

McGRAW-HILL  
HANDBOOKS

# Printed Circuits Handbook

Sixth Edition

- Lead-free PCB design and manufacturing techniques
- Lead-free materials
- Lead-free reliability models
- High-Density Interconnection (HDI) best practices

Clyde F. Coombs, Jr.

---

**PRINTED  
CIRCUITS  
HANDBOOK**

## ABOUT THE EDITOR

---

**Clyde F. Coombs, Jr.** recently retired from Hewlett-Packard, where he had worked as an electronics engineer and manager. One of the most successful editors in professional publishing today, he developed and edited all five previous editions of the *Printed Circuits Handbook*, and also edited the *Electronic Instrument Handbook* and the *Communications Network Test and Measurement Handbook*, three of McGraw-Hill's best-selling technical handbooks.

# CONTENTS

---

**List of Contributors**   xxi  
**Preface**   xxiii

## **Part 1 Lead-Free Legislation**

### **Chapter 1. Legislation and Impact on Printed Circuits** **1.3**

---

1.1 Legislation Overview / 1.3  
1.2 Waste Electrical and Electronic Equipment (WEEE) / 1.3  
1.3 Restriction of Hazardous Substances (RoHS) / 1.3  
1.4 RoHS' Impact on the Printed Circuit Industry / 1.6  
1.5 Lead-Free perspectives / 1.10  
1.6 Other Legislative Initiatives / 1.10

## **Part 2 Printed Circuit Technology Drivers**

### **Chapter 2. ELECTRONIC PACKAGING AND HIGH-DENSITY INTERCONNECTIVITY** **2.3**

---

2.1 Introduction / 2.3  
2.2 Measuring the Interconnectivity Revolution (HDI) / 2.3  
2.3 Hierarchy of Interconnections / 2.6  
2.4 Factors Affecting Selection of Interconnections / 2.7  
2.5 ICS and Packages / 2.10  
2.6 Density Evaluations / 2.14  
2.7 Methods to Increase PWB Density / 2.16  
References / 2.21

### **Chapter 3. Semiconductor Packaging Technology** **3.1**

---

3.1 Introduction / 3.1  
3.2 Single-Chip Packaging / 3.5  
3.3 Multichip Packages / 3.15  
3.4 Optical Interconnects / 3.18  
3.5 High-Density/High-Performance Packaging Summary / 3.21  
3.6 Roadmap Information / 3.21  
References / 3.21

### **Chapter 4. Advanced Component Packaging** **4.1**

---

4.1 Introduction / 4.1  
4.2 Lead-Free / 4.2  
4.3 System-on-a-Chip (SOC) versus System-on-a-Package (SOP) / 4.3

4.4 Multichip Modules / 4.5  
4.5 Multichip Packaging / 4.6  
4.6 Enabling Technologies / 4.10  
4.7 Acknowledgment / 4.18  
References / 4.18

---

**Chapter 5. Types of Printed Wiring Boards** **5.1**

5.1 Introduction / 5.1  
5.2 Classification of Printed Wiring Boards / 5.1  
5.3 Organic and Nonorganic Substrates / 5.3  
5.4 Graphical and Discrete-Wire Boards / 5.3  
5.5 Rigid and Flexible Boards / 5.5  
5.6 Graphically Produced Boards / 5.6  
5.7 Molded Interconnection Devices / 5.10  
5.8 Plated-Through-Hole (PTH) Technologies / 5.10  
5.9 Summary / 5.13  
References / 5.14

**Part 3 Materials**

---

**Chapter 6. Introduction to Base Materials** **6.3**

6.1 Introduction / 6.1  
6.2 Grades and Specifications / 6.3  
6.3 Properties Used to Classify Base Materials / 6.9  
6.4 Types of FR-4 / 6.13  
6.5 Laminate Identification Scheme / 6.14  
6.6 Prepreg Identification Scheme / 6.18  
6.7 Laminate and Prepreg Manufacturing Processes / 6.18  
References / 6.24

---

**Chapter 7. Base Material Components** **7.1**

7.1 Introduction / 7.1  
7.2 Epoxy Resin Systems / 7.1  
7.3 Other Resin Systems / 7.5  
7.4 Additives / 7.7  
7.5 Reinforcements / 7.12  
7.6 Conductive Materials / 7.18  
References / 7.25

---

**Chapter 8. Properties of Base Materials** **8.1**

8.1 Introduction / 8.1  
8.2 Thermal, Physical, and Mechanical Properties / 8.1  
8.3 Electrical Properties / 8.13  
References / 8.16

---

**Chapter 9. Base Materials Performance Issues** **9.1**

9.1 Introduction / 9.1  
9.2 Methods of Increasing Circuit Density / 9.2  
9.3 Copper foil / 9.2  
9.4 Laminate Constructions / 9.7  
9.5 Prepreg Options and Yield-Per-Ply Values / 9.9

- 9.6 Dimensional Stability / 9.10
- 9.7 High-Density Interconnect/Microvia Materials / 9.13
- 9.8 CAF Growth / 9.15
- 9.9 Electrical Performance / 9.22
- References / 9.33

---

## **Chapter 10. The Impact of Lead-Free Assembly on Base Materials** **10.1**

- 10.1 Introduction / 10.1
- 10.2 RoHS Basics / 10.1
- 10.3 Base Material Compatibility Issues / 10.2
- 10.4 The Impact of Lead-Free Assembly on Base Material Components / 10.4
- 10.5 Critical Base Material Properties / 10.4
- 10.6 Impact on Printed Circuit Reliability and Material Selection / 10.18
- 10.7 Summary / 10.21
- References / 10.22

---

## **Chapter 11. Selecting Base Materials for Lead-Free Assembly Applications** **11.1**

- 11.1 Introduction / 11.1
- 11.2 Pcb fabrication and Assembly Interactions / 11.1
- 11.3 Selecting the Right Base Material for Specific Application / 11.6
- 11.4 Example Application of this Tool / 11.14
- 11.5 Discussion of the Range of Peak Temperatures for Lead-Free Assembly / 11.15
- 11.6 Lead-Free Applications and Ipc-4101 Specification Sheets / 11.15
- 11.7 Additional Base material Options for Lead-Free Applications / 11.16
- 11.8 Summary / 11.17
- References / 11.18

---

## **Chapter 12. Laminate Qualification and Testing** **12.1**

- 12.1 Introduction / 12.1
- 12.2 Industry Standards / 12.2
- 12.3 Laminate Test Strategy / 12.4
- 12.4 Initial Tests / 12.5
- 12.5 Full Material Characterization / 12.9
- 12.6 Characterization Test Plan / 12.22
- 12.7 Manufacturability in the Shop / 12.23

## **Part 4 Engineering and Design**

---

### **Chapter 13. Physical Characteristics of the PCB** **13.3**

- 13.1 Classes of PCB Designs / 13.3
- 13.2 Types of PCBs or Packages for Electronic Circuits / 13.9
- 13.3 Methods of Attaching Components / 13.14
- 13.4 Component Package Types / 13.15
- 13.5 Materials Choices / 13.18
- 13.6 Fabrication Methods / 13.22
- 13.7 Choosing a Package Type and Fabrication Vendor / 13.24

---

### **Chapter 14. The PCB Design Process** **14.1**

- 14.1 Objective of the PCB Design Process / 14.1
- 14.2 Design Processes / 14.1

- 14.3 Design Tools / 14.6
- 14.4 Selecting a Set of Design Tools / 14.10
- 14.5 Interfacing Cae, Cad, and CAM Tools to Each Other / 14.11
- 14.6 Inputs to the Design Process / 14.11

---

**Chapter 15. Electrical and Mechanical Design Parameters** **15.1**

- 15.1 Printed Circuit Design Requirements / 15.1
- 15.2 Introduction to Electrical Signal Integrity / 15.1
- 15.3 Introduction to Electromagnetic Compatibility / 15.3
- 15.4 Noise Budget / 15.4
- 15.5 Designing for Signal Integrity and Electromagnetic Compatibility / 15.4
- 15.6 Mechanical Design Requirements / 15.9
- References / 15.17

---

**Chapter 16. Current Carrying Capacity in Printed Circuits** **16.1**

- 16.1 Introduction / 16.1
- 16.2 Conductor (Trace) Sizing Charts / 16.1
- 16.3 Current Carrying Capacity / 16.2
- 16.4 Charts / 16.6
- 16.5 Baseline Charts / 16.10
- 16.6 Odd-Shaped Geometries and the “Swiss Cheese” Effect / 16.19
- 16.7 Copper Thickness / 16.20
- References / 16.21

---

**Chapter 17. PCB Design for Thermal Performance** **17.1**

- 17.1 Introduction / 17.1
- 17.2 The PCB as a Heat Sink Soldered to the Component / 17.2
- 17.3 Optimizing the PCB for Thermal Performance / 17.3
- 17.4 Conducting Heat to the Chassis / 17.12
- 17.5 PCB Requirements for High-Power Heat Sink Attach / 17.14
- 17.6 Modeling the Thermal Performance of the PCB / 17.15
- References / 17.18

---

**Chapter 18. Information Formating and Exchange** **18.1**

- 18.1 Introduction to Data Exchange / 18.1
- 18.2 The Data Exchange Process / 18.3
- 18.3 Data Exchange Formats / 18.9
- 18.4 Drivers for Evolution / 18.22
- 18.5 Acknowledgment / 18.23
- References / 18.23

---

**Chapter 19. Planning for Design, Fabrication, and Assembly** **19.1**

- 19.1 Introduction / 19.1
- 19.2 General Considerations / 19.3
- 19.3 New Product Design / 19.4
- 19.4 Layout Trade-off Planning / 19.10
- 19.5 PWB Fabrication Trade-off Planning / 19.17
- 19.6 Assembly Trade-Off Planning / 19.24
- References / 19.27

---

## **Chapter 20. Manufacturing Information, Documentation, and Transfer Including CAM Tooling for Fab and Assembly** **20.1**

---

- 20.1 Introduction / 20.1
- 20.2 Manufacturing Information / 20.2
- 20.3 Initial Design Review / 20.7
- 20.4 Design Input / 20.15
- 20.5 Design Analysis and Review / 20.19
- 20.6 The CAM-Tooling Process / 20.19
- 20.7 Additional Processes / 20.31
- 20.8 Acknowledgment / 20.32

## **Chapter 21. Embedded Components** **21.1**

---

- 21.1 Introduction / 21.1
- 21.2 Definitions and Example / 21.1
- 21.3 Applications and Trade-Offs / 21.2
- 21.4 Designing for Embedded Component Applications / 21.3
- 21.5 Materials / 21.6
- 21.6 Material Supply Types / 21.9

## **Part 5 High Density Interconnection**

### **Chapter 22. Introduction to High-Density Interconnection (HDI) Technology** **22.3**

---

- 22.1 Introduction / 22.3
- 22.2 Definitions / 22.3
- 22.3 HDI Structures / 22.7
- 22.4 Design / 22.11
- 22.5 Dielectric Materials and Coating Methods / 22.13
- 22.6 HDI Manufacturing Processes / 22.26
- References / 22.34
- Bibliography-Additional Reading / 22.35

### **Chapter 23. Advanced High-Density Interconnection (HDI) Technologies** **23.1**

---

- 23.1 Introduction / 23.1
- 23.2 Definitions of HDI Process Factors / 23.1
- 23.3 HDI Fabrication Processes / 23.3
- 23.4 Next-Generation HDI Processes / 23.33
- References 23.37

## **Part 6 Fabrication**

### **Chapter 24. Drilling Processes** **24.3**

---

- 24.1 Introduction / 24.3
- 24.2 Materials / 24.4
- 24.3 Machines / 24.11
- 24.4 Methods / 24.15
- 24.5 Hole Quality / 24.18
- 24.6 Postdrilling Inspection / 24.20
- 24.7 Drilling Cost Per Hole / 24.20

---

**Chapter 25. Precision Interconnect Drilling** **25.1**

---

- 25.1 Introduction / 25.1
- 25.2 Factors Affecting High-Density Drilling / 25.1
- 25.3 Laser versus Mechanical / 25.2
- 25.4 Factors Affecting High-Density Drilling / 25.5
- 25.5 Depth-Controlled Drilling Methods / 25.10
- 25.6 High-Aspect-Ratio Drilling / 25.10
- 25.7 Innerlayer Inspection of Multilayer Boards / 25.13

---

**Chapter 26. Imaging** **26.1**

---

- 26.1 Introduction / 26.1
- 26.2 Photosensitive Materials / 26.2
- 26.3 Dry-Film Resists / 26.4
- 26.4 Liquid Photoresists / 26.7
- 26.5 Electrophoretic Depositible Photoresists / 26.8
- 26.6 Resist Processing / 26.8
- 26.7 Design for Manufacturing / 26.27
- References / 26.29

