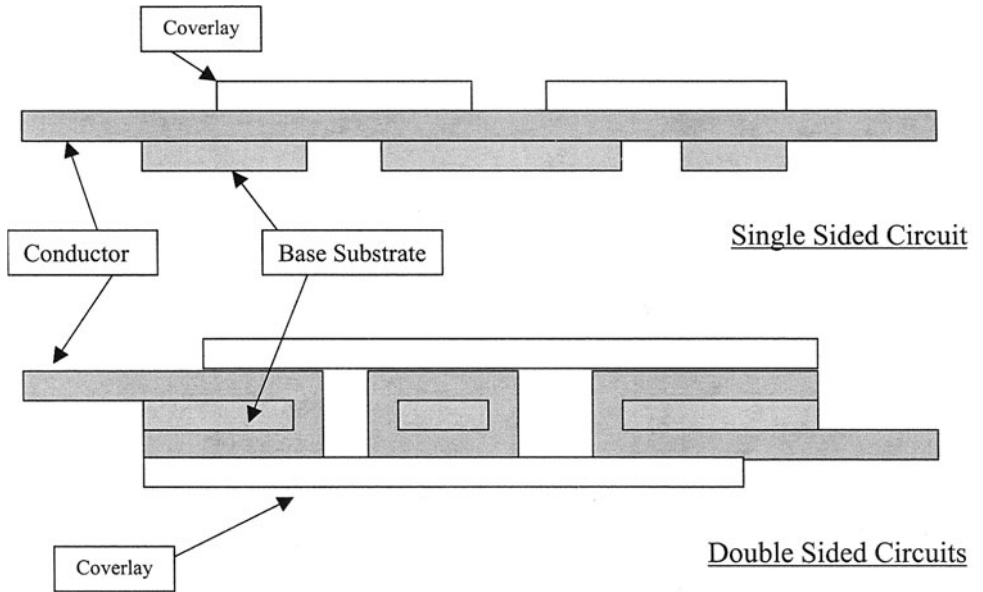

FIGURE 66.1 Basic constructions for Flying-leads for flexible circuits.

removed by various methods., Dual access is created by removing the coverlayer in the same area on both sides.

Figure 66.1 indicates two basic structures of dual-access conductors, in both the single sided and double-sided types of flexible circuits. Figure 66.2 shows actual examples of the fine flying leads built on the single side circuits and double side circuits. Basically, a coverlayer is applied to the side of the conductive layer opposite the substrate. The coverlayer can be processed easily to create the top-side exposure. The flying lead is created when the base substrate is also removed in the same area.

(a)

(b)

FIGURE 66.2 Typical fine flying leads construction (a) Single side, (b) Double side.

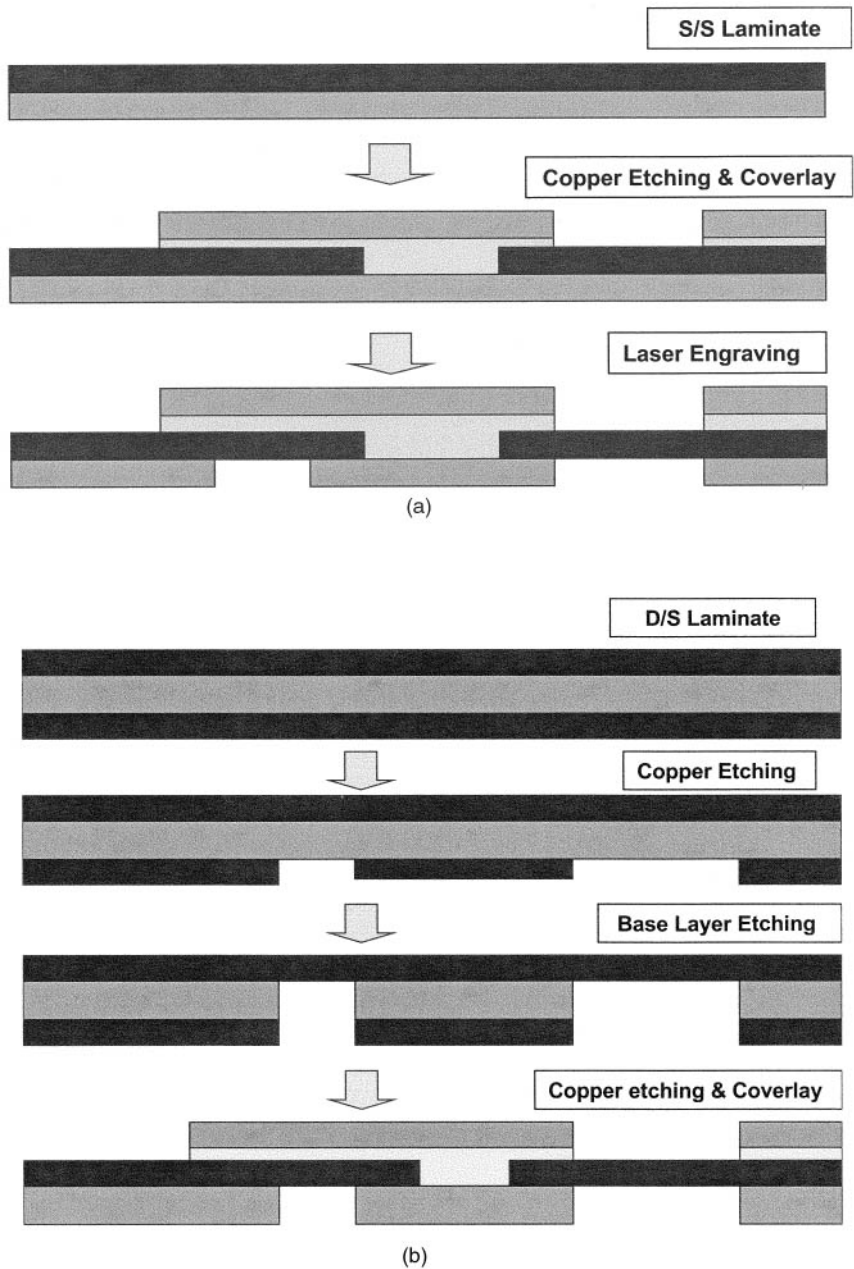

**FIGURE 66.3** “Manufacturing process for flying-lead flexible circuit construction using prepunching method.”

## 66.2.2 Manufacturing Processes for Flying Leads

The fragility of flying leads, caused by the lack of dielectric support, is probably the largest disadvantage in the manufacturing process. Proper circuit design and layout is the key to the manufacturing process yield and subsequent cost and physical performance of the circuit. The most conventional manufacturing process for generating a flying-lead construction involves a pre-punching process similar to the device hole process of tape automated bonding (TAB). Figure 66.3 shows this process schematically. There is no proprietary technology or special tooling required for manufacturing the pre-punched window in the base substrate. This process, however, offers the manufacturer very little flexibility and is fairly labor intensive, which makes it difficult to maintain high productivity rates.

The handling of unstable punched films, along with thin, fragile copper foils, makes it difficult to achieve the high manufacturing yields required to support the cost model associated with high-density flexible circuits. These unstable film substrates also make it difficult to maintain dimensional accuracy between the fingers and the window, a key element for HDI flexible circuits. Adhesive flow or squeeze-out from the edge of the punched film along the conductor can also be an issue when dealing with small window exposures. Openings of less than 1.0 mm are difficult to create with high dimensional accuracy and yield.

Alternative technologies have been developed to generate high-density flying-lead designs with higher accuracy. Laser ablation, plasma etching, and chemical etching are just a few of the possibilities and are illustrated schematically in Fig. 66.4. A comparison of small opening capabilities of each of the processes is illustrated in Fig. 66.5, while a comparison of the technical capabilities of the processes is shown in Table 66.1. With these manufacturing technologies, many kinds of flying-lead constructions became possible.

**FIGURE 66.4** Manufacturing process for flying lead flexible circuit construction using (a) laser ablation and (b) plasma etching or chemical etching.

**FIGURE 66.5** “Comparison of opening sizes of flying-lead flexible circuit manufacturing processes.”

**TABLE 66.1** Comparison of Flying-Lead Manufacturing Technologies

	Prepunching (NC routing)	Laser abrasion	Plasma etching	Chemical etching
Minimum slit width ( $\mu\text{m}$ )	800	50	100	70
Material availability	Fair	Wide	Wide	Limited
Design flexibility	Limited	Wide	Limited	Limited
Capability for high-density flying leads	Limited	Wide	Fair	Fair
Technical hurdles	Low	Fair	High	High
Registration	Difficult	Fair	Fair	Fair
Damage on flying leads	Serious	Small	Fair	Fair
Process cost	High	High	Low	Low
Investment for large volume	Small	High	High	Medium

### 66.2.3 Laser Abrasion

The excimer laser process has the capability to generate small openings with clearly defined edges on high-density flexible circuits. The narrow slit openings can be made smaller than  $50 \mu\text{m}$  wide. The excimer process is available for all types of flexible circuit materials with high accuracy and fine openings. A carbon residue, typically removed by a suitable wet cleaning process, is found around the edges of the openings. One of the biggest disadvantages of excimer laser system is its slow speed, which accounts for the high processing cost when dealing with larger openings.

The UV:YAG laser process offers a higher productivity rate than the excimer laser for very small openings. It has the ability to cut both copper foil and organic substrate materials with

good quality, which makes it suitable for cutting small openings on a wide range of high-density flexible circuits. Unfortunately, the productivity rate becomes extremely slow when cutting larger openings. Actually, it becomes impractical from a cost standpoint to utilize a UV:YAG laser system for openings larger than  $10,000 \mu\text{m}^2$ .

Carbon dioxide TEA lasers, as well as diamond carbon dioxide lasers, have a much higher productivity rate when producing openings wider than  $70 \mu\text{m}$ . The definition of the opening and quality of the edges, however, is somewhat less desirable than for other laser systems. In order to facilitate surface plating, a suitable cleaning process such as plasma is required to remove the thin residue remaining on the copper surface. A copper mask process helps to improve both quality and speed of the carbon dioxide laser process.

The excimer laser process, like the UV:YAG laser system, minimizes the potential for thermal damage on very thin flying leads. The carbon dioxide laser generates a remarkable amount of heat. The beam power density of the laser must be controlled carefully in order to process  $18\text{-}\mu\text{m}$  copper with high-density flying leads narrower than  $100 \mu\text{m}$  wide.

#### 66.2.4 Plasma Etching and Chemical Etching

Plasma and chemical etching processes are other suitable choices for generating high-density flying-lead structures. Although their capabilities are somewhat less than those of laser processing, these processes can provide a lower-cost model of high-volume processing. A copper foil mask is required in order to define the exposure area, and specific process conditions are required to remove organic substrates effectively. These processes are quite effective for single-sided substrates. Double-sided substrates can be processed in this manner given very specific materials and construction.

A big advantage of these processes is the unlimited number of holes or openings that can be processed simultaneously. Performance value is high, while manufacturing costs remain fixed when larger sizes or higher numbers of holes are processed. The plasma process is capable of etching all kinds of organic materials; however, it must be performed in a vacuum chamber.

Capital investment is relatively large for high-volume production. Another issue involves uniform quality over a large working area/panel size in a vacuum chamber of limited size.

Depending on the process conditions, plasma etching creates a wall slope of  $30$  to  $60^\circ$  at the edge of the openings, and it is difficult to make holes smaller than  $100 \mu\text{m}$  in diameter on a  $50\text{-}\mu\text{m}$ -thick polyimide layer.

Chemical etching also offers a low-cost process for creating access openings in high volume on polyimide-based high-density flexible circuits. This process offers the capability of generating openings smaller than  $100 \mu\text{m}$  in diameter or slit width on  $25\text{-}\mu\text{m}$  substrates, while providing a very small slope on the wall definition of the opening. The issue in this process is finding the appropriate chemicals and creating the suitable conditions to etch the various flexible substrates.

Sodium hydroxide and potassium hydroxide are popular chemicals for etching Kapton® type polyimide materials. Dangerous chemistries and tightly controlled process conditions are required to etch dimensionally stable polyimide substrates such as Upilex™. Serious consideration must be given to choosing the appropriate circuit design, materials, and manufacturing processes. On the other hand, chemical processing such as this requires no specialized capital equipment, and it is extremely suitable for high-volume roll-to-roll manufacturing systems.

Typical high-density flying leads produced by new processes are shown in Fig. 66.6

#### 66.2.5 Economical Comparison

Each technology has its own cost structure, which is dependent on the conditions. Figure 66.7 shows a comparison from an economic study of the various technologies. This study was conducted on  $25\text{-}\mu\text{m}$ -thick polyimide substrate with a  $300\text{-mm}^2$  working size. The opening size is assumed to be  $0.1 \times 3 \text{ mm}$ , with flying leads at a  $150\text{-}\mu\text{m}$  pitch processed on  $18\text{-}\mu\text{m}$ -thick copper.

**FIGURE 66.6** “An example of a tab-shaped flying lead flexible circuit construction.” (Source: Asahi Fine Technology).

Plasma and chemical etching processes have little dependency on the size or numbers of openings because they are based on batch processing of the materials in sheets. In contrast, the relative costs of the excimer and carbon dioxide laser process are proportional to the size of the area being processed as well as the opening sizes. This is primarily based on the small size of the laser beam as compared to the size of the opening, and on the need to overlap with each pass of the laser in order to remove the substrate in larger areas. The carbon dioxide

**FIGURE 66.7** Cost comparison of flying-lead flexible circuit manufacturing processes.

laser, however, has higher manufacturing costs than the excimer laser process because of the additional chemical processes required to remove the organic residue left on the copper surface, but it has a lower associated manufacturing cost for larger opening sizes due to faster abrasion speeds.

## 66.3 TAPE AUTOMATED BONDING

---

TAB has been developed as the special wiring material for IC chips and liquid crystal displays (LCDs). Although it was developed separately from standard flexible circuits, they have similar constructions and they use similar materials, and can be categorized as one kind of flexible circuits.

### 66.3.1 Basic Concepts

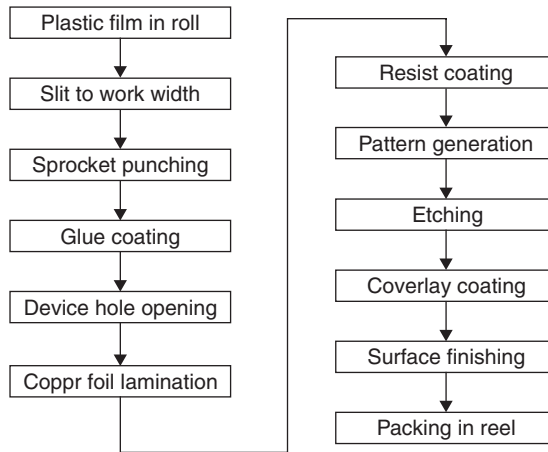

Basic construction of TAB is the same as that of the flying-lead structure of flex circuits except for the web size used in manufacturing and the sprocket holes made for reel-to-reel conveyor systems which give TAB an appearance similar to that of cinema film. A 35-mm-wide web is the most common standard width for TAB. Webs 70 and 155 mm wide are available for larger circuits, nowadays. Because of the small working areas, TAB is good at producing fine traces with flying leads. The reeled circuits are convenient for automation of circuit manufacturing and termination. A short strip circuit made by standard manufacturing processes for flex circuits is also called a TAB circuit because it has the same functions. (Examples of TAB are shown in Fig. 66.8.)

**FIGURE 66.8** “Examples of TAB high-density flexible circuits.”

### 66.3.2 Manufacturing Processes

The basic manufacturing flow of single-sided TAB is the same as that of the traditional pre-punch manufacturing process of flying-lead construction. Basically, all manufacturing processes of TAB are designed for automatic reel-to-reel equipment. Actual processing steps are slightly

**FIGURE 66.9** Manufacturing process flow of TAB.

different as shown in Fig. 66.9. The process starts from a plain film, mostly polyimide film. The first parts of the manufacturing are glue coating and punching of the hole generation. Secondary, a copper foil is laminated and the fine traces are generated by photolithography and chemical etching. Thirdly, final finishing such as cover coating and surface finishing is conducted. All of the processing equipment has to have loader and un-loader by reels. The machines should be free from manual handling to eliminate the mechanical damages on the fragile fine flying leads. The whole process has to be kept in clean rooms to avoid the contamination for the fine lithography processes.

Because of the narrower material width, TAB constructions have high capability for fine-line generation with good dimensional accuracy. The chemical etching process is also available to generate device holes. The technology can generate 40- $\mu\text{m}$ -pitch traces as the flying leads.

The manufacturing process for the double side TAB with fine flying leads and micro via holes is much more complicated. Very few manufacturers are capable to produce the products with high yield.

### 66.3.3 Technology movement of TAB

The TAB manufacturing technology has been experiencing a great progress since 1980s. However, it has been facing a turning point to change the basic process drastically for the finer circuitries.

TAB's manufacturing capabilities are very different from traditional flexible circuits and they cover different application area as shown in Fig. 66.10. TAB has been focusing single side fine traces with flying lead constructions. It has advantages for the volume productions of the small size circuitries because of special reel-to-reel manufacturing.

In early usage, only 35 mm wide web was available to have high dimensional stabilities. But the latest RTR manufacturing equipment can manage 155 mm wide materials to generate 40 microns pitch flying leads. Several new processes such as laser drilling and through hole plating have been introduced to produce double side TAB with fine flying leads.

Forty microns pitch of traces is almost the technical limit to manage the fragile fine flying leads for both of manufacturing and termination. Therefore, the technology is moving to COF (Chip on Film), that does not have device holes and flying leads, to have finer traces than 40 microns pitches. The manufacturing process and materials do not have significant differences from the

**FIGURE 66.10** Recent movement of TAB and high density flexible circuits.

roll-to-roll manufacturing process of the fine flexible circuits. On the other hand, the fine line capabilities of the flexible circuits have been getting better reducing their RTR web size.

TAB and flexible circuits had different capabilities in the past. But they have been moving to the same fine circuit area, and there have not been remarkable differences in their manufacturing processes as shown in Fig. 66.10.

## 66.4 MICROBUMP ARRAYS

A variety of shapes and materials for micro bump arrays on flexible circuits have been developed to accommodate specific applications.

### 66.4.1 Varieties of the Bump Shapes and Applications

There are several choices of places to build micro bumps on flexible circuits, as described in Chap. 64 (see Sec. 64.3.8). The same processes used to build ball grid arrays on rigid circuit boards are appropriate for flexible circuits with flexible photo-imageable solder mask. It is possible to build micro bumps on bare conductors using plating masks. Many micro bumps are built on fine flying leads without solder masks. A valuable construction of a flexible circuit is micro bumps built on the other side of the circuit through the dielectric layer. This can provide a reliable micro bump array because of the stable construction.

Many different shapes have been developed for micro bump arrays. The fusing solder process can make a spherical bump shape easily. Electrical plating of copper, nickel, gold, and combinations of these elements can provide many varieties of bump shapes. Changing the combination ratios and other factors can generate flat disks, flat domes, straight columns, etc. (Fig. 66.11). The best combination can provide 100- to 150- $\mu\text{m}$ -pitch micro bump arrays on 50- $\mu\text{m}$ -thick dielectric layers.

Most of the micro bump array constructions of flexible circuits have been developed for high-density termination (e.g., flip-chip, CSP, test probes, etc.). A suitable design shape and materials should be chosen according to the requirements of the termination. Several examples are shown in Fig. 66.12

**FIGURE 66.11** Microbump arrays on flexible circuits: examples of bump shapes.

(a)

(b)

(c)

(d)

**FIGURE 66.12** Various micro bump arrays on flexible circuits (a): Column shape copper bump array on the bare traces (b): Column shape Ni/Au bump array built through cove layer (c): Solder ball array built through base substrate (d): Combination of flying leads and solder ball array.

### 66.4.2 Manufacturing

There are two kinds of manufacturing processes for the micro bump array on flex circuits:

1. The same technology as for ball grid arrays may be used. Solder paste is dispensed on the pads of the circuits with a liquid dispenser or screen printer. The solder paste will form spherical shapes for a reflowing process. The process is available for relatively large solder balls.
2. Electroplating processes are used for small solder balls and non-spherical micro bumps.

Suitable combinations of different metal plating can provide wide varieties of micro bumps.

There are several factors that determine the shape and size of the bumps. The thickness of the dielectric layer and the size of the opening are the major factors in determining the bump shapes. The bump shapes will be more spherical when the aspect ratio of the opening is large.

The bump shapes will be like flat discs when the aspect ratio is small. An appropriate plating mask will help to build straight, high bumps.

When the micro bumps need to be built through the insulation layers, it requires a suitable hole generation process. Several laser drilling processes are recommended for small sizes but exact dimensions. Plasma etching and chemical etching are recommended for low cost processing with large numbers of the holes.

## 66.5 THICK-FILM CONDUCTOR FLEX CIRCUITS

---

A thick-film circuit is a type of additive manufacturing process. If an organic resin matrix is used, the conductor can be flexible, and this process has been applied in flexible circuits.

### 66.5.1 Materials

A silver paste conductor with an acrylic resin matrix is the most popular conductor material as the major thick-film conductor material for flexible circuits. It can provide very flexible conductor layers via a simple screen-printing process. Copper-based and carbon-based paste materials have been developed as the low-cost materials, but their conductivity is very low and unstable, and therefore their applicable areas are limited.

The screen printing process with conductive paste provide low cost solutions for the large size flexible circuit employing economical plastic films such as PET films.

### 66.5.2 Applications

A silver paste thick-film flexible circuit built on polyester film can provide the lowest-cost solution for large circuits. Unfortunately, the conductivity of the traces is much lower than for copper foil conductors, and this material is not available for power circuits or signal layers of high-speed circuits. Standard soldering is not available because of the acrylic-based matrix.

The largest application of thick-film-based flexible circuits is in membrane switches, which need large circuit spaces but do not carry large currents. The majority of membrane switches are covered by silver paste thick-film flexible circuits. Major switching circuits of keyboard switches are also covered by the same constructions. Most of the key board circuits are covered by the silver paste base membrane switches. Most of the touch panel switches designed for micro waves, office appliances and medical equipment also use PET based membrane switches. Several examples are shown in Fig. 66.13.

**FIGURE 66.13** Membrane switch made by thick film process.

PET based thick film flexible circuits have been consumed for the touch panel switches of the electronic terminals such as PDA because of their transparency.

### 66.5.3 Manufacturing Process

It is a very simple process to build a thick-film flexible circuit. There are two steps:

1. Screen printing on a flexible film followed by baking.
2. Blanking.

This still requires that the process conditions be controlled carefully. The basic properties of these circuits change significantly depending on these conditions. A pre-baking step is recommended for polyester film substrate to eliminate thermal shrinkage during baking for printed conductor paste. It is not difficult to apply the roll-to-roll manufacturing system for large volume because of the simplicity of the processes.

The latest technologies of the printers and screens are able to produce 10 to 15 micron line space with low cost. The electrical properties and trace densities are very depend on the conductor paste. A combination with screen printable nano conductive paste will provide fine conductive traces by a simple manufacturing process.

## 66.6 SHIELDING OF THE FLEXIBLE CABLES

---

When the flexible circuits are used as the cables for the high-speed telecommunications, appropriate shielding systems are required. Generally, the cable will be bent frequently, therefore the shielding layers should also have high flexibilities.

**FIGURE 66.14** Shielding of the flexible cables (a): Screen-printing of silver paste (b): Screen-printing of carbon paste (c): Lamination of thin aluminum foil.

Several materials and constructions are available for the shielding of the flexible cables as shown in Fig. 66.14. Screen-printing of silver paste provides both high shielding effect and high flexibility. Screen-printing of carbon paste provides low cost solution. But its shielding effects are limited. Thermal lamination of a thin aluminum foil with thin flexible adhesive provides a reliable solution for both shielding efficiencies and flexibilities.

## 66.7 FUNCTIONAL FLEXIBLE CIRCUITS

Various new processes have been developed to build functional elements and devices on the flexible substrates. They have been generating more functions than wiring or assembling board of the discrete components. They are the similar ideas as embedded passive technologies of multilayer boards, but they generate more values with flexible substrates. Table 66.2 shows several material examples and applications.

**TABLE 66.2** Functional materials for flexible circuits

Materials	Functions
NiCr, W	Embedded resistors Heater Mechanical sensors
BaTiO	Embedded capacitance
Tin oxide	Transparent electrode
Poly silicone	Embedded active devices Transistors and diodes Sensor devices
Organic EL	Flexible displays

Figure 66.15 shows examples of sputtered nickel/chromium alloy. The first one is embedded resistors and the second one is a small strain gage built on the flexible substrates.

# CHAPTER 67

---

# QUALITY ASSURANCE OF FLEXIBLE CIRCUITS

---

**Dominique K. Numakura**  
*DKN Research, Haverhill, Massachusetts*

---

## 67.1 INTRODUCTION

---

Because of the different design concepts and materials, there are several significant differences in quality assurance for flex circuits vs. that for typical rigid circuit boards. In addition, special test methods are required to guarantee the finished quality of high-density flex circuits, and new inspection technologies have been developed for this purpose.