---

**Chapter 27. Multilayer Materials and Processing** **27.1**

---

- 27.1 Introduction / 27.1
- 27.2 Printed Wiring Board Materials / 27.2
- 27.3 Multilayer Construction Types / 27.16
- 27.4 ML-PWB Processing and Flows / 27.37
- 27.5 Lamination Process / 27.51
- 27.6 Lamination Process Control and Troubleshooting / 27.59
- 27.7 Lamination Overview / 27.63
- 27.8 ML-PWB Summary / 27.63
- References / 27.63

---

**Chapter 28. Preparing Boards for Plating** **28.1**

---

- 28.1 Introduction / 28.1
- 28.2 Process Decisions / 28.1
- 28.3 Process Feedwater / 28.3
- 28.4 Multilayer PTH Preprocessing / 28.4
- 28.5 Electroless Copper / 28.8
- 28.6 Acknowledgment / 28.11
- References / 28.11

---

**Chapter 29. Electroplating** **29.1**

---

- 29.1 Introduction / 29.1
- 29.2 Electroplating Basics / 29.1
- 29.3 High-Aspect Ratio Hole and Microvia Plating / 29.2
- 29.4 Horizontal Electroplating / 29.4
- 29.5 Copper Electroplating General Issues / 29.6
- 29.6 Acid Copper Sulfate Solutions and Operation / 29.14
- 29.7 Solder (Tin-Lead) Electroplating / 29.19
- 29.8 Tin Electroplating / 29.21
- 29.9 Nickel Electroplating / 29.23
- 29.10 Gold Electroplating / 29.25
- 29.11 Platinum Metals / 29.28
- 29.12 Silver Electroplating / 29.29

29.13 Laboratory Process control / 29.29  
 29.14 Acknowledgment / 29.31  
 References / 29.31

---

## **Chapter 30. Direct Plating** **30.1**

30.1 Direct Metallization Technology / 30.1  
 References / 30.11

---

## **Chapter 31. PWB Manufacture Using Fully Electroless Copper** **31.1**

31.1 Fully Electroless Plating / 31.1  
 31.2 The Additive Process and its Variations / 31.2  
 31.3 Pattern-Plating Additive / 31.2  
 31.4 Panel-Plate Additive / 31.7  
 31.5 Partly Additive / 31.8  
 31.6 Chemistry of Electroless Plating / 31.9  
 31.7 Fully Electroless Plating Issues / 31.12  
 References / 31.14

---

## **Chapter 32. Printed Circuit Board Surface Finishes** **32.1**

32.1 Introduction / 32.1  
 32.2 Alternative Finishes / 32.3  
 32.3 Hot Air Solder Level (Hasl or Hal) / 32.4  
 32.4 Electroless Nickel Immersion Gold (ENIG) / 32.6  
 32.5 Organic Solderability Preservative (OSP) / 32.8  
 32.6 Immersion Silver / 32.10  
 32.7 Immersion Tin / 32.11  
 32.8 Other Surface Finishes / 32.13  
 32.9 Assembly Compatibility / 32.14  
 32.10 Reliability Test Methods / 32.17  
 32.11 Special Topics / 32.18  
 32.12 Failure Modes / 32.19  
 32.13 Comparing Surface Finish Properties / 32.23  
 References / 32.23

---

## **Chapter 33. Solder Mask** **33.1**

33.1 Introduction / 33.1  
 33.2 Trends and Challenges for Solder Mask / 33.2  
 33.3 Types of Solder Mask / 33.3  
 33.4 Solder Mask Selection / 33.4  
 33.5 Solder Mask Application and Processing / 33.9  
 33.6 VIA Protection / 33.18  
 33.7 Solder Mask Final Properties / 33.19  
 33.8 Legend and Marking (Nomenclature) / 33.19

---

## **Chapter 34. Etching Process and Technologies** **34.1**

34.1 Introduction / 34.1  
 34.2 General Etching Considerations and Procedures / 34.2  
 34.3 Resist Removal / 34.4  
 34.4 Etching Solutions / 34.6  
 34.5 Other Materials for Board Construction / 34.18  
 34.6 Metals Other than Copper / 34.19  
 34.7 Basics of Etched Line Formation / 34.20

34.8 Equipment and Techniques / 34.26  
References / 34.29

---

**Chapter 35. Machining and Routing** **35.1**

35.1 Introduction / 35.1  
35.2 Punching Holes (Piercing) / 35.1  
35.3 Blanking, Shearing, and Cutting of Copper-Clad Laminates / 35.3  
35.4 Routing / 35.6  
35.5 Scoring / 35.13  
35.6 Acknowledgment / 35.15

**Part 7 Bare Board Test**

---

**Chapter 36. Bare Board Test Objectives and Definitions** **36.3**

36.1 Introduction / 36.3  
36.2 The Impact of HDI / 36.3  
36.3 Why Test? / 36.4  
36.4 Circuit Board Faults / 36.6

---

**Chapter 37. Bare Board Test Methods** **37.1**

37.1 Introduction / 37.1  
37.2 Nonelectrical Testing Methods / 37.1  
37.3 Basic Electrical Testing Methods / 37.2  
37.4 Specialized Electrical Testing Methods / 37.9  
37.5 Data and Fixture Preparation / 37.13  
37.6 Combined Testing Methods / 37.20

---

**Chapter 38. Bare Board Test Equipment** **38.1**

38.1 Introduction / 38.1  
38.2 System Alternatives / 38.1  
38.3 Universal Grid Systems / 38.3  
38.4 Flying-Probe/Moving-Probe Test Systems / 38.17  
38.5 Verification and Repair / 38.21  
38.6 Test Department Planning and Management / 38.22

---

**Chapter 39. HDI Bare Board Special Testing Methods** **39.1**

39.1 Introduction / 39.1  
39.2 Fine-Pitch Tilt-Pin Fixtures / 39.2  
39.3 Bending Beam Fixtures / 39.3  
39.4 Flying Probe / 39.3  
39.5 Coupled Plate / 39.3  
39.6 Shorting Plate / 39.4  
39.7 Conductive Rubber Fixtures / 39.5  
39.8 Optical Inspection / 39.5  
39.9 Noncontact Test Methods / 39.5  
39.10 Combinational Test Methods / 39.7

## **Part 8 Assembly**

### **Chapter 40. Assembly Processes**

**40.3**

- 40.1 Introduction / 40.3
- 40.2 Through-Hole Technology / 40.5
- 40.3 Surface-Mount Technology / 40.16
- 40.4 Odd-Form Component Assembly / 40.42
- 40.5 Process Control / 40.48
- 40.6 Process Equipment Selection / 40.54
- 40.7 Repair and Rework / 40.57
- 40.8 Conformal Coating, Encapsulation, and Underfill Materials / 40.64
- 40.9 Acknowledgment / 40.66

### **Chapter 41. Conformal Coating**

**41.1**

- 41.1 Introduction / 41.1
  - 41.2 Types of Conformal Coatings / 41.3
  - 41.3 Product Preparation / 41.6
  - 41.4 Application Processes / 41.7
  - 41.5 Cure, Inspection, and Finishing / 41.11
  - 41.6 Repair Methods / 41.13
  - 41.7 Design for Conformal Coating / 41.14
- References / 41.17

## **Part 9 Solderability Technology**

### **Chapter 42. Solderability: Incoming Inspection and Wet Balance Technique**

**42.3**

- 42.1 Introduction / 42.3
- 42.2 Solderability / 42.4
- 42.3 Solderability Testing—a Scientific Approach / 42.8
- 42.4 The Influence of Temperature on Test Results / 42.13
- 42.5 Interpreting the Results: Wetting Balance Solderability Testing / 42.14
- 42.6 Globule Testing / 42.15
- 42.7 PCB Surface Finishes and Solderability Testing / 42.16
- 42.8 Component Solderability / 42.22

### **Chapter 43. Fluxes and Cleaning**

**43.1**

- 43.1 Introduction / 43.1
  - 43.2 Assembly Process / 43.2
  - 43.3 Surface Finishes / 43.3
  - 43.4 Soldering Flux / 43.5
  - 43.5 Flux Form Versus Soldering Process / 43.6
  - 43.6 Rosin Flux / 43.7
  - 43.7 Water-Soluble Flux / 43.8
  - 43.8 Low Solids Flux / 43.9
  - 43.9 Cleaning Issues / 43.10
  - 43.10 Summary / 43.12
- References / 43.12

## Part 10 Solder Materials and Processes

### Chapter 44. Soldering Fundamentals 44.3

---

- 44.1 Introduction / 44.3
- 44.2 Elements of a Solder Joint / 44.4
- 44.3 The Solder Connection to the Circuit Board / 44.4
- 44.4 The solder Connection to the Electrical Component / 44.5
- 44.5 Common Metal-Joining Methods / 44.5
- 44.6 Solder Overview / 44.9
- 44.7 Soldering Basics / 44.9

### Chapter 45. Soldering Materials and Metallurgy 45.1

---

- 45.1 Introduction / 45.1
- 45.2 Solders / 45.2
- 45.3 Solder Alloys and Corrosion / 45.4
- 45.4 PB-Free Solders: Search for Alternatives and Implications / 45.5
- 45.5 PB-Free Elemental Alloy Candidates / 45.5
- 45.6 Board Surface Finishes / 45.11
- References / 45.19

### Chapter 46. Solder Fluxes 46.1

---

- 46.1 Introduction to Fluxes / 46.1
- 46.2 Flux Activity and Attributes / 46.2
- 46.3 Flux: Ideal Versus Reality / 46.3
- 46.4 Flux Types / 46.4
- 46.5 Water-Clean (Aqueous) Fluxes / 46.4
- 46.6 No-Clean Flux / 46.7
- 46.7 Other Fluxing Caveats / 46.9
- 46.8 Soldering Atmospheres / 46.12
- References / 46.15

### Chapter 47. Soldering Techniques 47.1

---

- 47.1 Introduction / 47.1
- 47.2 Mass Soldering Methods / 47.1
- 47.3 Oven Reflow Soldering / 47.1
- 47.4 Wave Soldering / 47.28
- 47.5 Wave Solder Defects / 47.39
- 47.6 Vapor-Phase Reflow Soldering / 47.42
- 47.7 Laser Reflow Soldering / 47.43
- 47.8 Tooling and the Need for Coplanarity and Intimate Contact / 47.50
- 47.9 Additional Information Sources / 47.53
- 47.10 Hot-Bar Soldering / 47.53
- 47.11 Hot-Gas Soldering / 47.58
- 47.12 Ultrasonic Soldering / 47.59
- References / 47.61

### Chapter 48. Soldering Repair and Rework 48.1

---

- 48.1 Introduction / 48.1
- 48.2 Hot-Gas Repair / 48.1

- 48.3 Manual Solder Fountain / 48.5
- 48.4 Automated Solder Fountain / 48.6
- 48.5 Laser / 48.6
- 48.6 Considerations for Repair / 48.6
- Reference / 48.7

## **Part 11 Nonsolder Interconnection**

### **Chapter 49. Press-Fit Interconnection**

**49.3**

- 49.1 Introduction / 49.3
- 49.2 The Rise of Press-Fit Technology / 49.3
- 49.3 Compliant Pin Configurations / 49.4
- 49.4 Press-Fit Considerations / 49.6
- 49.5 Press-Fit Pin Materials / 49.7
- 49.6 Surface Finishes and Effects / 49.8
- 49.7 Equipment / 49.10
- 49.8 Assembly Process / 49.11
- 49.9 Press Routines / 49.12
- 49.10 PWB Design and Board Procurement Tips / 49.14
- 49.11 Press-Fit Process Tips / 49.15
- 49.12 Inspection and Testing / 49.16
- 49.13 Soldering and Press-Fit Pins / 49.17
- References / 49.17

### **Chapter 50. Land Grid Array Interconnect**

**50.1**

- 50.1 Introduction / 50.1
- 50.2 LGA and the Environment / 50.1
- 50.3 Elements of the LGA System / 50.2
- 50.4 Assembly / 50.5
- 50.5 Printed Circuit Assembly (PCA) Rework / 50.7
- 50.6 Design Guidelines / 50.8
- Reference / 50.8

## **Part 12 Quality**

### **Chapter 51. Acceptability and Quality of Fabricated Boards**

**51.3**

- 51.1 Introduction / 51.3
- 51.2 Specific Quality and Acceptability Criteria by PCB Type / 51.4
- 51.3 Methods for Verification of Acceptability / 51.6
- 51.4 Inspection Lot Formation / 51.7
- 51.5 Inspections Categories / 51.8
- 51.6 Acceptability and Quality After Simulated Solder Cycle(s) / 51.8
- 51.7 Nonconforming PCBs and Material Review Board (MRB) Function / 51.10
- 51.8 The Cost of the Assembled PCB / 51.11
- 51.9 How to Develop Acceptability and Quality Criteria / 51.11
- 51.10 Class of Service / 51.13
- 51.11 Inspection Criteria / 51.13
- 51.12 Reliability Inspection Using Accelerated Environmental Exposure / 51.32

---

**Chapter 52. Acceptability of Printed Circuit Board Assemblies** **52.1**

---

- 52.1 Understanding Customer Requirements / 52.1
- 52.2 Handling to Protect the PCBA / 52.7
- 52.3 PCBA Hardware Acceptability Considerations / 52.10
- 52.4 Component Installation or Placement Requirements / 52.15
- 52.5 Component and PCB Solderability Requirements / 52.25
- 52.6 Solder-Related Defects / 52.25
- 52.7 PCBA Laminate Condition, Cleanliness, and Marking Requirements / 52.32
- 52.8 PCBA Coatings / 52.34
- 52.9 Solderless Wrapping of Wire to Posts (Wire Wrap) / 52.35
- 52.10 PCBA Modifications / 52.37
- References / 52.39

---

**Chapter 53. Assembly Inspection** **53.1**

---

- 53.1 Introduction / 53.1
- 53.2 Definition of Defects, Faults, Process Indicators, and Potential Defects / 53.3
- 53.3 Reasons for Inspection / 53.4
- 53.4 Lead-Free Impact on Inspection / 53.6
- 53.5 Miniaturization and Higher Complexity / 53.8
- 53.6 Visual Inspection / 53.8
- 53.7 Automated Inspection / 53.12
- 53.8 Three-Dimensional Automated Solder Paste Inspection / 53.14
- 53.9 PRE-Reflow Aoi / 53.16
- 53.10 Post-Reflow Automated Inspection / 53.17
- 53.11 Implementation of Inspection Systems / 53.23

References /	59.35

## **Part 14 Environmental Issues**

---

### **Chapter 60. Process Waste Minimization and Treatment** **60.3**

60.1 Introduction /	60.3
60.2 Regulatory Compliance /	60.3
60.3 Major Sources and Amounts of Wastewater in a Printed Circuit Board Fabrication Facility /	60.5
60.4 Waste Minimization /	60.6
60.5 Pollution Prevention Techniques /	60.8
60.6 Recycling and Recovery Techniques /	60.15
60.7 Alternative Treatments /	60.18
60.8 Chemical Treatment Systems /	60.21
60.9 Advantages and Disadvantages of Various Treatment Alternatives /	60.26

## Part 15 Flexible Circuits

### Chapter 61. Flexible Circuit Applications and Materials

61.3

- 
- 61.1 Introduction to Flexible Circuits / 61.3
  - 61.2 Applications of Flexible Circuits / 61.6
  - 61.3 High-Density Flexible Circuits / 61.6
  - 61.4 Materials for Flexible Circuits / 61.8
  - 61.5 Substrate Material Properties / 61.9
  - 61.6 Conductor Materials / 61.13
  - 61.7 Copper-Clad Laminates / 61.14
  - 61.8 Coverlay Material / 61.19
  - 61.9 Stiffener Materials / 61.22
  - 61.10 Adhesive materials / 61.22
  - 61.11 Restriction of Hazardous Substances (RoHS) Issues / 61.23

### Chapter 62. Design of Flexible Circuits

62.1

- 
- 62.1 Introduction / 62.1
  - 62.2 Design Procedure / 62.1
  - 62.3 Types of Flexible Circuits / 62.2
  - 62.4 Circuit Designs for Flexibility / 62.12
  - 62.5 Electrical Design of the Circuits / 62.15
  - 62.6 Circuit Designs for Higher Reliability / 62.16
  - 62.7 Circuit Designs for RoHS Compliance / 62.17

### Chapter 63. Manufacturing of Flexible Circuits

63.1

- 
- 63.1 Introduction / 63.1
  - 63.2 Special Issues with HDI Flexible Circuits / 63.1
  - 63.3 Basic Process Elements / 63.3
  - 63.4 New Processes for Fine Traces / 63.14
  - 63.5 Coverlay Processes / 63.24
  - 63.6 Surface Treatment / 63.30
  - 63.7 Blanking / 63.31
  - 63.8 Stiffener Processes / 63.33
  - 63.9 Packaging / 63.33
  - 63.10 Roll-to-Roll Manufacturing / 63.34
  - 63.11 Dimension Control / 63.36

### Chapter 64. Termination of Flexible Circuits

64.1

- 
- 64.1 Introduction / 64.1
  - 64.2 Selection of Termination Technologies / 64.1
  - 64.3 Permanent Connections / 64.4
  - 64.4 Semipermanent Connections / 64.11
  - 64.5 Nonpermanent Connections / 64.13
  - 64.6 High-Density Flexible Circuit Termination / 64.20

### Chapter 65. Multilayer Flex and Rigid/Flex

65.1

- 
- 65.1 Introduction / 65.1
  - 65.2 Multilayer Rigid/flex / 65.1

**Chapter 66. Special Constructions of Flexible Circuits** **66.1**

---

- 66.1 Introduction / *66.1*
- 66.2 Flying-Lead Construction / *66.1*
- 66.3 Tape Automated Bonding / *66.8*
- 66.4 Microbump Arrays / *66.10*
- 66.5 Thick-Film Conductor Flex Circuits / *66.12*
- 66.6 Shielding of the Flexible Cables / *66.13*
- 66.7 Functional Flexible Circuits / *66.14*

**Chapter 67. Quality Assurance of Flexible Circuits** **67.1**

---

- 67.1 Introduction / *67.1*
- 67.2 Basic Concepts in Flexible Circuit Quality Assurance / *67.1*
- 67.3 Automatic Optical Inspection Systems / *67.2*
- 67.4 Dimensional Measurements / *67.3*
- 67.5 Electrical Tests / *67.3*
- 67.6 Inspection Sequence / *67.3*
- 67.7 Raw Materials / *67.6*
- 67.8 Flexible Circuit Feature Inspection / *67.6*
- 67.9 Standards and Specifications for Flexible Circuits / *67.8*

# PREFACE

---

With the implementation of the European Union (EU) directive on Restriction of Hazardous Substances (RoHS), the printed circuit industry has been forced to undergo a revolution in technology that is unprecedented in its history. The result is commonly called lead-free, a term that the reader will find used throughout this book, even though the restrictions are on several materials in addition to lead, as described in Chapter 1. The reason for this emphasis is that the biggest impact on the industry is the elimination of lead in the solder that is used for interconnection of the components and the board.

These changes are not driven by demands from the marketplace or the advancement of technology; rather, they have been legislated for reasons perceived to benefit society in general. Although the net effect, either positive or negative, on the global environment of elimination of lead in printed circuit assemblies has been the source of great debate, the reality is that it has been adopted worldwide and is a fact of life for all those who design, fabricate, and assemble printed circuits.

Tin-lead solder has been the basis for interconnections since the beginning of the use of printed circuits, and all associated materials and processes have been developed with the use of that material in mind. As a result, the abrupt shift to new solder alloys poses many questions about the related or affected processes and technologies that must now adapt and change to meet the lead-free requirements. Past experience or previous literature cannot be relied on to provide answers to these questions. The purpose of this book is to provide this information as specifically and in as much detail as possible, using industry standards, where they exist, or best practice that has a sound technical foundation and has been shown to work.

The most obvious change is in the metallurgy of the solder and in mating surfaces. However, all alternative solder alloys melt at a higher temperature than eutectic solder, and this has required new base materials, new assembly processes, as well as new test, inspection, and reliability criteria and methods. With specific regard to the lead-free alternative alloys, we start with the periodic table of elements and describe what elements are candidates for use, and what the effect each has when incorporated into an alloy. Thus we rely on physics and material science to help define the appropriate alternative for a given application. Similarly, to help the reader choose the best base material for the higher assembly and operating temperatures and higher component speeds, we describe the chemistry of the material.

The issues of defining and predicting reliability of products in this new situation have absorbed a great deal of corporate resources since the EU directive was announced. The predictive models and history were based on tin-lead alloys, and new models are needed for lead-free alloys. For this edition, we have added new material and expanded existing discussions on this subject.

Although the lead-free technology revolution has gotten much more attention, there have also been important evolutionary changes in the technology as the industry continues to meet the need for higher circuit and component density and faster circuits. As a result, printed circuit boards continue to be designed to be ever smaller, or larger, to suit the requirements of specific applications. This book updates the reader on these advancements. In addition, with the continuing global nature of the printed circuit industry, along with the constant pressure to decrease both time to market and time to volume, there is a growing need for international standards covering layout and design information and communications that enable each organizational element in the supply chain to function effectively with minimum manual intervention and delays for design clarification. For the first time, we have added chapters that describe

these parts of the overall process. In addition, we have introduced discussions on embedded components and conformal coatings, both important issues in many applications of the technology.

This edition addresses these new elements of the printed circuit processes, both revolutionary and evolutionary, while still maintaining its foundation on the basics of the technology. No matter how sophisticated the leading edge of the technology becomes, at the core of all printed circuits is the plated-through hole in its various forms. This remains one of the most important technical achievements of the twentieth century. Although based on the plated-through hole, printed circuits technology has evolved over the years to be more reliable, efficient, and reproducible, but the process described in the first edition of this book is still recognizable in the sixth. As a result, those new to the technology will still find introductory information, while experienced practitioners will find industry standard methods and best practices to help them with the most recent developments.

As the industry has grown, it has become more specialized. This has created the need to standardize documentation and communication techniques as well as to understand the specific capabilities of all suppliers in the overall value delivery chain. The result is that process capabilities and limitations at each step must be known, the board must be designed with these clearly in mind, and consistent acceptability criteria must be agreed to in advance, before the responsibility for the board passes from designer to fabricator to assembler to end user. This has created a community of people who have not been intimately involved in printed circuit issues before, and who now find a working knowledge of printed circuits critical for performance in their jobs. This book provides information for these people as well. They not only will find the basic information useful in understanding the issues, but also find specific guidelines on the development and management of the value chain for the success of all.

Although the industry's preferred term for the subject of this book is *printed wiring* or *etched wiring*, the term *printed circuits* has passed into the world's languages as representing the process and products described. As a result, we will use the terms interchangeably.

The impact of all these changes in the printed circuit technology is reflected in this book, as over 75 percent of the chapters are either revised or new to this edition. That means that this sixth edition contains the most new information since the first edition.

The continuing cooperation and support of the leadership and staff of the IPC-Association Connecting Electronic Industries (IPC) are acknowledged, not just for this edition, but for all the previous editions. IPC, under the leadership of Ray Pritchard, now retired, and Dieter Bergman, celebrated its 50th anniversary in 2007, and it would be impossible to overemphasize the contribution it has made, not just to the electronics industry but to a world that increasingly relies on electronic products. Special appreciation goes to Jack Crawford for the help in identifying and providing IPC material critical for the preparation of this edition.

Finally, I want to acknowledge and thank the authors, who have given so liberally of their time and skill in preparing the chapters for this book. They have made a great contribution to the literature and to the industry.

# LEGISLATION AND IMPACT ON PRINTED CIRCUITS

---

**Gary M. Freedman**

*Hewlett-Packard Corporation, Business Critical Systems, Singapore*

---

## 1.1 LEGISLATION OVERVIEW

---

The dramatic rise in output and rapid obsolescence of consumer and commercial electronic goods has prompted the European Union (EU) to draft two pieces of environmental legislation that impact the electronics industry:

- Directive 2002-96-EC 27 Jan 2003 of the European Parliament and of the Council on Waste Electrical & Electronic Equipment, commonly abbreviated as WEEE.
- Directive 2002-95-EC of the European Parliament and of the Council 27 Jan 2003, which restricts the use of certain hazardous substances in electrical and electronic equipment. This directive is also known as RoHS (Restriction of Hazardous Substances).

---

## 1.2 WASTE ELECTRICAL AND ELECTRONIC EQUIPMENT (WEEE)

---

This European Community Directive was fully effective in August 2005. It requires manufacturers selling electrical or electronic equipment to member countries of the European Union to be responsible for end-of-life disposal of their finished goods. The directive attempts to limit the stream of waste materials to landfills, encourage recycling, and pressure equipment designs and materials to be more environmentally friendly. The end results are tariffs for purchasing electronic products to help with disposal costs and encouraging electronic manufacturers to institute take-back programs for recycling. The list of affected goods is very long. Table 1.1 includes examples of affected products.

The directive also mandates that the symbol shown in Fig. 1.1 be placed conspicuously on products signifying separate collection for disposal.

---

## 1.3 RESTRICTION OF HAZARDOUS SUBSTANCES (RoHS)

---

The second piece of legislation has the biggest impact on the electronics industry. The RoHS directive makes it illegal to manufacture or import into the member states of the EU any electrical or electronic equipment that contains restricted materials—materials that have been the

**TABLE 1.1** Examples of Products Affected by the WEEE Directive

Category	Examples
Large household appliances	Washers, dryers, refrigerators, freezers, microwave ovens, air conditioners, etc.
Small household appliances	Vacuum cleaners, toasters, irons, clocks, hair dryers, etc.
IT and telecommunications equipment	Computers, printers, monitors, copying equipment, calculators, data storage equipment, projectors, telephones, etc.
Consumer equipment	Radios, televisions, cameras, audio equipment, musical instruments, etc.
Lighting equipment	Light bulbs, lamps, other lighting equipment, etc.
Electrical and electronic tools	Tools for drilling, sawing, sewing, turning, milling, sanding, grinding, cutting, shearing, making holes, punching, folding, bending, riveting, nailing, welding, soldering, etc.
Toys, leisure and sports equipment	Electric trains; car racing sets; video game consoles; computers for biking, diving, running, rowing, etc.; sports equipment with electric or electronic components; slot machines; etc.
Medical devices	Equipment for radiotherapy, cardiology, dialysis, and nuclear medicine; pulmonary ventilators; laboratory equipment for in vitro fertilization, diagnosis, analyzers, freezers, etc.
Monitoring and control instruments	Smoke detectors, thermostats, instruments for measuring and weighing, laboratory equipment, industrial monitoring equipment, etc.
Automatic dispensers	Automatic dispensers for hot drinks, cold drinks, bottles, cans, solid products, money, etc.