---

## 67.2 BASIC CONCEPTS IN FLEXIBLE CIRCUIT QUALITY ASSURANCE

---

The basic concept of quality assurance for flexible circuits is the same as that for rigid boards, in the sense that any critical defect must be eliminated before shipping. This includes failures due to opens and shorts; dimensional degradation of pad arrays, serious defects on conductors, substrates, coverlay, and so on. These defects need to be inspected for each circuit, whether it is flexible or rigid. Technically, however, there are several differences in quality assurance for flexible circuits because of their additional functions, such as dynamic flexing capability.

A common issue is damage incurred during the manufacturing process because of the fragile materials. Even though the fine traces are inspected by a high-resolution automatic optical inspection (AOI) system during processing, it is possible that subsequent processes may cause new damage to the inspected circuits. This is a special issue for flying leads, which have no mechanical support under the traces. Therefore, a final inspection is necessary at the end of the manufacturing process.

The basic quality assurance concept for high-density flexible circuits is the same as for other circuit types. However, a difference for high-density flexible circuits is the acceptable defect size, which is one order smaller than that for traditional flexible circuits, necessitating higher inspection capabilities. Furthermore, new high-density flexible circuits contain additional structures such as flying leads and microbump arrays that require additional inspection capabilities for reliable termination. Exact 3-D accuracy and uniform surface conditions are required. Dimensional allowances are smaller than 0.3 percent, and sometimes 2- $\mu\text{m}$  accuracy is required.

This is true for trace pitches, but it is also true for linewidths and spaces. Three-dimensional measurements are required to guarantee the quality of microbump arrays. Usually, it takes time to measure exact dimensions for each circuit, and this is one of the major costs of the circuits when the specification is very tight compared to the process capability.

There have been several basic technical issues regarding quality assurance for high-density flex circuits, as listed in Table 67.1. Because of the fine circuits and the severe acceptable level of the defects, low-magnification scopes and low-resolution AOI do not work effectively. Magnification of  $20\times$  to  $50\times$  is required for visual inspections of fine circuits, and higher resolutions are required for AOI systems. Low contrast between copper and polyimide base creates another difficulty for traditional AOI equipment. It is not easy for common AOI systems to distinguish the copper traces from the circuits on the other side of a double-sided circuit built on adhesiveless substrate, because the base layer is very transparent and the sensor detects both sides of the circuits as one.

**TABLE 67.1** Key Inspection Issues for High-Density Flex Circuit

Item	Issues
Finer traces	Resolution of AOI
Micro-blind via holes	Low contrast for AOI Resolution of AOI
Unstable materials	Dimensional accuracy
Photoimageable coverlay	Low contrast for AOI
Fragile traces	Damage during processes Damage from test probe pins
Fragile flying leads	Damage after AOI
Microbump arrays	3-D constructions
Cosmetic defects	Serious failures caused by small defects

### 67.3 AUTOMATIC OPTICAL INSPECTION SYSTEMS

AOI is the most valuable inspection equipment for detecting dimensional defects in the traces and spaces of the printed circuits, especially for high-density traces. It's also very useful for the detection of cosmetic defects on the surfaces. Further sensitivities are required for AOI systems to detect small defects on coverlay, flying leads, microbumps, narrow space perimeters, and so on. These small defects have low contrast, different kinds of brightness, and different defect shapes, among other things. Traditional AOI systems are usually not appropriate for inspection in these circumstances.

Traditional AOI systems were designed for rigid circuit boards, and they were originally only good for the detection of copper trace qualities. They could work for  $50\text{-}\mu\text{m}$ -line/space fine traces, but their inspection speed could be very slow. Therefore, remarkable progress has been made in the resolution and productivity of the newer AOI systems; and as a result, systems can now detect  $1.5\text{-}\mu\text{m}$  defects on  $15\text{-}\mu\text{m}$  traces. Also, the systems have other capabilities for detecting various defects on polyimide films and coverlay films. A careful review of AOI capabilities, compared to the specified design requirements, should be done prior to committing to a particular equipment.

## 67.4 DIMENSIONAL MEASUREMENTS

---

It seems to be an impossibility to require accurate dimensions on an unstable, thin, flexible material. However, high-density interconnects in particular demand very high accuracy in the termination area of the circuits, even though the dimensional allowance is smaller than the dimensional stability of flexible substrate materials. Therefore, high-accuracy 2-D or 3-D dimension measurement technologies are required.

There has been continuous progress in dimension-measuring equipment. The newest 3-D measurement equipment has a resolution higher than  $0.2\text{-}\mu\text{m}$  and accuracy higher than  $1\ \mu\text{m}$ , with statistical data in a 200-mm square 100-mm high. It has automatic measuring capabilities to detect each measuring point, producing statistical data. It can provide standard deviation data for each point with  $Cpk$  value.

Usually, there are several critical points that require exact dimensional accuracy in a flexible circuit. They are guide marks and termination areas, and customers ask exact tolerance for each dimension. The stable dimensions, such as punched perimeters processed by blanking dies, can be represented with the first article. However, unstable dimensions such as line width and pad pitch should be checked for each circuit. A statistical method is available. The measurement can be conducted by sampling when  $Cpk$  is larger than 1.3, but 100 percent measurement should be done when  $Cpk$  is smaller than 1.0. See MIL-STD-414 for help in reducing the number of samples.

## 67.5 ELECTRICAL TESTS

---

Electrical tests of high-density flex circuits could be one of the largest issues. Electrical open/short performance must be guaranteed as the minimum function of flex circuits. A traditional contact electrical testing method presents two basic barriers in inspection of high-density flex circuits. The first is a geometric limit of probe pins. The costs of test fixtures are in inverse proportion to pitches of pin arrays, and  $150\text{-}\mu\text{m}$ -pitch arrays could be the physical limit of pin probes. The second problem is physical damage caused by probe pins on fine traces, especially on fragile flying leads. A bus bar trace for a plating process is a problem in detecting shorts in circuits with the traditional pin-contact electrical-test method. A new additional electrical test method is required.

A noncontact electrical test system can detect all open/short failures for  $50\text{-}\mu\text{m}$ -pitch fine traces without pin contacts. It does not make any dents or cause damage on the fine traces. It works for fragile, fine flying leads because it is a non-contact inspection system. The basic principle of the method is illustrated in Fig. 67.1.

An electric field sensor or a magnetic field sensor prepared for each circuit will detect all opens and shorts in branched circuits. Another big advantage of the non-contact test system is that it works for general circuits that have a common bus bar for electrical plating. The circuits must be isolated to conduct the electrical short test when traditional contact test methods are being used.

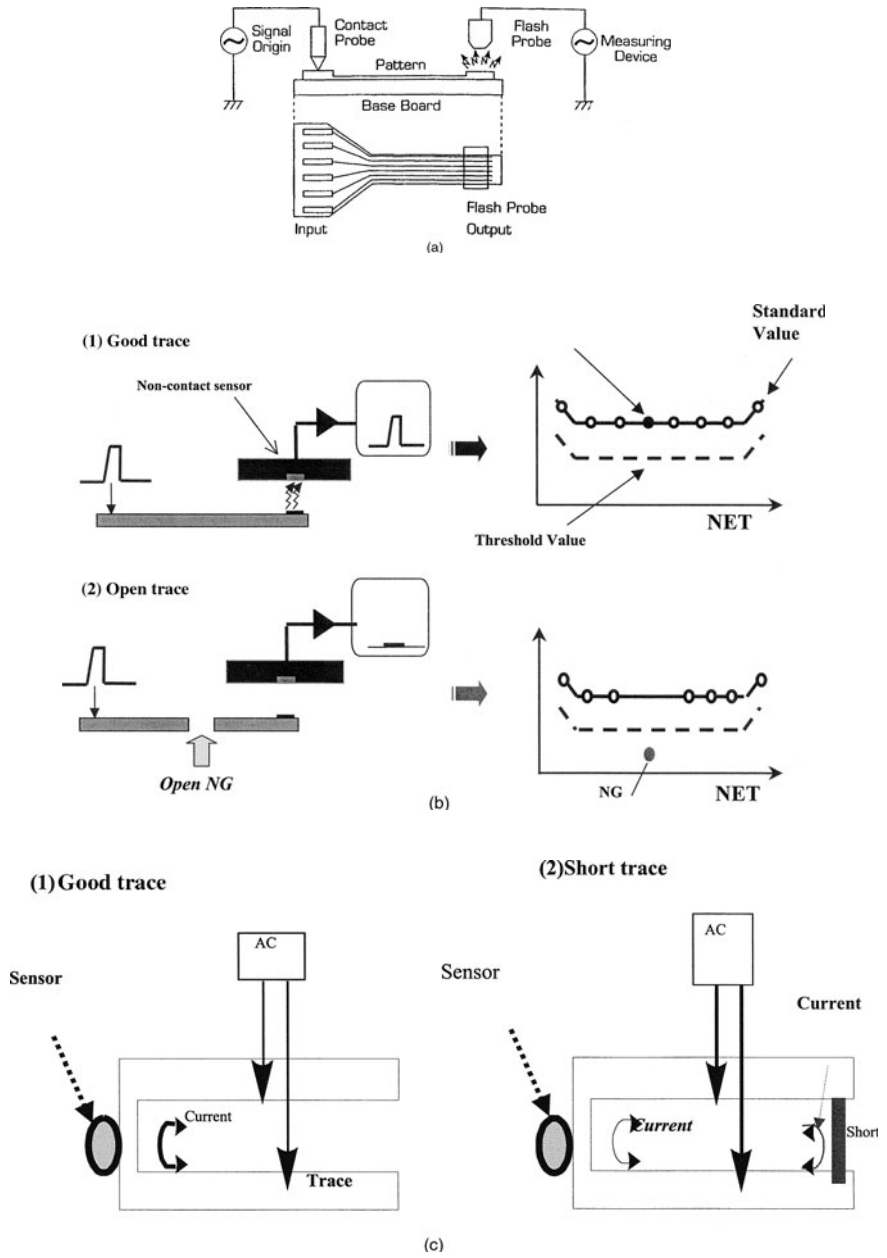

A non-contact electrical test system can inspect more than 5000 traces in a few seconds, eliminating physical damage to the circuits. It is also possible to use it in reel-to-reel processes. On the other hand, it still requires electrical contact on the other side of the fine traces, and therefore appropriate extra leads are required for pin or conductive rubber contacts.

## 67.6 INSPECTION SEQUENCE

---

Table 67.2 shows major quality assurance items for the final high-density flexible circuit products.

It is difficult to check all items after each manufacturing process. Therefore, an appropriate inspection sequence in the total manufacturing flow should be designed.

**FIGURE 67.1** Noncontact electrical testing of flexible circuits (a) General principle of noncontact electrical testing showing contact only at the input. (b) Principle of noncontact testing for open circuits where NG means “no go” (rejected). (c) Principle of noncontact testing for short-circuits, using a bus bar circuit. (Source:OHT.)

**TABLE 67.2** Quality Assurance Items for High-Density Flex Circuits

Item	Requirements
Physical properties	Sampling tests of raw materials Sampling tests of coupons
Opens/shorts	100% electrical inspection
Reliability of micro via holes	Cross sections obtained by sampling Daisy-chain test by coupon
Dimensional accuracy	Sampling by MIL-414 or 100%
Trace quality	100% inspection
Coverlay opening	Visual inspection, 100% or by sampling
Flying leads	Sampling test for dimensions 100% for straightness
Cosmetic defects	100% visual inspection, audit by MIL-105

On the other hand, it is a basic concept that failures should be eliminated as early as possible to ensure a high process yield, from a quality control standpoint, especially for long manufacturing processes. Figure 67.2 shows the general manufacturing flow of high-density flexible circuits, and a recommended inspection procedure.

**FIGURE 67.2** Manufacturing process for HDI flexible circuits and key inspection steps.

## 67.7 RAW MATERIALS

---

The basic properties of the raw materials should be guaranteed by material vendors; however, it is still necessary to conduct incoming inspections by circuit manufacturers. There is less experience with the new materials developed for high-density flex circuits than with traditional materials. Physical properties and cosmetic defects should be inspected by sampling.

## 67.8 FLEXIBLE CIRCUIT FEATURE INSPECTION

---

Flexible circuit features that require special consideration include:

- Micro-size holes
- Trace quality
- Coverlay and surface treatments

### 67.8.1 Micro-Size Hole Inspection

Several new technologies have been developed to generate blind holes smaller than 100  $\mu\text{m}$ .