**FIGURE 1.1** Symbol for separate collection for disposal.

mainstay of electronics manufacturing. The legislation took full effect on July 1, 2006. Its implications are far reaching and apply to all electrical and electronic equipment unless specifically addressed by the main body of the legislation or an exemption. Definitions of terms within the RoHS legislation have been slow to come; some of the exemptions have yet to be fully defined, whereas others have been revised. Imprecision of the legislation delayed early adoption within the electronics industry. As a result, there is no standard industry set of materials and evaluation of alternative materials for manufacturability or for long-term reliability. Chapter 45 on “Soldering Materials” lists and describes alternative materials to tin-lead solder. Chapters 58 and 59 on “Reliability” provide information on methods to predict product life.

### 1.3.1 RoHS Restricted Materials

The RoHS directive targets six widely used materials (see Table 1.2).

### 1.3.2 Analysis for RoHS Compliance

The directive focuses on the smallest homogeneous part or material that can be separated from the mass of a component or assembly. As an example, take the case of a plastic packaged integrated circuit (IC) with a copper (Cu) lead-frame, where the lead-frame is plated with some surface finish for solderability. The surface finish would be evaluated for RoHS compliance separate from the whole package or even from the weight of the lead-frame itself. Instead, the weight-percent of (Pb) within the surface finish would be evaluated on the ratio of the weight of any Pb to the weight of the surface finish plated upon the lead-frame. Similarly, any Pb alloyed within the Cu lead-frame would be evaluated based on the total weight of the assayed Pb to the total weight of the Cu lead-frame. Similarly, the IC’s encapsulant would be evaluated for the weight of any PBB or PBDE as compared to the weight of the encapsulant in which it is contained or upon which it is coated.

**TABLE 1.2** Materials Impacted by “Restriction of Hazardous Substances” Legislation

Substance	Symbol or Abbreviation	Maximum Allowable Value (Wt%)	Uses in Electronics
Hexavalent chromium	Cr <sup>+6</sup>	0.1	Platings, especially for surface passivation of environmentally unstable metals, pigments, and plastics; colorant as lead chromate; hexavalent chromate finish for plated metal enclosures, fasteners, clips, and screws
Cadmium	Cd	0.01	Platings, ink pigments, paint pigments, batteries, detectors, and thick film circuits
Mercury	Hg	0.1	Pigments, curing catalyst for plastics and foams, switch contacts, batteries PVC stabilizer, and colorant
Lead	Pb	0.1	Solder PWB surface finish; component terminations; surface finish; PVC stabilizer and colorant; plastics colorant as lead chromate; cables and harnesses; sheet metal plating (to reduce risk of Zn whiskers); alloy agent for steel, copper, aluminum, etc.
Polybrominated biphenyls	PBB	0.1	Circuit board flame retardant and other electrical insulators
Polybrominated diphenyl ethers	PBDE	0.1	Circuit board flame retardant and other electrical insulators, and flame retardant for plastics

### 1.3.3 Analytical Methods for RoHS Compliance

The RoHS legislation does not set forth specific recommendations for analysis, nor is there wide consensus within the electronics community on standard analytical screening methods for determining compliance with RoHS legislation. Simple wet chemistry spot tests can be conducted for presence or absence of Cr<sup>+6</sup>, Hg, Cd, and Pb. These tests, if conducted properly, have good sensitivity for qualitative analysis. Atomic absorption spectrophotometry (AAS), x-ray fluorescence (XRF), energy dispersive spectroscopy (EDS or EDAX), infrared (IR) or ultraviolet (UV) spectrophotometry, and gas chromatography-mass spectroscopy (GC-MS, that is effective for PBB or PBDE) are but a few of the methods requiring expensive analytical instrumentation. Quantitative data can be gleaned from these and other methods, but capital investment is high, trained personnel are required, and use of traceable calibration standards are a must.

### 1.3.4 Exceptions and Exclusions

The RoHS legislation exempts numerous applications of the four targeted elemental species. Most are not relevant to the discussion of printed circuit board soldering. Relevant applications are listed in Table 1.3.

**TABLE 1.3** RoHS Exemptions as per the Second Amendment of RoHS Legislation\*

Lead in high melting temperature type solders (i.e., lead-based alloys containing 85 percent by weight or more lead)
Lead in solders for servers; storage and storage array systems; network infrastructure equipment for switching, signaling, and transmission; and network management for telecommunications
Lead in electronic ceramic parts (e.g., piezoelectronic devices)
Lead as a coating material for the thermal conduction module c-ring
Lead in solders consisting of more than two elements for the connection between the pins and the package of microprocessors with a lead content of more than 80 percent and less than 85 percent by weight
Lead in solders to complete a viable electrical connection between semiconductor die and carrier within integrated circuit Flip Chip packages
Cadmium and its compounds in electrical contacts and cadmium plating except for applications banned under Directive 91-338-EEC

\* Source: L 280-18 EN *Official Journal of the European Union* 25.10.2005, 2nd Amendment Annex to Directive 2002-95-EC.

It should be noted that even in cases where Pb is removed from a component or solder, that the package must be otherwise RoHS-compliant.

Although counterintuitive, the directive declares an exemption for Pb-based interconnects where the Pb content is greater than 85 percent. This exemption is meant to address specific devices, such as ceramic ball grid arrays (CBGAs), ceramic column grid arrays (CCGAs), flip-chip devices, and other high-Pb interconnection schemes. CBGAs and CCGAs rely on high Pb-content balls or columns, respectively, which melt at higher temperatures than eutectic Sn-Pb and thus will not collapse upon reflow. Since these ceramic devices are heavy, if the solder balls or columns beneath were to collapse, then interconnect-to-interconnect shorting would take place. Several years are typically needed to determine reliability impact of metallurgical changes to IC packages. In the case of these area-array devices, the high-lead content solder connection is an integral part of the package and not just a link between a component lead and bonding pad on a circuit board. Further, these packages are generally used in high-end systems such as telecommunications equipment and powerful computers. The RoHS legislation exempts such equipment from restrictions on Pb until 2010. In the meantime, package manufacturers are working to find and test reliable replacements for Pb-based solders for high-end packages. Some smaller ICs have already made the switch to Pb-free interconnects. Other exclusions or exemptions detailed in the current RoHS directive are Cd and Pb in batteries, Pb in video monitor screens, and Hg in fluorescent light bulbs. It is curious to note that RoHS legislation targets Pb in solders even though solder represents a minor use of Pb (it is estimated to comprise less than 10 percent of world Pb usage). Conversely, the exempted Pb-acid storage battery is the major consumer of Pb accounting for more than 85 percent worldwide Pb usage.

In August 2006, additional exemptions were allowed for the RoHS legislation. As will be discussed in subsequent chapters, lead has been used to reduce or eliminate the occurrence of tin whiskers (metallic dendrites of tin that grow from pure tin surfaces). Metallic whiskers, such as from tin or zinc, are known to pose a reliability risk in terms of electrical shorting between oppositely charged conductors. Therefore, the RoHS legislation has been amended to allow lead in surface finishes of components with pitch  $\leq 0.65$  mm for tin whisker repression. This applies to NiFe (Alloy 42, also known as Kovar) lead-frames as well as to components with copper lead-frames. Curiously, the exemption does not cover connectors.

## **1.4 RoHS' IMPACT ON THE PRINTED CIRCUIT INDUSTRY**

---

Never has there been such a sweeping change in electronics manufacturing as imparted by WEEE and RoHS—particularly the latter. Every industry is being impacted either by processes and materials or materials availability.

### **1.4.1 Components**

Generally, ICs, passive devices, and connectors are not rated to survive temperature excursions much above that of eutectic Sn-Pb solder and are rated only to survive a brief thermal cycle. IC makers and component manufacturers have worked to understand the impact of the higher process temperatures required for Pb-free soldering.

Plastic encapsulated components are known to absorb water from the atmosphere. As these components are heated to reflow soldering temperature, the water expands and can cause component cracking. This phenomenon is popularly known as “popcorning” since the plastic package often bulges prior to cracking and remains deformed upon cooling. To counter this, plastic packaged components are “baked out” prior to soldering. The higher temperature regimes of most lead-free solders will exacerbate the issue of popcorning requiring more attention to component drying cycles. In addition, the higher reflow temperature of Pb-free soldering has

necessitated revamping of the classification schedule for package moisture sensitivity. This is especially relevant to components that are not hermetically sealed. Also, longer bake-out cycles are likely required.

Many components, such as ICs and passive devices (resistors, capacitors, and so on), may not be suited for the higher process temperatures generally associated with lead-free soldering. The higher temperature may result in changes to electrical characteristics, cracking, melting, or other component damage or degradation. Only components certified by the parts manufacturer or by the user should be considered for Pb-free assembly.

The manufacturer of each component assigns it a moisture sensitivity classification that dictates how long the component can be stored in a normal workplace environment before requiring a controlled bake-out cycle. Detailed information can be found about component moisture sensitivity classification, storage conditions, and bake-out requirements in joint industry standards J-STD-020<sup>1</sup> and J-STD-033.<sup>2</sup>

In addition to changes in moisture sensitivity, component laminates, encapsulants, or overmolding compounds may be prone to degradation as a result of the higher temperature exposures and times. Other negative attributes are associated with the move to Pb-free solders. Most of the Pb-free solders are poorer wetting (slower to spread on a solderable surface), have grainier appearance (which is not necessarily a negative attribute, but different from what is generally accepted as a positive attribute in lead-based solder joints).

With the advent of Pb-free solders as a mainstream technology, electrical components meant for surface mounting are being reformulated or requalified to withstand the higher requisite temperatures of Pb-free processing. Similarly, standards organizations such as the Joint Electron Devices Engineering Council (JEDEC) have respecified the maximum safe temperature regime for components due to the generally higher reflow soldering temperature required for Pb-free soldering. The process engineer must consult component manufacturer's specifications to establish safe reflow parameters for Pb-free soldering.

#### 1.4.2 Workmanship Standards

The most widely used workmanship standard, IPC-A-610, has been rewritten to accommodate the inspection of Pb-free soldered assemblies. The changes were introduced with version D of that document. Inspection personnel require retraining to give proper attention to the changes and renewed inspection criteria.

#### 1.4.3 Laminates

Many of the widely used printed wiring board (PWB) laminates for leaded (Pb'd) solder assembly will not endure the higher temperatures of Pb-free processing. Only laminates with characteristic high-glass transition temperature ( $T_g$ ) and high-decomposition temperature ( $T_d$ ) should be investigated for use in the Pb-free process. PWB laminates are more likely to sag during Pb-free reflow. Some may even darken in color or delaminate when exposed to Pb-free soldering temperatures. Careful attention to material selection and testing is a must for Pb-free soldering. Reformulation of circuit board laminates for higher temperature use is required to reduce the possibility of warpage, charring, delamination, sagging, via- or barrel-cracking, and so on. High-temperature PWB laminates are available but are typically more expensive than those used for Sn-Pb processing.

<sup>1</sup> J-STD-020: Joint IPC-JEDEC Standard for Moisture-Reflow Sensitivity Classification for Nonhermetic Solid State Surface Mount Devices, Joint Electron Device Engineering Council (JEDEC), Arlington, VA, USA, and IPC-Association Connecting Electronic Industries, Bannockburn, IL, USA.

<sup>2</sup> J-STD-033: Joint IPC-JEDEC Standard for Handling, Packing, Shipping, and Use of Moisture-Reflow Sensitive Surface Mount Devices, JEDEC, Arlington, VA, USA, and IPC, Bannockburn, IL, USA.

### 1.4.4 Solder Flux

Some of the fluxes in use for tin-lead soldering may not be compatible with the higher reflow temperatures associated with most Pb-free alloys. Critical materials in the flux may boil off, decompose, or oxidize before thorough fluxing can take place. Also, the flux must remain on metal surfaces to be bonded until reflow occurs since it serves as an oxygen barrier. Were the flux to disappear too soon, reoxidation of the solder and bonding surfaces may occur, which will retard solder wetting. Fluxes for Pb-free solders must be tailored to the composition of the new solder alloys and their inherently higher soldering process temperatures, and to the Pb-free surface finishes on component leads and PWB bonding pads.

### 1.4.5 Hygiene

Distinct health benefits are associated with the removal of Pb from printed circuit assemblies. Pb's toxicity is well documented, and the most serious problems are associated with direct ingestion of Pb-bearing materials (for example, children ingesting peeling Pb-based paint or lead in drinking water from Pb-soldered plumbing). This accumulating heavy metal dissolves slowly in the human body. Although there is conflicting evidence as to whether Pb from solder can leach into the water table from landfills at a rate that warrants concern, it is in everyone's best interest to explore alternative solder alloys and migrate from Pb-based solders.

Printed circuit board assembly operations will certainly benefit in that the labor force will encounter lower toxicity. Solder dross generated during wave soldering or disturbed while performing wave solder maintenance is a major source of Pb inhalation in manufacturing plants. Airborne dross is also generated at solder fountain operations, hot-air rework, and even during hand soldering. The move to a Pb-free environment will also eliminate concerns for ingested fines from Pb-contaminated hands.

### 1.4.6 Lead Replacement Cost

In the United States and other countries, some legislative initiatives aimed at restricting the use of Pb have failed. This failure spurred research for solder replacement alloys. Several corporations and universities devised Pb-free solders, some of which were patented. As is the case with any patented item or process, the rights to invention reside with the inventor or sponsoring corporation in the short term, and several of these alloys may not be used freely. In some cases, only slight modifications in alloy composition separate commonly available solder alloys from patented solder compositions. The cost of patent licensing, whether by the end user or solder manufacturer, will be borne largely by the end user.

In almost every case, the cost of Pb-free solder is at minimum 20 percent higher than for Sn-Pb solder. PWB laminates are more costly, as are many of the components. Energy costs go up with the need for higher reflow soldering temperatures. There is significant cost in training of personnel to deal with the change to a Pb-free environment. Separate lines for Pb'd and Pb-free solder may be required.

Both tin and lead are abundant, easy to refine, and thus inexpensive. This is not the case for some of the constituents of lead-free solders being considered, such as indium (In), gallium (Ga), and silver (Ag). Even bismuth (Bi) is a minor constituent of Pb ore and comes largely from Pb refining. In wave soldering, a large volume (hundreds of pounds) of solder is required to fill the wave solder reservoir (solder pot). The cost and availability of some of the lead-free alloys make them impractical for the large volume of the solder pot. Compare Sn-Pb solder at roughly USD \$1.50 per pound to Sn-0.7Cu at USD \$2.30 and Sn<sub>2</sub>Ag<sub>0.8</sub>Cu<sub>0.5</sub>Sb at USD \$4.00 per pound. Granted, with lead being such a heavy element, price per pound is not the best metric; price per unit volume is a more significant measure. Nonetheless, moving away from the Sn-Pb binary

eutectic will mean significantly higher manufacturing materials costs. Also, during wave soldering, the molten and flowing wave will tend to dissolve certain surface finishes, which may eventually build up and change the composition of the solder alloy. Different solder alloys have different metals dissolution properties. Therefore, using the same lead-free solder alloy for wave soldering as for reflow may be impractical.

Some of the overt costs and impacts of moving to lead-free solders were mentioned previously in this chapter. There are other potentially hidden costs. Soldering equipment may not have the bandwidth to handle the higher temperatures of some of the pb-free alloys. Reflow ovens may need to be constructed out of different materials to handle long-term effects of the higher temperatures. Fan bushings and polymeric seals to maintain inert atmosphere integrity may not withstand much above the temperature regimes required for Sn-Pb processing. These same considerations apply to wave soldering. Hand soldering irons will require higher temperatures, and more boards will likely have to be scrapped due to localized charring while trying to attain reflow during the hand soldering operation or at repair. Board materials, fluxes, and such may require reformulating, which is also likely to drive costs higher.

#### 1.4.7 Equipment Changes

In some cases, soldering equipment changes are required to accommodate higher process temperatures and contact with materials other than Sn and Pb. Such changes are discussed in more detail in Chap. 47.

#### 1.4.8 Scrapping and Material Mistakes

There will be costs associated with segregating materials (Pb'd versus Pb-free) and associated increased floor space for carrying two inventories (Pb'd and Pb-free). Noncompliant materials will have to be scrapped or sold off to those still using leaded processes. It is anticipated that in the early throes of the conversion to Pb-free, parts inventories occasionally will be inadvertently mixed, which may impact finished goods reliability and also make these products unacceptable for import to Europe after July 1, 2006, due to tenets of the RoHS directive.

#### 1.4.9 Training

Every facet of manufacturing is touched by this change, whether it is the soldering process, solder joint inspection, electrical testing, material inventories, bill-of-materials verification, purchase specifications, inventory separation, and incoming materials inspection. The adaptations of RoHS and Pb-free standards for printed circuit assembly certainly require the most extensive changes that the electronics industry has ever needed to make. Great care has to go into training of personnel at every level of printed circuit assembly (PCA) building and support.

#### 1.4.10 Reliability Testing

The change of materials and solders to accommodate the elimination of Pb necessitates reliability testing of the Pb-free assemblies to ensure that reliability is comparable to that of Sn-Pb assemblies. Reliability test methods, parameters, and models will have to be refined to match material properties of Pb-free assemblies.

### 1.4.11 In-Circuit Test (ICT)

Since the process temperature for most lead-free solders are higher than for eutectic- or near-eutectic Sn-Pb solder, any flux residues associated with No-Clean soldering are more thoroughly baked onto PWB surface metals. This inhibits electrical test probe contact. Even with today's No-Clean solder pastes and with Sn-Pb solders, electrical probing can be a challenge. Often the residues that cover test points necessitate multiple seating cycles of the test probes to penetrate the flux residue.

## 1.5 LEAD-FREE PERSPECTIVES

---

The relative benefits of removing or reducing lead remain controversial. Some studies have shown a net negative effect due to the energy materials and processes required for the production and use of replacement lead-free materials. Whatever the long-term environmental impact, the short-term consequences clearly create a technical challenge to ensure reliable, cost-effective printed circuit assemblies. There are neither drop-in replacements for Sn-Pb solder nor industry wide consensus for a single-solder alloy. The alloys that are most promising have significant challenges due to raw materials pricing, limited reliability data, and yet-to-be-determined interactions with other materials. It has taken many years to understand the properties of Sn-Pb solder, its metallurgical behavior, solder joint properties, and soldering methodologies. Any new solders will have to undergo scrutiny to determine key characteristics of process and reliability. Since the paradigm for characterizing solders and reliability has been honed through the millennia-long use of Sn-Pb solder, the development cycle for Pb-free solder should be significantly streamlined. On the other hand, the rapid changeover to Pb-free solder brings with it risks with regard to process effectiveness and control, as well as the long-term reliability of the end product. These risks will require continuous reevaluations of the solder alloy choice, appropriate surface finishes, soldering conditions, materials compatibility (PWB, IC packages, and such), redefinition of solder volume requirements for reliable solder joint strength, and even some equipment changes. As a result, the Chap. 45 on "Solder Materials" contains a detailed discussion of "lead-free" alloys and materials and offer several choices on materials and discussion of their characteristics.

Since nearly all the practical Pb-free alloy choices have a higher melting temperature, a requisite higher energy consumption and energy cost is associated with the new soldering materials. Equipment changes needed for Pb-free processing will be discussed in Chaps. 46 and 47.

Also, as Pb-based solder will remain in use until at least 2010 as per RoHS, another likely mode of failure will be the inadvertent use of Pb-free solder with Pb'd packages or Pb'd solder with Pb-free packages. Although there is some backward and forward compatibility in terms of solders, packages, and surface finishes, there are also some difficulties. Some packages meant for use in the Pb'd process will not tolerate the higher soldering temperatures associated with most Pb-free solders. In the case of a Pb-free ball grid array (BGA) soldered with Pb'd solder, or vice versa, it is already known that there will be a negative impact to the resultant solder joint reliability for the leading Pb-free candidate solders. Increased tensile strength with increased brittleness is commonly reported for the tin-silver-copper system—a leading replacement candidate.

China, Japan, and Korea have legislative initiatives taking shape that are similar to the EU's, WEEE, and RoHS directives. This is the case for several U.S. states also. There is no escaping the fact that Pb-free soldering will be the mainstay of all future electronics interconnections.

## 2.1 INTRODUCTION

---

All electronic components must be interconnected and assembled to form a functional and operating system. The design and the manufacture of these interconnections have evolved into a separate discipline called *electronic packaging*. Since the early 1950s, the basic building block of electronic packaging is the printed wiring board (PWB), and it will remain that into the foreseeable future. This book outlines the basic design approaches and manufacturing processes needed to produce these PWBs.

This chapter outlines the basic considerations, the main choices, and the potential trade-offs that must be accounted for in the selection of the interconnection methods for electronic systems. Its main emphasis is on the analysis of potential effects that the selection of various printed wiring board types and design alternatives could have on the cost and performance of the complete electronic product.

---

## 2.2 MEASURING THE INTERCONNECTIVITY REVOLUTION (HDI)

---

The continuing increase in component performance and lead density, along with the reduction in package sizes, has required that PWB technology find corresponding ways to increase the interconnection density of the substrate. With the introduction and continued refinement of such packaging techniques as the ball grid array (BGA), chip-scale packaging (CSP), and chip-on-board (COB), traditional PWB technology has approached a point where alternative ways of providing high-density interconnection have had to be developed. (See Chaps. 3 and

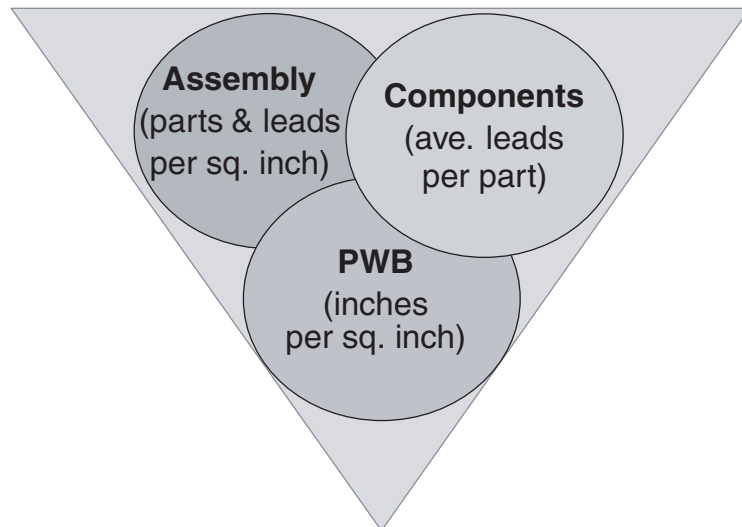

---

\* Adapted from Coombs, Clyde F. Jr., *Printed Circuits Handbook* (4th ed.), chap. 1, "Electronic Packaging and Interconnectivity," (McGraw-Hill, New York, 1996.)

4 for detailed discussions of component and packaging technologies.) This has been called at times high-density interconnects (HDI), the interconnection revolution, or the density revolution, because doing the same things in the same way, only smaller, was no longer sufficient.

### 2.2.1 Interconnect Density Elements

The extent of these interconnect density issues is not always observable, but the chart<sup>1</sup> in Fig. 2.1 can help one define and understand it. The chart portrays the interrelationship between component packaging, surface-mount technology (SMT) assembly, and PWB density. As can be seen, these three elements are interlinked. A change in one has a significant effect on the overall interconnection density. The metrics are as follows:

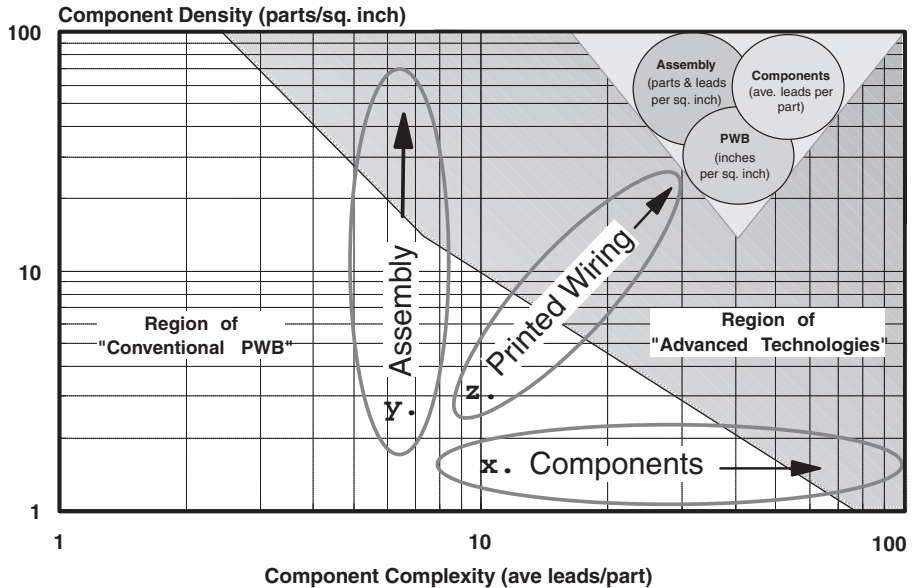

**FIGURE 2.1** Representation of the metrics of assembly, component, and PWB technologies and their general relationship to each other.