These include lasers, plasma etching, and chemical etching. Unfortunately, the reliability of micro-hole generation processes has not been established exactly, and a suitable inspection system should be used. Traditional hole checkers do not work on blind holes. An AOI system is sensitive to the low contrast of copper foil surfaces.

There is no perfect, nondestructive test method for evaluating the reliability of micro via holes. It is not easy to create suitable conditions for uniform plating of copper in very small holes. As a result, cross-sectional inspections should be done periodically. Also, a daisy-chain coupon arranged beside the circuits in the work should be tested periodically.

### 67.8.2 Trace Quality

As there is no perfect circuit generation process for fine traces, a high-resolution AOI system is required for high-density flex circuits. All serious defects larger than one-fourth of conductor widths or spaces must be detected by AOI. This means the AOI system must have a resolution higher than 5  $\mu\text{m}$  for 25- $\mu\text{m}$  traces. An appropriate sensitivity should be set in the AOI system to distinguish the copper traces from the polyimide base film and the traces on the other side of the film. It makes sense to apply AOI before etching to avoid a material loss. An algorithm of PC-Micro II can reduce the inspection time by applying high-resolution capabilities focusing on specific areas.

### 67.8.3 Coverlay and Surface Treatments

Coverlays and surface treatments are very difficult for current AOI systems to inspect because of the small optical contrast between coverlay materials and conductors or substrate materials. It may be better to apply AOI after a surface treatment, which will increase the contrast.

Gold plating and tin plating create a clear contrast, and a small defect can be detected by AOI. The thickness and quality of surface treatments should be inspected immediately after the processes.

### 67.8.4 Microbump Arrays

Both cosmetic inspections and dimensional measurements are required for microbump arrays.

Also, new ideas for inspecting 3-D constructions are needed. The uniformity of the bumps and cosmetic defects could be inspected by a suitable AOI system. The 3-D size of the bump and array pitches should be measured by a high-accuracy 3-D measuring system.

### 67.8.5 Flying Leads

The appropriate places for inspection of flying leads depend on the manufacturing process of the circuits. Flying leads should be inspected just after they are generated by copper etching or by engraving of the substrate. Both AOI inspection and dimensional measurement are required.

Usually, flying leads have a severe dimensional allowance for both line-width and pitches for reliable termination.

### 67.8.6 Electrical Testing (Opens/Shorts)

The electrical function is the basic and most important performance of the circuit. Unfortunately, the reliability of manufacturing processes for high-density flex circuits has not been established perfectly. There are many possibilities to cause further damage to the traces after the etching process and the AOI process, and therefore a 100 percent electrical test is necessary at the end of manufacturing to guarantee the circuit's performance. This is similar in objective to rigid, bare-board testing, and Chaps. 36 to 38 provide a detailed discussion of these issues.

Certainly, final electrical tests must not cause any additional damage to the fragile, fine traces.

The best solution is a non-contact electrical test. An appropriate design of non-contact sensors combining flash probe, flash shock, common flash, and surface probe of OHT can reduce the total inspection cost. A suitable circuit pattern should be arranged at the beginning. The inspection should be conducted before blanking for handling convenience when final circuits are very tiny.

### 67.8.7 Physical Properties (Final Properties)

The properties of raw materials do not represent final properties of the circuits. They undergo change during the manufacturing process, and therefore final properties should be measured at the end of the manufacturing process. Generally, most of electrical, mechanical, and chemical properties are different from those of raw materials. Critical properties such as flexing endurance, insulation resistance, and heat resistance should be measured carefully.

IPC-TM-650 indicates a flexing endurance test method based on a flexing mode, as shown in Fig. 67.3. Unfortunately, the test method takes a very long time (sometimes more than a month) to give a final result by conductor failure. JIS-C5016 indicates an alternative test method called the MIT test, as shown in Fig. 67.4. This method does not require more than 1 hour for one test. It is not specified by a public industrial standard, however, a new flexing endurance test method for the spiral wiring illustrated in Fig. 67.5 has been required by the mobile equipment manufacturers such as notebook computers or clamshell type cellular phones.

FIGURE 67.3 IPC test method for flexing endurance.

**FIGURE 67.4** JIS-C5016 MIT test method for flexing endurance. R is the radius of the bend during the test symbol for “theta” is the angle from vertical.

**FIGURE 67.5** Flexing endurance test for spiral wiring.

### 67.8.8 Cosmetic Quality

There is no perfect automatic inspection system that can detect all cosmetic defects. Visual inspection at high magnification is the most reliable inspection method of eliminating all kinds of defects in high-density flex circuits. A stereomicroscope with high magnification helps the inspection procedure, but inspectors need training with exact criteria sample books. A final audit to confirm the level of the inspections is also recommended. MIL-STD-105 could help to reduce number of samples for the audit.

## 67.9 STANDARDS AND SPECIFICATIONS FOR FLEXIBLE CIRCUITS

Most of the major standards associations have generated new standards or upgraded existing ones for flexible circuits. Major flexible circuit standards and relating standards are listed in the following sections.

### 67.9.1 IEC

- IEC 249-2-15: Flexible copper-clad polyimide film of defined flammability grade
- IEC 326-7: Specification for single- and double-sided flexible printed boards without through-hole connections

- IEC 326-8: Specification for single- and double-sided flexible printed boards with through hole connections
- IEC 326-9: Specification for multilayer flexible printed boards with through-hole connections
- IEC 326-10: Specification for flex/rigid double-sided printed boards with through-hole connections
- IEC 326-11: Specification for flex/rigid multilayer printed boards with through-hole connections

### **67.9.2 IPC**

- IPC-FC-231C: Flexible bare dielectrics for use in flexible printed wiring
- IPC-FC-232C: Specification for adhesive coated dielectric films for use as cover sheets for flexible printed wiring
- IPC-FC-234: Pressure sensitive adhesives assembly guidelines for single-sided and double-sided printed circuits
- IPC-FC-241C: Flexible metal-clad dielectrics for use in fabrication of flexible printed wiring
- IPC-RF-245: Performance specification for rigid-flex printed boards
- IPC-D-249: Design standard for flexible single and double-sided printed boards
- IPC-FC-250A: Specification for single and double-sided flexible printed wiring
- IPC-FA-251: Guidelines for assembly of single and double-sided flex circuits
- IPC-6013A: Qualification and performance specification for flexible printed boards

### **67.9.3 JIS**

- JIS-C 5016: Test methods for flexible printed wiring boards
- JIS-C 5017: Flexible printed wiring boards, single-sided and double-sided
- JIS-C 6471: Test methods for copper-clad laminates of flexible printed wiring boards
- JIS-C 6472: Copper-clad laminates for flexible printed wiring boards (polyester film, polyimide film)

### **67.9.4 JPCA**

- JPCA-BM 01: Copper-clad laminates of flexible printed circuits, polyester films, and polyimide films
- JPCA-FC 01: Single-sided flexible printed circuits
- JPCA-FC 02: Double-sided flexible printed circuits
- JPCA-FC 03: Visual defect criteria for flexible printed circuits

### **67.9.5 MIL**

- MIL-STD-2118: Flexible and rigid-flex printed-wiring for electronic equipment
- MIL-C-28809: Circuit card assemblies, rigid, flexible and rigid-flex
- MIL-P-50884C: Printed wiring, flexible and rigid-flex

### **67.9.6 UL**

- UL796F: Flexible materials interconnect constructions

## APPENDIX

---

# SUMMARY OF KEY COMPONENT, MATERIAL, PROCESS, AND DESIGN STANDARDS

---

**David W. Bergman**

*(IPC)-Association Connecting Electronics Industries, Bannockburn, Illinois*

The following documents center on surface-mount technology. These documents have been developed by standards organizations in the United States and internationally. The letters in each document designation indicate the organization that has responsibility for the document:

ECA: Documents prepared by the Electronic Components, Assemblies, Equipment and Supplies Association (ECA) of the Electronic Industries Alliance (EIA).

DoD: Documents prepared by the Department of Defense.

IEC: Documents prepared by the IEC — International Electrotechnical Commission.

IECQ: Documents prepared for Quality Assessment System for Electronic Components supported through the IEC.

IPC: Documents prepared by the IPC—Association Connecting Electronics Industries.

JEDEC: Documents of the Solid State Technology Association of the Electronic Industries Alliance (EIA).

JESD: Standards prepared by JEDEC.

J-STD: Joint industry standards (standards followed by more than one association).

MIL: Documents prepared by the military.

SMC: Documents published by the Surface Mount Council.

---

### ***SURFACE MOUNT COUNCIL PUBLICATIONS***

---

SMC-TR-001: An Introduction to Tape Automated Bonding Fine Pitch Technology

SMC-WP-001: Soldering Capability

SMC-WP-002: An Assessment of the Use of Lead in Electronic Assemblies

SMC-WP-003: Chip Mounting Technology  
SMC-WP-004: Design for Excellence  
SMC-WP-005: PWB Surface Finishes

## ***COMPONENTS, GENERAL***

---

EIA-186-E: Standard Test Methods for Passive Electronic Component Parts—General Instructions and Index  
EIA-481-2-A: Embossed Carrier Taping of Surface Mount Components for Automatic Handling (16, 24, 32, 44, and 56 mm)  
EIA-944: Surface Mount Ferrite Chip Bead Qualification Specification  
EIA-945: Surface Mount Inductor Qualification Specification  
EIA/IS-47: Contact Termination Finish Standard for Surface Mount Devices  
EIA/IS-760: Surface Mount Wirewound Inductor Qualification Specification  
EIA-PDP-100: Registered and Standard Mechanical Outlines for Electronic Parts  
EIA-JEP-95: JEDEC Registered and Standard Outlines for Solid State and Related Products  
EIA-JESD30B: Descriptive Designation System for Semiconductor Device Packages  
JESD-625A: Requirements for Handling Electrostatic-Discharge-Sensitive (ESDS) Devices

## ***PASSIVE COMPONENTS***

---

### **Capacitors**

ECA SP 4984: Surface Mount Aluminum Electrolytic Chip Capacitor with Polymer Cathode  
EIA-198-E: Ceramic Dielectric Capacitors Classes I, II, III, and IV  
EIA-469-C: Standard Test Method for Destructive Physical Analysis of High Reliability Ceramic Monolithic Capacitors  
EIA-479A: Film-Paper, Film Dielectric Capacitors for 50/60 Hz Voltage Doubler Power Supplies  
EIA-535: Series of Detail Specifications on Fixed Tantalum Capacitors  
EIA-595: Visual and Mechanical Inspection Multilayer Ceramic Chip Capacitors  
EIA/IS-35: Two-Pin Dual In-Line Capacitors  
EIA/IS-36: Chip Capacitors, Multi-Layer (Ceramic Dielectric)  
EIA/IS-37: Multiple Layer High Voltage Capacitors (Radial Lead Chip Capacitors)  
EIA/IS-717: Surface Mount Tantalum Capacitor Qualification Specification  
IEC-384-3: Sectional Specification, Tantalum Chip Capacitors  
IEC-384-10: Sectional Specification, Fixed Multilayer Ceramic Chip Capacitors  
IECQ Draft: Blank Detail Specification, Fixed Multilayer Ceramic Chip Capacitors  
IECQ-PQC-31: Sectional Specification, Fixed Tantalum Chip Capacitors with Solid Electrolyte  
IECQ-PQC-32: Blank Detail Specification, Fixed Tantalum Chip Capacitor

**Resistors**

EIA/ECA-575 Resistors, Rectangular, Surface Mount General Purpose  
 EIA/ECA-576 Resistors, Rectangular, Surface Mount Precision  
 EIA/IS-30 Resistors, Rectangular Surface Mount Thick Film  
 EIA/IS-34: Leaded Surface Mount Resistor Networks, Fixed Film  
 ECA SP 5052 Resistors, Rectangular, Surface Mount, General Purpose  
 ECA SP 5053 Resistors, Rectangular, Surface Mount, Precision

**ACTIVE COMPONENTS**

---

EIA-JEP-95: JEDEC Registered and Standard Outlines for Solid State and Related Products  
 EIA-JESD11: Chip Carrier Pinouts Standardized for CMOS 4000, HC, and HCT Series of Logic Circuits  
 EIA-JESD21-C: Configurations for Solid State Memories  
 EIA-JESD22-B: Test Methods and Procedures for Solid State Devices Used in Transportation/Automotive Applications (series format—consists of over 16 different test procedure documents)  
 EIA-JESD-26A: General Specification for Plastic Encapsulated Microcircuits for Use in Rugged Applications  
 EIA-JESD-30: Descriptive Designation System for Semiconductor Device Packages  
 EIA SP 4251 Detail Specification for Production Ball Grid Array (BGA), High Pin Count (1089 Pins and Greater) Socket for Use in Electronic Equipment