- *Assembly complexity*: the measure of the difficulty of assembling surface-mounted components in parts per square inch and leads per square inch.
- *Component packaging complexity*: the degree of sophistication of a component, measured by its average leads (I/Os) per part.
- *Printed wiring board density*: the amount of wiring a PWB has as measured by the average length of traces per square inch or the area of that board, including all signal layers. The metric is inches per square inch.

### 2.2.2 Interconnect Technology Map

To visualize the interrelationships of the three elements, see Fig. 2.2. It shows these elements as axes of a three-dimensional technology map that defines the passage from conventional PWB structures to advanced technologies and shows how changes in just one of the elements can increase or decrease the total density of the entire electronic package.

**FIGURE 2.2** Component technology map, showing the relationship of assembly, PWB, and component technologies on overall package density and technology.

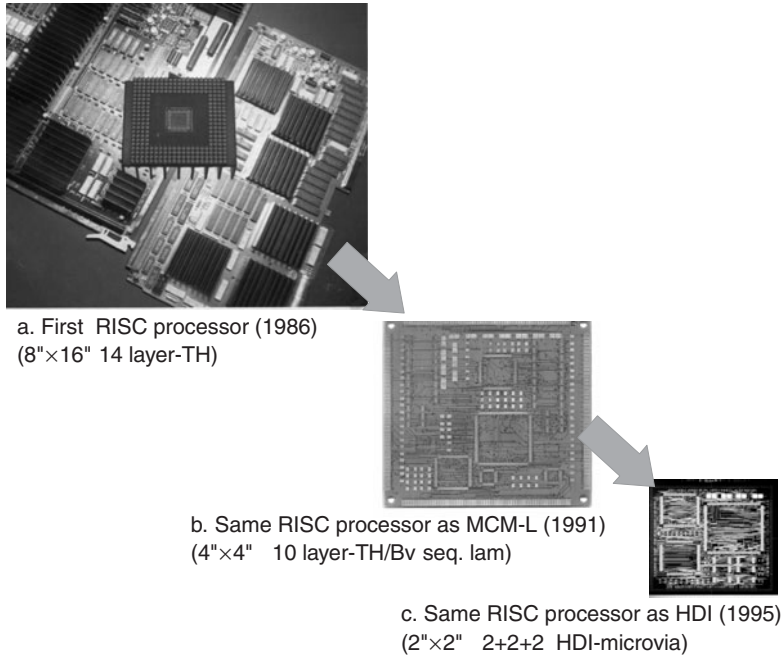

To describe the component complexity of an assembly, the total component connections (I/Os) include both sides of an assembly, as well as edge fingers, or contacts, which are divided by the total number of components on the assembly. The resulting average leads (I/Os) per part provides the  $x$ -axis of Fig. 2.2. The horizontal oval shape shows how the component complexity can vary from two leads per part in discrete circuit elements to the very large numbers seen on BGA and application-specific integrated circuits.

When Fig. 2.2 is used to describe surface-mount assemblies, the vertical ( $y$ -axis) dimension (shown as a vertical oval) indicates how complex it is to assemble the board by number of components per square inch or square centimeter for the surface area of the PWB. This vertical oval can vary from 1 to over 100 parts per square inch. As the parts become smaller and closer together, this number naturally goes up. A second assembly measure is average leads (I/Os) per square inch or square centimeter. This is the  $x$ -axis value multiplied by the  $y$ -axis value. (For a further description of these issues, and equations for quantifying them, see Chap. 18.)

The  $z$ -axis oval in Fig. 2.2 describes the printed wiring board's density. This is the wiring required to connect all the I/Os of the components at the size of the assembly specified, assuming three nodes per net. This axis has the units inches per square inch, or centimeters per square centimeter. A further description of this metric is provided in this chapter and in more detail in Chap. 19.

### 2.2.3 An Example of the Interconnect Revolution

By charting products of a particular type over time, an analysis will show how the interconnect technology has changed and continues to change, its rate of change, and the direction of these changes. An example is given in Fig. 2.3. This shows how component technology, assembly technology, and PWB technology have led to the evolution of the same computer CPU from:

**FIGURE 2.3** Example of the same computer CPU board as it used alternative component, assembly, and PWB technologies. (a) Size and appearance of each generation. (b) Movement of total board density from traditional to HDI. (c) HDI.

A 14-layer board through-hole with a surface area of 128 in<sup>2</sup> in 1986 (Fig. 2.3[a]) to  
 A 10-layer surface-mount technology board with a surface area of 16 in<sup>2</sup> in 1991 (Fig. 2.3[b]) to  
 A high-density interconnect board with sequential build-up microvias, buried and blind vias, and a surface area of 4 in<sup>2</sup> in 1995 (Fig. 2.3[c])

### 2.2.4 Region of Advanced Technologies

A second valuable feature of the chart in Fig. 2.2 is the area identified as the region of advanced technologies. This is where calculations and data have shown that it is necessary to have an HDI structure. Therefore, this is the barrier, or wall of HDI: on one side it is most cost effective to use traditional PWB technologies; on the other side it becomes cost effective to use HDI technologies. Continuing beyond this point, HDI becomes necessary.

## 2.3 HIERARCHY OF INTERCONNECTIONS

To have the proper perspective on where PWBs fit into electronic systems, it will be helpful to describe briefly the packaging hierarchy of electronic systems. Some time ago, the Institute for Interconnecting and Packaging Electronic Circuits (IPC)<sup>2</sup> proposed eight categories of

system elements in ascending order of size and complexity, which will be used here to illustrate typical electronic packaging structures. These are as follows:

*Category A* consists of fully processed active and passive devices. Bare or uncased chips and discrete capacitors, resistors, or their networks are typical examples of this category.

*Category B* comprises all packaged devices (active and passive) in plastic packages, such as DIPs, TSOPs, QFPs, and BGAs, as well as those in ceramic packages, such as PGAs, and connectors, sockets, and switches. All are ready to be connected to an interconnecting structure.

*Category C* is substrates that interconnect uncased or bare chips (i.e., the components of category A) into a separable package. Included here are all types of multichip modules (MCMs), chip-on-boards (COBs), and hybrids.

*Category D* covers all kinds of substrates that interconnect and form assemblies of already packaged components, i.e., those from categories B and C. This category includes all types of rigid PWBs, flexible and rigid-flexible, and discrete-wiring boards.

*Category E* covers the back planes made by printed wiring and discrete-wiring methods or with flexible circuits, which interconnect PWBs, but not components, from the preceding groups.

*Category F* covers all intraenclosure connections. Included in this category are harnesses, ground and power distribution buses, RF plumbing, and co-ax or fiberoptic wiring.

*Category G* includes the system assembly hardware, card racks, mechanical structures, and thermal control components.

*Category H* encompasses the entire integrated system with all its bays, racks, boxes, and enclosures and all auxiliary and support subsystems.

As seen from the preceding list, PWBs are exactly in the center of the hierarchy and are the most important and universally used element of electronic packaging.

The packaging categories F, G, and H are used mainly in large mainframes, supercomputers, central office switching, and some military systems. Since there is a strong trend toward the use of miniaturized and portable electronic products for the majority of electronic packaging designs, trade-offs are made in the judicious application and selection among the elements of the first five categories. These are discussed in this chapter.

## **2.4 FACTORS AFFECTING SELECTION OF INTERCONNECTIONS**

---

Selection of the packaging approaches among the various aforementioned elements is dictated not only by the system function, but also by the component types selected and by the operating parameters of the system, such as the clock speeds, power consumption, and heat management methods, and the environment in which the system will operate. This section provides a brief overview of these basic constraints that must be considered for proper packaging design of the electronic system.

### **2.4.1 Speed of Operation**

The speed at which the electronic system operates is a very important technical factor in the design of interconnections. Many digital systems operate at close to 100 MHz and are already reaching beyond that level. The increasing system speed is placing great demands on the ingenuity of packaging engineers and on the properties of materials used for PWB substrates.

The speed of signal propagation is inversely proportional to the square root of the dielectric constant of the substrate materials, requiring designers to be aware of the dielectric properties of the substrate materials they intend to use. The signal propagation on the substrate between chips, the so-called *time of flight*, is directly proportional to the length of the conductors and must be kept short to ensure the optimal electrical performance of a system operating at high speeds.

For systems operating at speeds above 25 MHz, the interconnections must have transmission line characteristics to minimize signal losses and distortion. Proper design of such transmission lines requires careful calculation of the conductor and dielectric separation dimensions and their precise manufacture to ensure the expected accuracy of performance. For PWBs, there are two basic transmission line types:

1. Stripline
2. Microstrip (for details, see Chap. 15)

## 2.4.2 Power Consumption

As the clock rates of the chips increase and as the number of gates per chip grows, there is a corresponding increase in their power consumption. Some chips require up to 30 W of power for their operation. With that, more and more terminals are required to bring power in and to accommodate the return flow on the ground planes. About 20 to 30 percent of chip terminals are used for power and ground connections. With the need for electrical isolation of signals in high-speed systems operation, the count may go to 50 percent.

Design engineers must provide adequate power and ground distribution planes within the multilayer boards (MLBs) to ensure efficient, low-resistance flow of currents, which may be substantial in boards interconnecting high-speed chips consuming tens of watts and operating at 5 V, 3.3 V, or lower. Proper power and ground distribution in the system is essential for reducing  $di/dt$  switching interference in high-speed systems, as well as for reducing undesirable heat concentrations. In some cases, separate bus-bar structures have been required to meet such high power demands.

## 2.4.3 Thermal Management

All the energy that has been delivered to power integrated circuits (ICs) must be efficiently removed from the system to ensure its proper operation and long life. The removal of the heat from a system is one of the most difficult tasks of electronic packaging. In large systems, huge heat-sink structures, dwarfing the individual ICs, are required to air-cool them, and some computer companies have built giant superstructures for liquid cooling of their computer modules. Some computer designs use liquid immersion cooling. Still, the cooling needs of large systems tax the capabilities of existing cooling methods.

The situation is not that severe in smaller, tabletop or portable electronic equipment, but it still requires packaging engineers to ameliorate the hot spots and ensure longevity of operation. Since PWBs are notoriously poor heat conductors, designers must carefully evaluate the method of heat conduction through the board, using such techniques as heat vias, embedded metal slugs, and conductive planes.

## 2.4.4 Electronic Interference

As the frequency of operation of electronic equipment increases, many ICs, modules, or assemblies can act as generators of radio frequency (RF) signals. Such electromagnetic interference (EMI) emanations can seriously jeopardize the operation of neighboring electronics

or even of other elements of the same equipment, causing failures, mistakes, and errors, and must be prevented. There are specific EMI standards defining the permissible levels of such radiation, and these levels are very low.

Packaging engineers, and especially PWB designers, must be familiar with the methods of reducing or canceling this EMI radiation to ensure that their equipment will not exceed the permissible limits of this interference.

## 2.4.5 System Operating Environment

The selection of a particular packaging approach for an electronic product is also dictated by its end use and by the market segment for which that product is designed. The packaging designer has to understand the major driving force behind the product use. Is it cost driven, performance driven, or somewhere in between? Where will it be used—for instance, under the hood of a car, where environmental conditions are severe, or in the office, where the operating conditions are benign? The IPC<sup>2</sup> has established a set of equipment operating conditions classified by the degree of severity, which are listed in Table 2.1.

**2.4.5.1 Cost.** The universal digitization of most electronic functions led to the merger of consumer, computer, and communication technologies. This development resulted in the increased appeal of electronics and the need for mass production of many electronic products. Thus, product cost has become the most important criterion in any design of electronic systems. While complying with all the aforementioned design and operation conditions, the design engineer must keep cost as the dominant criterion, and must analyze all potential trade-offs in light of the best cost/performance solution for the product.

**TABLE 2.1** Realistic Representative-Use Environments, Service Lives, and Acceptable Cumulative-Failure Probabilities for Surface-Mounted Electronics by Use Categories

Use category	Worst-case use environment					Years of service	Acceptable failure risk, %
	$T_{\min}$ , °C	$T_{\max}$ , °C	$\Delta T$ ,* °C	$t_D$ , h	Cycles/year

\*  $\Delta T$  represents the maximum temperature swing, but does not include power dissipation effects; for power dissipation, calculate  $\Delta T_p$ .

The importance of the rigorous cost trade-off analysis during the design of electronic products is underscored by the fact that about 60 percent of the manufacturing costs are determined in the first stages of the design process, when only 35 percent of the total design effort has been expended.

Attention to manufacturing and assembly requirements and capabilities (so-called design for manufacturability and assembly [DFM/A]) during product design can reduce assembly costs by up to 35 percent and PWB costs by up to 25 percent.

The elements that must be considered for the most cost-effective electronic packaging designs are:

- Optimization of the PWB design and layout to reduce its manufacturing cost
- Optimization of the PWB design to reduce its assembly cost
- Optimization of the PWB design to reduce testing and repair costs

The following sections provide some guidelines on how to approach such optimization of PWB designs. Basically, the costs of the electronic assemblies are directly related to their complexity and there are a number of measurements relating the effects of various PWB design elements to their costs to guide the design engineer in selection of the most cost-effective approach.