**ELECTROMECHANICAL COMPONENTS**

---

**Connectors**

EIA-364-C: Electrical Connector/Socket Test Procedures Including Environmental Classifications  
 EIA/IS-47: Contact Termination Finish Standard for Surface Mount Devices  
 IPC-CI-408: Design and Application Guidelines for the Use of Solderless Surface Mount Connectors

**Sockets**

EIA-5400000: Generic Specification for Sockets for Use in Electronic Equipment  
 EIA-540H000: Sectional Specification for Burn-In Sockets Used with Ball Grid Array Devices for Use in Electronic Equipment

**Switches**

EIA-448-23: Surface Mountable Switches, Qualification Test  
 EIA-520aad: Detail Specification for Single Pole, Single Throw, Surface Mount Pushbutton Switches

EIA-520daad: Detail Specification for Single Pole, Double Throw, Surface Mount Sub-miniature Size Toggle Switches  
EIA-5200000-C: Generic Specification for Special-Use Electromechanical Switches of Certified Quality  
EIA-SP-2186: Detail Specification for Single Pole, Double Throw, Surface Mount Sub-miniature Size Toggle Switches  
EIA-SP-3162: Detail Specification for Single Pole, Single Throw, Surface Mount Pushbutton Switches  
IECQ-PQC-41: Detail Specification, Dual-in-Line Switch, Surface Mountable, Slide Actuated US0003

### **Printed Boards**

IPC-6011: General Performance Requirements for Printed Boards  
IPC-6012: Performance Specification for Rigid Printed Boards  
IPC-6013: Performance Specification for Flexible Printed Boards  
IPC-6015: Performance Specification for Organic Multichip Module Structures (MCM-L)  
IPC-6016: Qualification and Performance Specification for High Density Interconnect (HDI) Layers or Boards  
IPC-6018: Microwave End Product Board Inspection and Test  
IPC/JPCA-6202: Performance Guide Manual for Single- and Double-Sided Flexible Printed Wiring Boards  
MIL-PRF-31032: Printed Circuit Board/Printed Wiring Board Manufacturing, General Specification  
MIL-P-50884: Military Specification for Printed Wiring, Flexible, and Rigid Flex  
MIL-PRF-55110: Performance Specification, Printed Wiring Boards, Rigid General Specification

### **Materials**

IPC-3406: Guidelines for Electrically Conductive Surface Mount Adhesive  
IPC-3407: General Requirements for Isotropically Conductive Adhesives  
IPC-3408: General Requirements for Anisotropically Conductive Adhesive Films  
IPC-4101: Specification for Base Materials for Rigid and Multilayer Boards  
IPC-4103: Specification for Plastic Substrates, Clad or Unclad, for High Speed/High Frequency Interconnection  
IPC-4110: Specification and Characterization Methods for Nonwoven Cellulose Based Paper for Printed Boards  
IPC-4121: Guidelines for Selecting Core Constructions for Multilayer Printed Wiring Board Applications  
IPC-4130: Specification and Characterization Methods for Nonwoven "E" Glass Mat  
IPC-4202: Flexible Base Dielectrics for Use in Flexible Printed Wiring  
IPC-4203: Adhesive Coated Dielectric Films for Use as Cover Sheets  
IPC-4204: Flexible Metal-Clad Dielectrics for Use in Fabrication of Flexible Printed Circuitry  
IPC-4411: Specification and Characterization Methods for Nonwoven Para-Aramid Reinforcement

IPC-4412: Specification for Finished Fabric Woven form “E” Glass for Printed Boards  
IPC-4552: Specification for Electroless Nickel/Immersion Gold (ENIG) Plating for Printed Circuit Boards  
IPC-4553: Specification for Immersion Silver Plating for Printed Circuit Boards  
IPC-4562: Metal Foil for Printed Wiring Applications  
IPC-CC-830A: Qualification and Performance of Electrical Insulation Compounds for Printed Board Assemblies  
IPC-CF-148: Resin Coated Metal for Multilayer Printed Boards  
IPC-CF-152A: Metallic Foil Specification for Copper/Invar/Copper (CIC) for Printed Wiring and Other Related Applications  
IPC/JPCA-4104: Specification for High Density Interconnect (HDI) and Microvia Materials  
IPC-SM-840C: Qualification and Performance of Permanent Solder Mask for Printed Boards  
J-STD-004: Requirements for Soldering Fluxes  
J-STD-005: General Requirements and Test Methods for Electronic Grade Solder Paste  
J-STD-006: General Requirements and Test Methods for Soft Solder Alloys and Fluxed and Non Fluxed Solid Solders for Electronic Soldering Applications

## ***DESIGN ACTIVITIES***

---

IPC-C-406: Design and Application Guidelines for Surface Mount Connectors  
IPC-D-279: Reliability Design Guidelines for Surface Mount Technology Printed Board Assemblies  
IPC-1902: Grid Systems for Printed Circuits (equivalent to IEC 60097)  
IPC-2141: Design Guide for High-Speed Controlled Impedance Circuit Boards  
IPC-2221: Generic Standard on Printed Board Design  
IPC-2222: Sectional Design Standard for Rigid Organic Printed Boards  
IPC-2223: Sectional Design Standard for Flexible Printed Boards  
IPC-2224: Sectional Standard for Design of PWBs for PC Cards  
IPC-2225: Sectional Design Standard for Organic Multichip Modules (MCM-L) and MCM-L Assemblies  
IPC-2226: Design Standard for High-Density Array or Peripheral Leaded Component Mounting Structures  
IPC-2251: Design Guidelines for Electronic Packaging Utilizing High Speed Techniques  
IPC-2252: Design and Manufacturing Guide for RF/Microwave Circuit Boards  
IPC-2615: Printed Board Dimensions and Tolerances  
IPC-7351: Generic Requirements for Surface Mount Design and Land Pattern Standard  
IPC-7525: Guidelines for Stencil Design  
IPC-7530: Guidelines for Temperature Profiling for Mass Soldering (Wave and Reflow) Processes  
IPC/JPCA-2315: Design Guide for High Density Interconnects (HDI) and Microvia  
J-STD-026: Semiconductor Design Standard for Flip Chip Applications  
J-STD-027: Mechanical Outline Standard for Flip Chip or Chip Scale Configurations  
MIL-STD-2118: Design Standard for Flexible Printed Wiring

## **COMPONENT MOUNTING**

---

EIA-CB-11: Guidelines for the Surface Mounting of Multilayer Ceramic Chip Capacitors  
IPC-CM-770D: Guidelines for Printed Board Component Mounting  
IPC-SM-780: Electronic Component Packaging and Interconnection with Emphasis on Surface Mounting  
IPC-SM-784: Guidelines for Direct Chip Attachment  
IPC-MC-790: Guidelines for Multichip Module Technology Utilization  
IPC-4104: Specification for High Density Interconnect (HDI) and Microvia Materials  
IPC-6016: Qualification and Performance Specification for High Density Interconnect (HDI) Layers or Boards  
IPC-7095: Design and Assembly Process Implementation for BGAs  
IPC/JPCA-2315: Design Guide for High Density Interconnects (HDI) and Microvias  
J-STD-012: Implementation of Flip Chip and Chip Scale Technology  
J-STD-013: Implementation of Ball Grid Array and Other High Density Technology  
J-STD-032: Performance Standard for Ball Grid Array Bumps and Columns

## **SOLDERING AND SOLDERABILITY**

---

EIA-448-19: Method 19: Test Standard for Electromechanical Components, Environmental Effects of Machine Soldering Using a Vapor Phase System  
EIA-534: Applications Guide, Soldering and Solderability Maintenance of Leaded Electronic Components  
EIA-638: Surface Mount Solderability Test  
EIA/IS-46: Test Procedure for Resistance to Soldering (Vapor Phase Technique) for Surface Mount Devices  
EIA/IS-86: Surface Mount Solderability Test  
EIA SP 3408: Surface Mount Solderability Test  
IPC-AJ-820: Assembly and Joining Handbook  
IPC-HDBK-001: Handbook and Guide to the Requirements for Soldered Electrical and Electronic Assemblies  
IPC-S-816: Troubleshooting for Surface Mount Soldering  
IPC-TR-460A: Troubleshooting Checklist for Wave Soldering Printed Wiring Boards  
IPC-TR-462: Solderability Evaluation of Printed Boards with Protective Coatings over Long-Term Storage  
IPC-TR-464: Accelerated Aging for Solderability Evaluations  
J-STD-001: Requirements for Soldered Electrical and Electronic Assemblies  
J-STD-002: Solderability Tests for Component Leads, Terminations, Lugs, Terminals and Wires  
J-STD-003: Solderability Tests of Printed Boards  
JESD22: B102C Solderability Test Methods

**QUALITY ASSESSMENT**

---

IPC-A-20/21: Stencil Pattern for Solder Paste Slump Test

IPC-A-24: Flux/Board Interaction Board

IPC-A-36: CFC Cleaning Alternatives Artwork

IPC-A-38: Fine Line Round Robin Test Pattern

IPC-A-48: Surface Mount Airforce Mantech Artwork

IPC-A-600: Acceptability of Printed Boards

IPC-A-610: Acceptability of Printed Board Assemblies

IPC-7912: Calculation of DPMO and Manufacturing Indices for Printed Wiring Assemblies

IPC-9191: General Guideline for Implementation of Statistical Process Control (SPC)

IPC-9194: Implementation of Statistical Process Control (SPC) Applied to Printed Board Assembly Manufacture Guideline

IPC-9199: SPC Quality Rating

IPC-9201: Surface Insulation Resistance Handbook

IPC-9251: Test Vehicles for Evaluating Fine Line Capability

IPC-9252: Guidelines and Requirements for Electrical Testing of Unpopulated Printed Boards

IPC-9261: In-Process DPMO and Estimated Yield for PWAs

IPC/JEDEC J-STD-020: Moisture/Reflow Sensitivity Classification for Plastic Integrated Circuits Surface Mount Devices

IPC/JEDEC-033: Standard for Handling, Packing, Shipping, and Use of Moisture Reflow Sensitive Surface Mount Devices

IPC/JEDEC J-STD-035: Acoustic Microscopy for Non-Hermetic Encapsulated Electronic Components

JEDEC JEP-150: Stress-Test-Driven Qualification of and Failure Mechanisms Associated with Assembled Solid State Surface-Mount Components

JEDEC JEP-179: Stress-Test-Driven Qualification of and Failure Mechanisms Associated with Assembled Solid State Surface-Mount Components

JEDEC JESD-51-3: Low Effective Thermal Conductivity Test Board for Leaded Surface Mount Packages

JEDEC JESD-51-5: Extension of Thermal Test Board Standards for Packages with Direct Thermal Attachment Mechanisms

JEDEC JESD-51-7: High Effective Thermal Conductivity Test Board for Leaded Surface Mount Packages

JEDEC JESD-51-9: Test Boards for Area Array Surface Mount Package Thermal Measurements

JEDEC JESD-51-10: Test Boards for Through-Hole Perimeter Leaded Package Thermal Measurements

JEDEC JESD 51-11 Test Boards for Through-Hole Area Array Leaded Package Thermal Measurements

J-STD-028: Performance Standard for Flip Chip/Chip Scale Bumps

MIL-STD-883: Methods and Procedures for Microelectronics

## ***SURFACE-MOUNT PROCESS***

---

IPC-SC-60: Post Solder Solvent Cleaning Handbook  
IPC-SA-61: Post Solder Semi Aqueous Cleaning Handbook  
IPC-AC-62: Post Solder Aqueous Cleaning Handbook  
IPC-CH-65: Guidelines for Cleaning of Printed Boards and Assemblies  
IPC-5701: Users Guide for Cleanliness of Unpopulated Printed Boards

## ***RELIABILITY***

---

IPC-D-279: Design Guidelines for Reliable Surface Mount Technology Printed Board Assemblies  
IPC-SM-785: Guidelines for Accelerated Surface Mount Attachment Reliability Testing  
IPC-9151: Printed Board Capability, Quality and Relative Reliability (PCQR<sup>2</sup>) Benchmark Test Standard and Database  
JEDEC JESD 22-A113: Preconditioning Of Nonhermetic Surface Mount Devices Prior to Reliability Testing  
JEDEC JESD 22-B113: Board Level Cyclic Bend Test Method for Interconnect Reliability Characterization of Components for Handheld Electronic Products