## 2.5 ICS AND PACKAGES

---

The most important factors influencing PWB design and layout are the component terminal patterns and their pitches, especially those of ICs and their packages, since these dictate the density of the interconnecting substrates. Thus, this element will be considered first.

Driven by the need for improved cost and performance, the complexity of ICs is constantly increasing. Due to relentless progress in IC technology, the gate density on a chip is increasing by about 75 percent per year, resulting in the growth of IC chip I/O terminals by 40 percent per year, which places ever increasing demands on the methods of their packaging and interconnection.

As a result, the physical size of electronic gears keeps shrinking by 10 to 20 percent per year, while the surface area of substrates is being reduced by about 7 percent per year. This is accomplished by continuously increasing wiring densities and reducing linewidths, which has severely stressed PWB manufacturing methods, reduced processing yields, and increased the costs of the boards.

### 2.5.1 IC Packages

Since their inception, IC chips have been placed within ceramic or plastic packages. Until about 1980, all IC packages had terminal leads that were soldered into plated through-holes (PTHs) of the PWBs. Since then, an increasing number of IC packages have their terminals made in a form suitable for surface-mounting technology (SMT), which has become the prevailing method of component mounting.

There has been a proliferation of IC package types, both for through-hole assembly as well as for surface mounting, varying in their lead configurations, placement, and pitches. Also, IPC-SM-782<sup>3</sup> provides a good catalog of the available SMT packages and of the PWB footprint formats they require for their assembly.

Basic I/O termination methods of IC packages include the following:

- *Peripheral*, where the terminations are located around the edges of the chip or package
- *Grid-array*, where the terminations are located on the bottom surface of the chip or package

Most IC packages have peripheral terminations at their edges. The practical limit on the peripheral lead pitches on packages is about 0.3 mm, which permits locating, at most, 500 I/Os on a large IC package, as shown in Table 2.2. It has also become evident that, in typical board assembly operations, the yields plummet as the lead pitches go below 0.5 mm.

**TABLE 2.2** Various Array Package Body Sizes, Configurations, and Lead Pitches

Body size (mm)	Number of I/Os	Minimum pitch (mm)
8 × 8	24	0.5
9 × 9	68	0.5
10 × 10	144	0.5
13 × 13	154	0.65
23 × 23	168	1.27
23 × 23	208	1.27
23 × 23	217	1.27
23 × 23	240	1.27
23 × 23	249	1.27
27 × 27	225	1.27
27 × 27	256	1.27
27 × 27	272	1.27
27 × 27	292	1.27
27 × 27	300	1.27
27 × 27	316	1.27
31 × 31	304	1.50
31 × 31	329	1.27
31 × 31	360	1.27
31 × 31	385	1.27
35 × 35	313	1.27
35 × 35	352	1.27
35 × 35	388	1.27
35 × 35	420	1.27
35 × 35	456	1.27
37 × 37	676	0.8
42.5 × 52.5	1247	1.0
52.5 × 52.5	2577	1.0

Various area array components come with a large variety of body sizes, numbers of I/Os, and I/O pitches. These components are called chip-scale packages (CSPs), plastic ball grid arrays (PBGAs), ceramic ball grid arrays (CBGAs), plastic pin grid arrays (PPGAs), and ceramic column grid arrays (CCGAs).

It is expected that chips with terminal counts below 150 to 200 will continue to use packages with peripheral leads, if these can be soldered within practical assembly yields. But for IC packages with over 150 to 200 I/Os, it is very attractive to use the grid-array terminations, since in such a case the entire bottom surface area can be utilized for terminations, which makes it possible to place large numbers of I/Os within a limited area.

This consideration has led to the development of a number of area array solder-bumping termination methods for IC and multichip module (MCM) packages, variously called pad grid, land grid, or ball grid arrays (BGAs) with terminal grids set at 1 mm (0.040 in), 1.27 mm (0.050 in), and 1.50 mm (0.060 in), respectively.

Use of grid arrays provides a number of benefits. The most important is the minimal footprint area on the interconnecting substrate, but grid arrays also offer better electrical performance due to low electrical parasitics in high-speed operation, simplified adaptation into SMT

component placement lines, and better assembly yields, despite the impossibility of direct visual inspection of the joints.

Due to continuous decrease of the terminal pitches on packages, it is important that PWB designers carefully assess the manufacturing and assembly capabilities of PWB substrates requiring such fine-pitch terminations, to ensure the greatest yields and lowest cost of the product.

## 2.5.2 Direct Chip Attach

The relentless pressures of size, weight, and volume reduction of electronic products have resulted in a growth in interest in direct chip attach (DCA) methods, where bare IC chips are mounted directly to the substrate. These methods are extensively used on chip-on-board (COB) and multichip module (MCM) assemblies, as shown in Fig. 2.4.

**FIGURE 2.4** COB and MCM assemblies.

Three methods of bare chip attachment to the substrate are as follows:

1. *Wire-bonding* is the oldest and the most flexible and widely used method. (More than 96 percent of all chips today are wire-bonded.)
2. *Tape-automated bonding* (TAB) is useful with small I/O pitches and provides the ability to pretest the chips before assembly.
3. *Flip-chipping* is used for its compactness and improved electricals, typical of which is the C4 process of IBM.

The problems of thermal coefficient of expansion (TCE) mismatch between silicon chips that are directly flip-chipped onto a laminate substrate have been effectively eliminated by using a filled epoxy underfill encapsulation technique between the chip and the substrate (see

FIGURE 2.5 Underfill between the chip and PWB on flip-chip on board.

Fig. 2.5). This method distributes stresses over the entire area of the chip and thus significantly improves the reliability performance of this assembly method.

While the chips that need area array or flip-chip terminations—i.e., those with high pin counts—are the fastest-growing category of ICs, they still represent only a very small percent of all ICs used. Designers must, therefore, ascertain which of the DCA methods will be the most cost beneficial for a particular application.

2.5.3 Chip-Scale Packages (CSPs)

When mounting unpackaged chips on these interconnecting substrates, it is not always possible to ascertain that only properly operating chips have been assembled. By now, there are a number of methods proposed to solve this known good die (KGD) problem.

As one of the ways to resolve this problem, a number of manufacturers have developed a set of miniature packages, only slightly larger than the chip itself, which protect the chip and redistribute the chip termination to a grid array. These miniature packages permit testing and burning in of chips prior to their final assembly. A typical example of such chip scale packages is shown in Fig. 2.6. There are a number of such packages on the market.

FIGURE 2.6 CSP by Tessera, Inc., San Jose, California.

The designer, however, must analyze the termination pitches of these new CSPs because some use very tight grids, such as 0.5 mm (0.020 in) or less, which need special PWB techniques to permit signal redistribution from these packages to the rest of the board.

In general, the current PWB technology is adequate to provide direct chip terminations if wire-bonding or TAB techniques are used for interconnecting bare chips to the substrate. It requires placing suitable bonding pads spaced by the required pitch in one or two rows around the chip site. While this somewhat reduces the packaging efficiency of the board, it is still an effective method for DCA assemblies.

With grid array, the situation is more difficult because the signals from internal rows of area grid terminations must be routed between the terminals located closer to the edge, which

do not permit more than one, or at most two, conductors to pass through. In most cases, these signals from internal rows are brought down into internal layers of MLBs.

The conventional PCB constructions today cannot handle any grid arrays with pitches below 0.020 in, while some flip-chip ball grid arrays go below 0.010-in pitch. In cases when grid distances of the area terminations are below 0.50 mm (0.040 in), special redistribution layers are frequently used, which distribute signals to the conventionally made PTHs in supporting MLB.

Such layers consist of unsupported dielectric layers where small vias or blind holes are formed by laser or plasma etching or are photoformed and then plated using additive or semi-additive metallization processes. While this approach requires some extra area beyond the chip perimeter to complete the signal transfer and increases the costs of substrates, it permits the mounting of flip-chips and CSPs on PWBs. A typical method for forming such redistribution layers, called surface laminar circuit (SLC),<sup>4</sup> has been developed at IBM's Yasu plant.

## 2.6 DENSITY EVALUATIONS

### 2.6.1 Component Density Analysis

Because the components and their terminations exert a major effect on the design of the PWB, a number of metrics have been developed to establish the relationships between component density and PWB density. A major analysis of these relationships has been made by H. Holden<sup>5</sup> and some of his charts and derivations are provided here to guide the design engineers during the development of a rational PWB design.

This information is very useful in determining where the designed product will fit in the component density spectrum and what, therefore, is to be expected for PWB density.

Figure 2.7 provides a generalized view of the relationships among the component density, their terminal density, and the necessary wiring density that will be required to accommodate the selected degree of component complexity. The definition of the wiring connectivity  $W_f$  is provided.

FIGURE 2.7 Plot of general relations between component and wiring density.

### 2.6.2 PWB Density Metrics

It is essential for the proper design of PWBs to determine the density requirements and then analyze alternative methods of board construction for the most cost-effective design. There are a number of basic terms and equations used for the calculation and analysis of PWB wiring density.

$$W_c = \frac{T * L}{G} \text{ in/in}^2 \quad (2.1)$$

where  $W_c$  = wiring capacity  
 $T$  = tracks per channel  
 $L$  = number of signal layers  
 $G$  = channel width

But it is more important to determine the required wiring density that will be sufficient to interconnect all the components on the desired board size. There have been a number of empirically developed equations that permit the calculation of such a wiring demand. The simplest has been developed by Dr. D. Seraphim:<sup>6</sup>

$$W_d = 2.25 N_i * P \quad (2.2)$$

where  $W_d$  = wiring demand  
 $N_i$  = number of I/Os  
 $P$  = pitch between packages

### 2.6.3 Special Metrics for Direct Chip Attach

The assembly of uncased or bare chips on substrates has become popular mostly due to the ability of such assemblies to reduce the area of interconnections. The ideal limit for such assembly would be to place all the chips tightly together, without any space in between. This would result in 100 percent packaging efficiency, a metric measuring the ratio of silicon area to the substrate area. Naturally, such 100 percent efficiency is not achievable, but this metric is still useful in ranking various substrate construction or bare chip attachment methods, as shown in Fig. 2.8.

FIGURE 2.8 Packaging efficiency. (Courtesy of BPA, used with permission.)

Packaging efficiency of 100 percent is impossible to achieve because all chip-mounting methods require some space around the chips. Even with flip-chips, there must be a distance left between the chips to permit room for the placement tool.

Package Penalties: Excess Interconnect Area

**FIGURE 2.9** Chip area required to accommodate bonding methods.

Dr. H. Charles<sup>7</sup> of Johns Hopkins University has listed the dimensions in Table 2.3 for the necessary spacing between the chips (or the total width of the frame around the chips) for various chip attachment methods. These or very similar distances have also been cited by a number of other sources.

Even with the flip-chip mounting, packaging efficiency must be derated to about 90 percent, for wire-bonding to 70 percent and for TABs to about 50 percent, and in some cases much more. A very similar situation is shown graphically in Fig. 2.9. The packaging efficiency deratings shown in Fig. 2.9 are required to accommodate only the wiring bond pads on the substrates. But the mounting of bare chips on PWBs requires additional signal redistribution area to permit placement of larger-diameter PTHs farther out for communication with internal layers. It is evident that the packaging efficiencies on PWBs could be reduced to the range of only 20 to 30 percent, unless special surface signal redistribution layers (as previously mentioned) are used, which are made of unreinforced dielectric material. In such cases, packaging efficiency and the chip-to-chip distances will again be similar to the values cited in Table 2.3.

**TABLE 2.3** Spacing Required Between Chips

Attachment method	Chip spacing, mils
Flip-chip	15–20
Wire-bonding	70–80
Flip TAB	100–120
Regular TAB	150–400

It is apparent that direct chip attach on PWBs will result in the significant reduction of the packaging efficiency of such assemblies, except for the fact that components can be mounted on both sides of the PWB substrate. It has been shown that wire-bonding can be done on both sides of a PWB with some special fixturing; also, outer lead bonding (OLB) of TABs can be done on both sides of the PWB substrate. Thus, while single-sided bare chip assembly on PWBs reduces its packaging efficiency to about half that of other types of substrate constructions, the ability to place components on both sides of PWBs brings it back to the same packaging efficiency level as others.

## 2.7 METHODS TO INCREASE PWB DENSITY

There are three basic ways to increase the connectivity or available conductor capacity of PWBs:<sup>8</sup>

- Reduce hole and pad diameters
- Increase the number of conductive channels between pads by reducing the widths of the conductors
- Increase the number of signal planes

The effect of each approach on manufacturing yields, and thus on board costs, will be discussed in sequence. It should be noted that the last option is the simplest but the most costly solution, and thus should be used only after the methods suitable for resolving the first two conditions have been proven inadequate for achieving the desirable board density.