## ***NUMERICAL CONTROL STANDARDS***

---

IPC-2511: Generic Requirements for Implementation of Product Manufacturing Description Data and Transfer Methodology  
IPC-2512: Sectional Requirements for Implementation of Administrative Methods for Manufacturing Data Description  
IPC-2513: Sectional Requirements for Implementation of Drawing Methods for Manufacturing Data Description  
IPC-2514: Sectional Requirements for Implementation of Printed Board Manufacturing Data Description  
IPC-2515: Sectional Requirements for Implementation of Bare Board Product Electrical Testing Data Description  
IPC-2516: Sectional Requirements for Implementation of Assembled Board Product Manufacturing Data Description  
IPC-2517: Sectional Requirements for Implementation of Assembly Circuit Testing Data Description  
IPC-2518: Sectional Requirements for Implementation of Bill of Material Product Data Description  
EIA-267-C: Axis and Motion Nomenclature for Numerically Controlled Machines  
EIA-274-D: Interchangeable Variable Block Data Contouring, Format for Positioning and Contouring/Positioning Numerically Controlled Machines  
EIA-358-C: ANSI X3.4 American National Standard Code for Information Interchange for Numerical Machine Control Perforated Tape

EIA-408: Interface between Numerical Control Equipment on Data Terminal Equipment Employing Parallel Binary Data Interchange

EIA-431: Electrical Interface between Numerical Control and Machine Tools

EIA-441: Operator Interface Function of Numerical Controls

EIA-484-A: Electrical and Mechanical Interface Characteristics and Line Control Protocol Using Communication Control Characters for Serial Data Link between a Direct Numerical Control System and Numerical Control Equipment Employing Asynchronous Full Duplex Transmission

EIA-494-B: 32 Bit Binary CL (BCL) and 7 Bit ASCII CL (ACL) Exchange Input Format for Numerically Controlled Machines

## **TEST METHODS**

---

EIA-469-C: Standard Test Method for Destructive Physical Analysis of High Reliability Ceramic Monolithic Capacitors

EIA-638: Surface Mount Solderability Test

EIA IS 46: Test Procedure for Resistance to Soldering (Vapor Phase Technique) for Surface Mount Devices

IPC-9501: PWB Assembly Process Simulation for Evaluation of Electronic Components

IPC-9502: PWB Assembly Soldering Process Guidelines for Non-IC Electronic Components

IPC-9503: Moisture Sensitivity Classification for Non-IC Components

IPC-9504: Assembly Process Simulation for Evaluation of Non-IC Components

IPC-9701: Qualification and Performance Test Methods for Surface Mount Solder Attachments

IPC-9850: Surface Mount Equipment Performance Characterization

IPC/JEDEC-9702: Monotonic Bend Characterization of Board-Level Interconnects

IPC/JPCA-6801: Terms & Definitions, Test Methods, and Design Examples for Build-Up/High Density Interconnection

IPC-TM-650: Test Methods Manual

JEDEC Standard 22 Series: Test Methods

JEDEC JESD 22-A111: Evaluation Procedure for Determining Capability to Bottom Side Board Attach By Full Body Solder Immersion of Small Surface Mount Solid State Devices

JEDEC JESD 22-A112: Test Method A112, Moisture-Induced Stress Sensitivity for Plastic Surface Mount Devices

JEDEC JESD 22-B105-B: Test Method Lead Integrity

JEDEC JESD 22-B106: Test Method B106c, Resistance to Soldering Temperature for Through-Hole Mounted Devices

JEDEC JESD 22-B108: Coplanarity Test for Surface-Mount Semiconductor Devices

JEDEC JESD 22-B117: BGA Ball Shear

JEDEC JESD 51-8: Integrated Circuit Thermal Test Method Environmental Conditions Junction-to-Board

JESD 22-B108: Coplanarity Test for Surface Mount Semiconductor Devices

## **REPAIR**

---

IPC-7711A/7721A: Rework, Repair and Modification of Electronic Assemblies

## **TERMS AND DEFINITIONS**

---

IPC-T-50F: Terms and Definitions for Interconnecting and Packaging Electronic Circuits  
JEDEC JESD 12-1: Terms and Definitions for Gate Arrays and Cell-Based Integrated Circuits  
JEDEC JESD 77: Terms, Definitions and Letter Symbols for Discrete Semiconductor and Optoelectronic Devices  
JEDEC JESD 99: Terms, Definitions, and Letter Symbols for Microelectronic Devices  
JEDEC JESD 100: Terms, Definitions, and Letter Symbols for Microcomputers, Microprocessors, and Memory Integrated Circuits  
JEDEC JEP 99: Glossary of Microelectronic Terms, Definitions, Symbology

## **HOW TO OBTAIN THESE DOCUMENTS**

---

Following are the addresses of the IPC and EIA, as well as other sources for documents shown in this SMT listing:

IPC—Association Connecting Electronics Industries  
3000 Lakeside Drive #309S  
Bannockburn, IL 60015-1249  
Electronic Industries Alliance (EIA)  
2500 Wilson Boulevard  
Arlington, VA 22201-3834  
Phone: (703) 907-7500

Global Engineering Documents (Part of IHS)  
15 Inverness Way  
East Englewood, CO 80112  
Phone: (800) 854-7179

Military documents are available from the following address:

Standardization Documents Order Desk  
Building 4D, 700 Robbins Avenue  
Philadelphia, PA 19111-5094

Central office address of the IEC is as follows:

International Electrotechnical Commission (IEC)  
3 Rue de Varembe  
1211 Geneva 20, Switzerland

IEC documents are available from the following address:

American National Standards Institute (ANSI)  
11 West 42nd Street  
New York, NY 10036

# GLOSSARY\*

---

- ACCELERATOR:** A chemical that is used to speed up a reaction or cure, as cobalt naphthenate is used to accelerate the reaction of certain polyester resins. It is often used along with a catalyst, hardener, or curing agent. The term “accelerator” is often used interchangeably with the term “promoter.”
- ACCURACY:** The ability to place the hole at the targeted location.
- ADDITIVE PROCESS:** A process for obtaining conductive patterns by the selective deposition of conductive material on an unclad base material.
- ADHESIVE:** Broadly, any substance used in promoting and maintaining a bond between two materials.
- AGING:** The change in properties of a material with time under specific conditions.
- ANNULAR RING:** The circular strip of conductive material that completely surrounds a hole.
- ARC RESISTANCE:** The time required for an arc to establish a conductive path in a material.
- ARTWORK MASTER:** An accurately scaled configuration used to produce the production master.
- BACKUP MATERIAL:** A material placed on the bottom of a laminate stack in which the drill terminates its drilling stroke.
- BASE MATERIAL:** The insulating material upon which the printed wiring pattern may be formed.
- BASE MATERIAL THICKNESS:** The thickness of the base material excluding metal foil cladding or material deposited on the surface.
- BLIND VIA:** Conductive surface hole that connects an outerlayer with an innerlayer of a multilayer PWB without penetrating the entire board.
- BLISTERING:** Localized swelling and separation between any of the layers of the base laminate or between the laminate and the metal cladding.
- BONDING LAYER:** An adhesive layer used in bonding other discrete layers during lamination.
- BOND STRENGTH:** The force per unit area required to separate two adjacent layers by a force perpendicular to the board surface; usually refers to the interface between copper and base material.
- BOW:** A laminate defect in which deviation from planarity results in a smooth arc.
- B-STAGE:** An intermediate stage in the curing of a thermosetting resin. In it a resin can be heated and caused to flow, thereby allowing final curing in the desired shape.
- B-STAGE LOT:** The product from a single mix of B-stage ingredients.
- B-STAGE RESIN:** A resin in an intermediate stage of a thermosetting reaction. The material softens when heated and swells when in contact with certain liquids, but it may not entirely fuse or dissolve.
- BURIED VIA:** Conductive surface hole that connects one innerlayer to another innerlayer of a multilayer PWB without having a direct connection to either the top or bottom surface layer.
- BURR:** A ridge left on the outside copper surfaces after drilling.
- CAPACITANCE:** The property of a system of conductors and dielectrics which permits the storage of electricity when potential difference exists between the conductors.

---

\*Some terms may not be included in the glossary as they are treated in detail in the text. Please also see the index and subject chapters.

- CAPACITIVE COUPLING:** The electrical interaction between two conductors caused by the capacitance between the conductors.
- CARBIDE:** Tungsten carbide, formula WC. The hard, refractory material forming the drill bits used in PWB drillings.
- CATALYST:** A chemical that causes or speeds up the cure of a resin but does not become a chemical part of the final product.
- CERAMIC LEADED CHIP CARRIER (CLCC):** A chip carrier made from ceramic (usually a 90–96% alumina or beryllia base) and with compliant leads for terminations.
- CHIP CARRIER (CC):** An integrated circuit package, usually square, with a chip cavity in the center; its connections are usually on all four sides. (See *leaded chip carrier* and *leadless chip carrier*.)
- CHIP LOAD (CL):** The movement of the drill downward per revolution; usually given in mils (thousandths of an inch) per revolution.
- CHLORINATED HYDROCARBON:** An organic compound having chlorine atoms in its chemical structure. Trichloroethylene, methyl chloroform, and methylene chloride are chlorinated hydrocarbons.
- CIRCUIT:** The interconnection of a number of electrical devices in one or more closed paths to perform a desired electrical or electronic function.
- CLAD:** A condition of the base material, to which a relatively thin layer or sheet of metal foil (cladding) has been bonded on one or both of its sides. The result is called a metal-clad base material.
- CNC:** Computer numerically controlled. Refers to a machine with a computer which stores the numerical information about location, drill size, and machine parameters, regulating the machine to carry out that information.
- COAT:** To cover with a finishing, protecting, or enclosing layer of any compound.
- COLD FLOW:** The continuing dimensional change that follows initial instantaneous deformation in a nonrigid material under static load. Also called creep.
- COLLIMATION:** The degree of parallelism of light rays from a given source. A light source with good collimation produces parallel light rays, whereas a poor light source produces divergent, nonparallel light rays.
- COMPONENT HOLE:** A hole used for the attachment and electrical connection of a component termination, including pin or wire, to the printed board.
- COMPONENT SIDE:** The side of the printed board on which most of the components will be mounted.
- COMPOUND:** A combination of elements in a stable molecular arrangement.
- CONDUCTIVE FOIL:** The conductive material that covers one side or both sides of the base material and is intended for forming the conductive pattern.
- CONDUCTIVE PATTERN:** The configuration or design of the electrically conductive material on the base material.
- CONDUCTOR LAYER 1:** The first layer having a conductive pattern, of a multilayer board, on or adjacent to the component side of the board.
- CONDUCTOR SPACING:** The distance between adjacent edges (not centerline to centerline) of conductors on a single layer of a printed board.
- CONDUCTOR THICKNESS:** The thickness of the copper conductor exclusive of coatings or other metals.
- CONDUCTOR WIDTH:** The width of the conductor viewed from vertically above, that is, perpendicularly to the printed board.
- CONFORMAL COATING:** An insulating protective coating which conforms to the configuration of the object coated and is applied on the completed printed board assembly.
- CONNECTOR AREA:** The portion of the printed board that is used for providing external (input–output) electrical connections.
- CONTACT BONDING ADHESIVE:** An adhesive (particularly of the nonvulcanizing natural rubber type) that bonds to itself on contact, although solvent evaporation has left it dry to the touch.
- CONTROLLED IMPEDANCE:** The matching of substrate material properties with trace dimensions and locations to create a specific electric impedance as seen by a signal on the trace.

- COPOLYMER:** See *polymer*.
- CORE MATERIAL:** The fully cured inner-layer segments, with circuiting on one or both sides, that form the multilayer circuit.
- CORNER MARKS:** The marks at the corners of printed board artwork, the inside edges of which usually locate the borders and establish the contour of the board.
- COUPON:** One of the patterns of the quality conformance test circuitry area. (See *test coupon*.)
- CRAZING:** A base material condition in which connected white spots or crosses appear on or below the surface of the base material. They are due to the separation of fibers in the glass cloth and connecting weave intersections.
- CROSS-LINKING:** The forming of chemical links between reactive atoms in the molecular chain of a plastic. It is cross-linking in the thermosetting resins that makes the resins infusible.
- CROSS TALK:** Undesirable electrical interference caused by the coupling of energy between signal paths.
- CRYSTALLINE MELTING POINT:** The temperature at which the crystalline structure in a material is broken down.
- CTE:** Coefficient of thermal expansion. The measure of the amount a material changes in any axis per degree of temperature change.
- CURE:** To change the physical properties of a material (usually from a liquid to a solid) by chemical reaction or by the action of heat and catalysts, alone or in combination, with or without pressure.
- CURING AGENT:** See *hardener*.
- CURING TEMPERATURE:** The temperature at which a material is subjected to curing.
- CURING TIME:** In the molding of thermosetting plastics, the time in which the material is properly cured.
- CURRENT-CARRYING CAPACITY:** Maximum current which can be carried continuously without causing objectionable degradation of electrical or mechanical properties of the printed board.
- DATUM REFERENCE:** A defined point, line, or plane used to locate the pattern or layer of a printed board for manufacturing and/or inspection purposes.
- DEBRIS:** A mechanically bonded deposit of copper to substrate hole surfaces.
- DEBRIS PACK:** Debris deposited in cavities or voids in the resin.
- DEFINITION:** The fidelity of reproduction of the printed board conductive pattern relative to the production master.
- DELAMINATION:** A separation between any of the layers of the base laminate or between the laminate and the metal cladding originating from or extending to the edges of a hole or edge of the board.
- DIELECTRIC CONSTANT:** The property of a dielectric which determines the electrostatic energy stored per unit volume for a unit potential gradient.
- DIELECTRIC LOSS:** Electric energy transformed into heat in a dielectric subjected to a changing electric field.
- DIELECTRIC LOSS ANGLE:** The difference between  $90^\circ$  and the dielectric phase angle. Also called the dielectric phase difference.
- DIELECTRIC LOSS FACTOR:** The product of dielectric constant and the tangent of dielectric loss angle for a material.
- DIELECTRIC PHASE ANGLE:** The angular difference in phase between the sinusoidal alternating potential difference applied to a dielectric and the component of the resulting alternating current having the same period as the potential difference.
- DIELECTRIC POWER FACTOR:** The cosine of the dielectric phase angle (or sine of the dielectric loss angle).
- DIELECTRIC STRENGTH:** The voltage that an insulating material can withstand before breakdown occurs, usually expressed as a voltage gradient (such as volts per mil).
- DIMENSIONAL STABILITY:** Freedom from distortion by such factors as temperature changes, humidity changes, age, handling, and stress.
- DIRECT IMAGING:** The exposure of photo resist material with a laser without the use of positive or negative photo tool.

- DISSIPATION FACTOR:** The tangent of the loss angle of the insulating material. Also called loss tangent or approximate power factor.
- DRILL FACET:** The surface formed by the primary and secondary relief angles of a drill tip.
- DRILL WANDER:** The sum of accuracy and precision deviations from the targeted location of the hole.
- DUMMY:** A cathode with a large area used in a low-current-density pulsating operation for the removal of metallic impurities from solution. The process is called “dummying.”
- DWELL POINT:** The bottom of the drilling stroke before the drill bit ascends.
- EDGE-BOARD CONTACTS:** A series of contacts printed on or near an edge of a printed board and intended for mating with a one-part edge connector.
- EDX:** Energy dispersive x-ray fluorescent spectrometer
- ELASTOMER:** A material which at room temperature stretches under low stress to at least twice its length but snaps back to its original length upon release of the stress. Rubber is a natural elastomer.
- ELECTRIC STRENGTH:** The maximum potential gradient that a material can withstand without rupture. It is a function of the thickness of the material and the method and conditions of test. Also called dielectric strength or disruptive gradient.
- ELECTROLESS PLATING:** The controlled autocatalytic reduction of a metal ion on certain catalytic surfaces.
- EMULSION SIDE:** The side of the film or glass on which the photographic image is present.
- ENTRY MATERIAL:** A material placed on top of a laminate stack.
- EPOXY SMEAR:** Epoxy resin which has been deposited on edges of copper in holes during drilling either as a uniform coating or as scattered patches. It is undesirable because it can electrically isolate the conductive layers from the plated-through-hole interconnections.
- ETCHBACK:** The controlled removal of all the components of the base material by a chemical process acting on the sidewalls of plated-through holes to expose additional internal conductor areas.
- ETCH FACTOR:** The ratio of the depth of etch to lateral etch.
- EXOTHERM:** A characteristic curve which shows heat of reaction of a resin during cure (temperature) versus time. The peak exotherm is the maximum temperature on the curve.
- EXOTHERMIC REACTION:** A chemical reaction in which heat is given off.
- FIBER EXPOSURE:** A condition in which glass cloth fibers are exposed on machined or abraded areas.
- FILLER:** A material, usually inert, added to a plastic to reduce cost or modify physical properties.
- FILM ADHESIVE:** A thin layer of dried adhesive. Also, a class of adhesives provided in dry-film form with or without reinforcing fabric and cured by heat and pressure.
- FLEXURAL MODULUS:** The ratio, within the elastic limit, of stress to corresponding strain. It is calculated by drawing a tangent to the steepest initial straight-line portion of the load deformation curve and using the equation  $EB = L3m/4bd^3$ , where  $EB$  is the modulus,  $L$  is the span (in inches),  $m$  is the slope of the tangent,  $b$  is the width of beam tested, and  $d$  is the depth of the beam.
- FLEXURAL STRENGTH:** The strength of a material subjected to bending. It is expressed as the tensile stress of the outermost fibers of a bent test sample at the instant of failure.
- FLUOROCARBON:** An organic compound having fluorine atoms in its chemical structure, an inclusion that usually lends stability to plastics. Teflon\* is a fluorocarbon.
- GEL:** The soft, rubbery mass that is formed as a thermosetting resin goes from a fluid to an infusible solid. It is an intermediate state in a curing reaction, and a stage in which the resin is mechanically very weak.
- GEL POINT:** The point at which gelation begins.
- GLASS TRANSITION POINT:** The temperature at which a material loses properties and becomes a semiliquid.
- GLASS TRANSITION TEMPERATURE:** The temperature at which epoxy, for example, softens and begins to expand independently of the glass fabric expansion rate, usually symbolized as  $T_g$ .

---

\*Trademark of E. I. du Pont de Nemours & Company.

- GLUE-LINE THICKNESS:** Thickness of the fully dried adhesive layer.
- GRID:** An orthogonal network of two sets of parallel lines for positioning features on a printed board.
- GROUND PLANE:** A conducting surface used as a common reference point for circuit returns, shielding, or heat sinking.
- GULL WING LEAD:** A surface mounted device lead which flares outward from the device body.
- HALOING:** A light area around holes or other machined areas on or below the surface of the base laminate.
- HARDENER:** A chemical added to a thermosetting resin for the purpose of causing curing or hardening. A hardener, such as an amine or acid anhydride for an epoxy resin, is a part of the chemical reaction and a part of the chemical composition of the cured resin. The terms “hardener” and “curing agent” are used interchangeably.
- HEAT-DISTORTION POINT:** The temperature at which a standard test bar (ASTM D 648) deflects 0.010 in under a stated load of either 66 or 264 psi.
- HIGH-DENSITY INTERCONNECT (HDI):** Ultra fine-geometry multilayer PWB constructed with conductive surface microvia connections between layers. (Microvia is usually defined as a hole with a diameter less than 0.006 in.) These boards also usually include buried and/or blind vias and are made by sequential build-up lamination.
- HOLE PULL STRENGTH:** The force, in pounds, necessary to rupture a plated-through hole or its surface terminal pads when loaded or pulled in the direction of the axis of the hole. The pull is usually applied to a wire soldered in the hole, and the rate of pull is given in inches per minute.
- HOOK:** A geometric drill bit defect of the cutting edges.
- HOT-MELT ADHESIVE:** A thermoplastic adhesive compound, usually solid at room temperature, which is heated to fluid state for application.
- HYDROCARBON:** An organic compound containing only carbon and hydrogen atoms in its chemical structure.
- HYDROLYSIS:** The chemical decomposition of a substance involving the addition of water.
- HYGROSCOPIC:** Tending to absorb moisture.
- I-LEAD:** A surface mounted device lead which is formed such that the end of the lead contacts the board land pattern at a 90° angle. Also called a butt joint.
- IMPREGNATE:** To force resin into every interstice of a part, as of a cloth for laminating.
- INHIBITOR:** A chemical that is added to a resin to slow down the curing reaction and is normally added to prolong the storage life of a thermosetting resin.
- INORGANIC CHEMICALS:** Chemicals whose molecular structures are based on other than carbon atoms.
- INSULATION RESISTANCE:** The electrical resistance of the insulating material between any pair of contacts, conductors, or grounding devices in various combinations.
- INTERNAL LAYER:** A conductive pattern contained entirely within a multilayer board. **IPC:** Institute for Interconnecting and Packaging Electronic Circuits. A leading printed wiring industry association that develops and distributes standards as well as other information of value to printed wiring designers, users, suppliers, and fabricators. **IR:** Infrared heating for solder-reflow operation.
- J-LEAD:** A surface mounted device lead which is formed into a “J” pattern folding under the device body.
- JUMPER:** An electrical connection between two points on a printed board added after the printed wiring is fabricated.
- KIRKENDALL VOIDS:** In Cu-Au or Cu-Au-Sn systems, pores in the solder joint, or at copper interfaces occur through solid-state diffusion. Copper which has a relatively high solubility and solid-state mobility in gold diffuses into the gold. Transported by grain boundary diffusion at temperatures below 150°C, and by bulk diffusion above that temperature. Au-Sn regions result along with atomic vacancies. Then lattice vacancies are in profusion. Voids can be observed and this material depletion weakens the solder joint.
- LAMINATE:** The plastic material, usually reinforced by glass or paper, that supports the copper cladding from which circuit traces are created.

- LAMINATE VOID: Absence of epoxy resin in any cross-sectional area which should normally contain epoxy resin.
- LAND: See *terminal area*.
- LANDLESS HOLE: A plated-through hole without a terminal area.
- LASER PLOTTER (LASER PHOTO GENERATOR, OR LPG): A device that exposes photosensitive material, usually a silver halide or diazo material, subsequently used as the master for creating the circuit image in production.
- LAYBACK: A geometric drill bit defect of the cutting edges.
- LAYER-TO-LAYER SPACING: The thickness of dielectric material between adjacent layers of conductive circuitry.
- LAY-UP: The process of registering and stacking layers of a multilayer board in preparation for the laminating cycle.
- LCCC: Leadless ceramic chip carrier.
- LEAD-FREE: Referring to solder alloys made without lead, to conform with the requirements of the European Union directive on the Restriction of Hazard Substances (RoHS) the most important of which, to the printed circuit industry, is lead. Often used to refer to any process that is designed to be compatible with “lead-free” alloys.
- LEADED CHIP CARRIER: A chip carrier (either plastic or ceramic) with compliant leads from terminations.
- LEADLESS CHIP CARRIER: A chip carrier (usually ceramic) with integral metallized terminations and no compliant external leads.
- LEGEND: A format of lettering or symbols on the printed board, for example, part number, component locations, or patterns.
- LOOSE FIBERS: Supporting fibers in the substrate of the laminate which are not held in place by surrounding resin.
- MAJOR WEAVE DIRECTION: The continuous-length direction of a roll of woven glass fabric.
- MARGIN RELIEF: The area of a drill bit next to the cutting edge is removed so that it does not rub against the hole as the drill revolves.
- MASTER DRAWING: A document that shows the dimensional limits or grid locations applicable to any or all parts of a printed wiring or printed circuit base. It includes the arrangement of conductive or nonconductive patterns or elements; size, type, and location of holes; and any other information necessary to characterize the complete fabricated product.
- MEASLING: Discrete white spots or crosses below the surface of the base laminate that reflect a separation of fibers in the glass cloth at the weave intersection.
- MICROSTRIP: A type of transmission line configuration which consists of a conductor over a parallel ground plane separated by a dielectric.
- MICROVIA: Usually defined as a conductive hole with a diameter of 0.006 in or less that connects layers of a multilayer PWB. Often used to refer to any small-geometry connecting hole the creation of which is beyond the practical capabilities of traditional mechanical drilling processes.
- MINOR WEAVE DIRECTION: The width direction of a roll of woven glass fabric.
- MIXED ASSEMBLY: A printed wiring assembly that combines through-hole components and surface mounted components on the same board.
- MODULUS OF ELASTICITY: The ratio of stress to strain in a material that is elastically deformed.
- MOISTURE RESISTANCE: The ability of a material not to absorb moisture either from air or when immersed in water.
- MOUNTING HOLE: A hole used for the mechanical mounting of a printed board or for the mechanical attachment of components to a printed board.
- MULTILAYER BOARD: A product consisting of layers of electrical conductors separated from each other by insulating supports and fabricated into a solid mass. Interlayer connections are used to establish continuity between various conductor patterns.
- MULTIPLE-IMAGE PRODUCTION MASTER: A production master used to produce two or more products simultaneously.
- NAILHEADING: A flared condition of internal conductors.

- NC: Numerically controlled. Usually refers to a machine tool, in this case a drilling machine. The most basic type is one in which a mechanical guide locates the positions of the holes. NC machines are usually controlled by punched tape.
- NEMA STANDARDS: Property values adopted as standard by the National Electrical Manufacturers Association.
- NOBLE ELEMENTS: Elements that either do not oxidize or oxidize with difficulty; examples are gold and platinum.
- OILCANNING: The movement of entry material in the  $z$  direction during drilling in concert with the movement of the pressure foot.
- ORGANIC: Composed of matter originating in plant or animal life or composed of chemicals of hydrocarbon origin, either natural or synthetic.
- PAD: See *terminal area*.
- PADS ONLY: A multilayer construction with all circuit traces on inner layers and the component terminal area only on the surface of the board. This construction adds two layers but may avoid the need for a subsequent solder resist, and since inner layers usually are easier to form, this construction may lead to higher overall yields. PH: A measure of the acid or alkaline condition of a solution. A pH of 7 is neutral (distilled water); pH values below 7 represent increasing acidity as they go toward 0; and pH values above 7 represent increasing alkalinity as they go toward the maximum value of 14.
- PHOTOMASTER: An accurately scaled copy of the artwork master used in the photo fabrication cycle to facilitate photo processing steps.
- PHOTOPOLYMER: A polymer that changes characteristics when exposed to light of a given frequency.
- PINHOLES: Small imperfections which penetrate entirely through the conductor.
- PINK RING: The appearance of a halo of copper around the hole of a multilayer.
- PWB PITS: Small imperfections which do not penetrate entirely through the printed circuit.
- PLASTICIZER: Material added to resins to make them softer and more flexible when cured.
- PLASTIC LEADED CHIP CARRIER (PLCC): A chip carrier packaged in plastic, usually terminating in compliant leads (originally "J" style) on all four sides.
- PLATED-THROUGH HOLE: A hole in which electrical connection is made between printed wiring board layers with conductive patterns by the deposition of metal on the wall of the hole. (See *PTH*.)
- PLATING VOID: The area of absence of a specific metal from a specific cross-sectional area: (1) When the plated-through hole is viewed as cross-sectioned through the vertical plane, it is a product of the average thickness of the plated metal times the thickness of the board itself as measured from the outermost surfaces of the base copper on external layers. (2) When the plated-through hole is viewed as cross-sectioned through the horizontal plane (annular method), it is the difference between the area of the hole and the area of the outside diameter of the through-hole plating.
- PLOWING: Furrows in the hole wall due to drilling.
- POLYMER: A high-molecular-weight compound made up of repeated small chemical units. For practical purposes, a polymer is a plastic. The small chemical unit is called a mer, and when the polymer or mer is cross-linked between different chemical units (e.g., styrene-polyester), the polymer is called a copolymer. A monomer is any single chemical from which the mer or polymer or copolymer is formed.
- POLYMERIZE: To unite chemically two or more monomers or polymers of the same kind to form a molecule with higher molecular weight.
- POTLIFE: The time during which a liquid resin remains workable as a liquid after catalysts, curing agents, promoter, etc., are added. It is roughly equivalent to gel time.
- POWER FACTOR: The cosine of the angle between the applied voltage and the resulting current.
- PRECISION: The ability to repeatedly place the hole at any location.
- PREPRODUCTION TEST BOARD: A test board (as detailed in IPC-ML-950) the purpose of which is to determine whether, prior to the production of finished boards, the contractor has the capability of producing a multilayer board satisfactorily.

- PRESS PLATEN:** The flat heated surface of the lamination press used to transmit heat and pressure to lamination fixtures and into the lay-up.
- PRESSURE FOOT:** The tube like device on the drilling machine that descends to the top surface of the stack, holding it firmly down, before the drill descends through the center of the pressure foot. The vacuum system of the drilling machine separates through the pressure foot to remove chips and dust formed in drilling.
- PRINTED WIRING ASSEMBLY DRAWING:** A document that shows the printed wiring base, the separately manufactured components which are to be added to the base, and any other information necessary to describe the joining of the parts to perform a specific function.
- PRINTED WIRING LAYOUT:** A sketch that depicts the printed wiring substrate, the physical size and location of electronic and mechanical components, and the routing of conductors that interconnect the electronic parts in sufficient detail to allow for the preparation of documentation and artwork.
- PRODUCTION MASTER:** A 1:1 scale pattern used to produce one or more printed wiring or printed circuit products within the accuracy specified on the master drawing.
- PROMOTER:** A chemical, itself a feeble catalyst, that greatly increases the activity of a given catalyst.
- PTH:** Plated-through holes. Also refers to the technology that uses the plated-through hole as its foundation.
- QUADPACK:** Generic term for surface mount technology packages with leads on all four sides. Commonly used to describe chip carrier-like devices with gull wing leads.
- QUALITY CONFORMANCE CIRCUITRY AREA:** A test board made as an integral part of the multi-layer printed board panel on which electrical and environmental tests may be made for evaluation without destroying the basic board.
- RAW MATERIAL PANEL SIZE:** A standard panel size related to machine capacities, raw material sheet sizes, final product size, and other factors.
- REGISTER MARK:** A mark used to establish the relative position of one or more printed wiring patterns, or portions thereof, with respect to desired locations on the opposite side of the board.
- REGISTRATION:** The relative position of one or more printed wiring patterns, or portions thereof, with respect to desired locations on a printed wiring base or to another pattern on the opposite side of the base.
- REPAIR:** The correction of a printed wiring defect after the completion of board fabrication to render the board as functionally good as a perfect board.
- RESIN:** High-molecular-weight organic material with no sharp melting point. For current purposes, the term “resin,” “polymer,” and “plastic” can be used interchangeably.
- RESIST:** A protective coating (ink, paint, metallic plating, etc.) used to shield desired portions of the printed conductive pattern from the action of etchant, solder, or plating.
- RESISTIVITY:** The ability of a material to resist passage of electric current through its bulk or on a surface.
- RIFLING:** Spiral groove or ridge in the substrate due to drilling.
- RIGID/FLEX:** A PWB construction combining flexible circuits and rigid multilayer PWBs, usually either to provide a built-in connection or to make a three-dimensional form that includes components.
- ROCKWELL HARDNESS NUMBER:** A number derived from the net increase in depth of an impression as the load on a perpetrator is increased from a fixed minimum load to as higher load and then returned to minimum load.
- ROHS:** Acronym for “Restriction of Hazardous Substances,” The name given to a Directive of the European Union meant to reduce certain materials considered detrimental to the Environment.
- ROUGHNESS:** Irregular, coarse, uneven hole wall on copper or substrate due to drilling.
- SCHEMATIC DIAGRAM:** A drawing which shows, by means of graphic symbols, the electrical interconnections and functions of a specific circuit arrangement.
- SEM:** Scanning electron microscope.

- SEQUENTIAL BUILD-UP:** A process for making multilayer PWBs in which already finished multilayers are laminated together to form a higher-layer-count final board, or in which additional outerlayers are added to finished multilayer PWBs.
- SHADOWING:** Etchback to maximum limit without removal of dielectric material from conductors.
- SINGLE-IN-LINE PACKAGE (SIP):** Component package system with one line of connectors, usually spaced 0.100 in apart.
- SMC:** Surface mounted component. Component with terminations designed for mounting flush to printed wiring board.
- SMD:** Surface mounted device. Any component or hardware element designed to be mounted to a printed wiring board without penetrating the board.
- SMEAR:** Fused deposit left on copper or substrate from excessive drilling heat.
- SMOBC:** Solder mask over bare copper. A method of fabricating a printed wiring board which results in the final metallization being copper with no other protective metal; but the non-soldered areas are coated by a solder resist, exposing only the component terminal areas. This eliminates tin-lead under the solder mask.
- SMT:** Surface mount technology. Defines the entire body of processes and components which create printed wiring assemblies without components with leads that pierce the board.
- Sn-Au-Cu:** An alloy used as a replacement for eutectic tin-lead (Sn-Pb) in “lead-free” solders (often referred to, and pronounced as “snack”)
- SOI:** SOIC package with J-leads rather than gull wing leads.
- SOIC:** Small-outline integrated circuit. A plastic package resembling a small dual-in-line package (DIP) with gull wing leads on two sides for surface mounting.
- SOT:** Small outline transistor. A package for surface-mounting transistors.
- SPINDLE RUNOUT:** The measure of the wobble present as the drilling machine spindle rotates 360°.
- STORAGE LIFE:** The period of time during which a liquid resin or adhesive can be stored and remain suitable for use. Also called shelf life.
- STRAIN:** The deformation resulting from a stress. It is measured by the ratio of the change to the total value of the dimension in which the change occurred.
- STRESS:** The force producing or tending to produce deformation in a body. It is measured by the force applied per unit area.
- SUBSTRATE:** A material on whose surface an adhesive substance is spread for bonding or coating. Also, any material which provides a supporting surface for other materials used to support printed wiring patterns.
- SURFACE RESISTIVITY:** The resistance of a material between two opposite sides of a unit square of its surface. It may vary widely with the conditions of measurement.
- SURFACE SPEED:** The linear velocity of a point on the circumference of a drill. Given in units of surface feet per minute—sfm.
- TERMINAL AREA:** A portion of a conductive pattern usually, but not exclusively, used for the connection and/or attachment of components.
- TEST COUPON:** A sample or test pattern usually made as an integral part of the printed board, on which electrical, environmental, and micro sectioning tests may be made to evaluate board design or process control without destroying the basic board.
- TETRA-ETCH\*:** A nonpyrophoric (will not ignite when exposed to moisture) proprietary etchant.
- TETROFUNCTIONAL:** Describes an epoxy system for laminates that has four cross-linked bonds rather than two and results in a higher glass transition temperature, or  $T_g$ .
- $T_g$ :** Glass transition temperature. The temperature at which laminate mechanical properties change significantly.
- THERMAL CONDUCTIVITY:** The ability of a material to conduct heat; the physical constant for the quantity of heat that passes through a unit cube of a material in a unit of time when the difference in temperatures of two faces is 1°C.
- THERMOPLASTIC:** A classification of resin that can be readily softened and resoftened by repeated heating.

---

\*Trademark of W. L. Gore and Associates, Inc.

- THERMOSETTING:** A classification of resin which cures by chemical reaction when tested and, when cured, cannot be resoftened by heating.
- THIEF:** An auxiliary cathode so placed as to divert to itself some current from portions of the work which would otherwise receive too high a current density.
- THIXOTROPIC:** Said of materials that are gel-like at rest but fluid when agitated.
- THROUGH-HOLE TECHNOLOGY:** Traditional printed wiring fabrication where components are mounted in holes that pierce the board.
- THROWING POWER:** A measure of the degree of uniformity with which metal is deposited on an irregularly shaped cathode. Often refers to the ratio of amount of plated metal on the surface of a copper clad board to the amount plated on a side of a hole through the same board.
- TWIST:** A laminate defect in which deviation from planarity results in a twisted arc.
- UNDERCUT:** The reduction of the cross section of a metal foil conductor caused by the etchant removing metal from under the edge of the resist.
- VAPOR PHASE:** The solder-reflow process that uses a vaporized solvent as the source for heating the solder beyond its melting point, creating the component-to-board solder joint.
- VIA:** A metallized connecting hole that provides a conductive path from one layer in a printed wiring board to another. (1) *Buried via*—connects one inner layer to another inner layer without penetrating the surface. (2) *Blind via*—connects the surface layer of a printed wiring board to an internal layer without going all the way through the other surface layer.
- VOID:** A cavity left in the substrate.
- VOLUME RESISTIVITY:** The electrical resistance between opposite faces of a 1-cm cube of insulating materials, commonly expressed in ohm-centimeters. The recommended test is ASTM D 256 51T. Also called the specific insulation.
- VULCANIZATION:** A chemical reaction in which the physical properties of an elastomer are changed by causing the elastomer to react with sulfur or some other cross-linking agent.
- WATER ABSORPTION:** The ratio of the weight of water absorbed by a material to the weight of the dry material.
- WEAVE EXPOSURE:** A condition in which the unbroken woven glass cloth is not uniformly covered by resin.
- WEAVE TEXTURE:** A surface condition in which the unbroken fibers are completely covered with resin but exhibit the definite weave pattern of the glass cloth.
- WETTING:** Ability to adhere to a surface immediately upon contact.
- WICKING:** Migration of copper salts into the glass fibers of the insulating material.
- WORKING LIFE:** The period of time during which a liquid resin or adhesive, after mixing with catalyst, solvent, or other compounding ingredients, remains usable. (See *potlife*.)