### 2.7.1 Effect of Pads on Wiring Density

The major obstacles preventing increase of conductor channel capacity are large pad diameters around the plated through-holes (PTHs), since, at the present state of technology, PWBs still require pads wider than the conductors at their location. These pads reduce the obtainable connectivity of PWB boards and must be accounted for in a proper analysis of interconnection density  $I_d$ . For instance, in one design, the reduction of pad diameters from 55 to 25 mils (by 55 percent) doubled the interconnection density, while the reduction in conductor pitch  $C_p$  from 18 to 7 mils (by 61 percent) increased it only by 50 percent. It is obvious that the reduction of pad diameters, or their total elimination, could be a more efficient way to increase the wiring capacity of complex PWBs.

The purpose of copper pads surrounding the drilled holes in PWBs is to accommodate any potential layer-to-layer or pattern-to-hole misregistrations and thus prevent any hole breakout outside the copper area of the pads. This misregistration is caused mainly by the instability and movement of the base laminate during its processing through the PWB or multilayer board (MLB) manufacturing steps.

The base material standards specify that such movement be limited to a maximum of 300 ppm, but the actual base material excursions are closer to 500 ppm, producing 10 mils of layer movement within a 20-in distance. For many applications this tolerance is too wide, as it requires at least a 10-mil-wide annular ring around drilled holes, resulting in considerable conductor channel blockage.

Another cause of material instability in MLBs is the excessive material movement that occurs if the laminating temperature exceeds the glass transition temperature  $T_g$  of the laminate resin. On the other hand, if the laminating temperature remains below the  $T_g$  of the resin, there is minimal dimensional variation of the base material, as the resin is still in its linear expansion phase. This explains the need for use of high- $T_g$  resins in the PWB industry.

The data obtained from the performance of new, more stable unidirectional laminates indicate that the base material movement is reduced, for instance to 200 ppm from 500 ppm, and the requirements for the annular ring width will be reduced to 4 mils from 10 mils.

Table 2.4 illustrates the connectivity gains made possible when a more stable laminate material is used, permitting a reduction in the initial diameters of the pads (as given in the first column) spaced at 2.5 mm (0.100 in) while keeping the conductor pitches constant. The most effective use of the signal plane area is achieved when the pads are eliminated and the  $z$ -axis interconnects are confined within the width of the conductors forming the invisible vias.

This derivation is based on actual data obtained from the performance of new, more stable, unidirectional laminates. While MLBs using these new, more dimensionally stable, unidirectional laminates with reduced pad diameters could be manufactured by conventional manufacturing methods, the production of MLBs with invisible vias requires the use of a sequential manufacturing process similar to the SLC process previously described.

PWB manufacturers are reasonably comfortable with the production of boards with 4- or 5-mil-wide conductors, but they still require large pads around plated holes to ensure against hole breakout. This limits the currently available wiring density to about 40 to 60 in/in<sup>2</sup> per plane, as seen from Table 2.4. A technology that will permit PWB manufacturers to fabricate invisible vias could increase the connectivity per PWB signal plane from this current range to the level of 100 to 140 in/in<sup>2</sup>. Conductor widths of 0.002 in will offer a PWB of 200 to 250 in/in<sup>2</sup> per signal plane.

**TABLE 2.4** Effect of Pad Diameters on Interconnectivity Density

Pad dia, in	Cond pitch, in	$I_d$ @ 500 ppm, in/in <sup>2</sup>	$I_d$ @ 200 ppm, in/in <sup>2</sup>	$I_d$ @ invisible via, in/in <sup>2</sup>
0.055	0.010	20	37	55
0.036	0.018	30	48	55
0.025	0.009	40	96	100
0.025	0.007	60	130	143

**TABLE 2.5** Effect of Increased Connectivity on Reduction of Layers

Pad dia, in	Cond pitch, in	$I_d$ @ 500 ppm, layers	$I_d$ @ 200 ppm, layers	$I_d$ @ invisible via, layers
0.055	0.010	10	6	4
0.036	0.018	7	4	4
0.025	0.009	5	2	2
0.025	0.007	4	2	2

Table 2.5 illustrates the most important result of increased connectivity per layer: a reduction in the number of signal layers needed to provide the same wiring density  $W_d$ . Table 2.5 was constructed by applying connectivity data from Table 2.4 to a 50-in<sup>2</sup> MLB with total wiring length of 10,000 in. Note also that the layer count in Table 2.4 has been brought up to the next higher full-layer value, i.e., the calculated 1.4 layers have been recorded as 2 layers.

The major benefit of such a reduction in the layer count is that it can result in a significant reduction of the manufacturing cost while providing the same total interconnection length.

## 2.7.2 Reduction of Conductor Width

An obvious method of increasing the connectivity of PWBs is to reduce the widths of conductors and spaces and thus increase the number of available wiring channels on each signal plane, as described previously. This is the direction that has been used in the IC and PWB industries for many years. However, it is impossible to decrease conductor widths or spaces indefinitely. The reduction of the conductor width is limited by the current-carrying capacity of thin, small conductors, especially when these conductors are long, as they frequently are on PWBs. There are processing limits to this conductor reduction, since manufacturing yields may plummet if the reduction stretches the process capabilities beyond their normal limits.

There is also a limit to the reduction of the spaces between the conductors, governed mainly by electrical considerations, i.e., by the need to prevent excessive cross talk, to minimize noise, and to provide proper signal propagation conditions and characteristic impedance.

Still, such conductor reductions, if achieved within the described limits, can be an effective path for increasing the PWB density and the reduction of PWB manufacturing costs. As seen from Table 2.6, constructed from cost data derived from the Columbus program of BPA, the reduction of conductor widths from 6 to 3 mils halves the number of signal layers necessary to

**TABLE 2.6** Effect of Conductor Widths on Number of Layers and Board Cost for a 6-in × 8-in MLB, with  $I_d = 450$  in/in<sup>2</sup>, 65 to 68 Percent Yields

Line-space	Total no. of layers	No. of signal layers	Board cost, %
3-3	8	4	55
4-4	10	6	64
5-6	12	7	77
5-7	14	8	87
6-6	16	8	90
7-8	20	10	100

ensure the same connectivity (while their yields, interconnection density, and board area were kept constant). This reduction in the number of layers can significantly reduce the manufacturing costs of PWB boards.

### 2.7.3 Effect of Conductor Widths on Board Yields

It is obvious that any successful increase of conductor density  $I_d$  in PWBs would be effective only if the processes exist that permit manufacture with reasonable yields. Unfortunately, the yields of thin conductors in PWBs fall rapidly as their widths are reduced below 5 mils, as shown in Fig. 2.10. Therefore, the understanding of manufacturing yields is very important for analysis of the most cost-effective manufacturing process, because the process yields have a major effect on the cost of interconnection substrates.

FIGURE 2.10 Board yields vs. conductor width.

FIGURE 2.11 Yield loss from shorts.

A useful empirical equation for calculating the manufacturing cost is:

$$\text{Cost } C = \frac{(\text{material} + \text{process costs})}{\text{Yield } Y} \tag{2.3}$$

To establish the effect of the interconnection density  $I_d$  on the final yield of substrates, the total processing yield can be split into two components: one that depends on the conductor density, i.e.,  $Y_{I_d}$ , and the second, which is a function of the combined yields of the rest of the manufacturing processes:

$$Y_{\text{total}} = Y_{I_d} * Y_{\text{proc}} \tag{2.4}$$

In a well controlled manufacturing operation, the process-dependent yields (such as plating) remain fairly constant for a given technology, permitting the yield function to be based solely on the changes in the conductor widths.

FIGURE 2.12 Cost relationships between number of layers and conductor widths.

As seen from Fig. 2.11, the defects that affect this density-dependent yield function  $Y_{ld}$  are conductor opens and shorts between them. It would be reasonable to assume that such defects have a Poisson distribution over the total length TL of conductors of a substrate, with an average defect frequency of  $\nu$ . The yield is the probability of zero defects ( $n = 0$ ) in the total conductor length TL. Thus,

$$Y = (\text{at } n = 0) = e^{(-\nu * TL)} \quad (\text{Poisson distribution}) \quad (2.5)$$

As seen from Figs. 2.10 and 2.11, the defect frequency  $\nu$  depends also on the widths of lines and spaces, i.e., on the conductor pitch  $C_p$ . With a decrease of  $C_p$ ,  $\nu$  will increase, but for very large  $C_p$ ,  $\nu$  should be 0, since  $Y_{ld}$  will be 100 percent.

For instance, in the case of a design using invisible pads, where  $C_p = 2w$ , the interconnection density  $I_d$  can be expressed as  $I_d = TL/A$ , and  $I_d$  is proportional to  $C_p$ , i.e.,  $I_d * C_p = 1$ , and  $TL = A/C_p$ . Therefore,  $\nu$  in this equation can be empirically expressed as:

$$\nu = -\ln \frac{Y_0}{TL_0} * \left( \frac{C_{p0}}{C_p} \right)^b \quad (2.6)$$

where  $b$  is an exponent dependent on the technology or process used to form the conductors. This exponent  $b$  varies considerably from facility to facility and among various pattern formation methods, and must be empirically determined for each case.

## 2.7.4 Increase in Number of Conductor Layers

This is the simplest and most straightforward solution: when there is insufficient room on existing layers to place all the necessary interconnecting paths, add a layer. This approach has been widely practiced in the past, but when cost effectiveness of the substrates is of paramount importance, a very careful design analysis must be made to minimize layer counts in MLBs, because there is a significant cost increase with every additional layer in the board. As seen from Table 2.6, calculated for 6- × 8-in MLBs produced in large quantity with yields and conductor density kept constant, there is almost a linear relationship between board costs and layer count.

Table 2.6 also shows that any increase in the number of signal layers in boards operating at frequencies requiring transmission line characteristics will double the total number of layers, due to the need to interleave ground or DC power planes between signal planes.

A typical example of the effect of layer count on the finished MLB yield can be seen from Fig. 2.12, prepared some years ago by BPA. We can see that there is a definite decrease in the manufacturing yields with an increased number of layers in any of the linewidth categories. This is rather a typical situation in board manufacturing because increased complexity and thickness of MLB with a higher number of layers usually leads to a larger number of problems on the production floor.

## 3.1 INTRODUCTION

---

A revolution has occurred in the electronics industry due to advances in semiconductor design and manufacturing, the packaging of semiconductor die, the packaging of electronics systems, and product physical design.

The driving force in this revolution originates with the advances that have occurred in integrated circuit (IC) technology and the levels of integration obtained. The initial driver to this was the development of a micrometer-level lithographic capability.<sup>1</sup> Semiconductor packaging and printed circuit board (PCB) evolution tracks the advances in IC technology. Figures 3.1 and 3.2 show the trend of chip transistor density and the increase in chip frequency versus time. There is concern that, with the current semiconductor technology advances, by about 2010 we may begin to approach significant process and technology obstacles. As a consequence of being able to put more circuitry on a silicon IC, its package size and the number of package input/output (I/O) pins have increased, as has the wiring density required of the medium that interconnects the packaged ICs.

This continuing thrust for higher levels of integration has forced an ongoing effort for smaller and cheaper means of packaging these ICs so they can be interconnected in a cost-effective manner that does not degrade the electrical performance of the assembled circuit. As a result, high-performance systems require consideration of both the IC design and its packaged format and the design of the interconnect that connects the ICs.

Table 3.1 compares the computing capability available over the years. What has occurred is that there has been a constant increase in functionality (i.e., instructions per second) along with continuous decreases in the cost per instruction. The results of this trend are the ever increasing functionality of portable wireless communications, such as pagers and cellular phones, and their reduction in size to minimum ergonomic standards.

Worldwide in 1998 there were some 308 million cell phone subscribers; the number grew to 475 million in 1999. It is estimated that in 2001 there were 1000 million (i.e., 1 billion) cell phone subscribers. From 2000 to 2001, more than half a billion cellular phones were manufactured, and these are now considered a commodity product. This same technology trend is spawning new wireless products for local area networks. These applications will allow cellular

**FIGURE 3.1** Chip density trend for logic and DRAM components.

phones, personal computers, etc. to exchange data (including video) using appropriate radio frequency (RF) protocols (Bluetooth operating in the 2.4-GHz frequency range is one such protocol) if they are in proximity to one another.

The requirements of the Internet for increasing functionality and bandwidth and lower cost will require new concepts for electronic physical design as well as the incorporation of optical components and interconnects. These trends will continue indefinitely.

**FIGURE 3.2** Chip frequency requirement trend.

**TABLE 3.1** Cost Comparison

	Approx. no. of instructions/s	Price	Cents/instruction
1975 IBM mainframe	10,000,000	\$10,000,000	100
1976 Cray 1	160,000,000	\$20,000,000	12.5
1979 Digital VAX	1,000,000	\$ 200,000	20.0
1981 IBM PC	250,000	\$ 3,000	1.2
1984 Sun Microsystems 2	1,000,000	\$ 10,000	1.0
1994 Pentium PC	66,000,000	\$ 3,000	0.0045

### 3.1.1 Packaging and Printed Circuit Technology Relationships

The packaging density trend lines (package area/die area) are summarized in Fig. 3.3. The area efficiencies of array package concepts are evident and have been maintained over a period of 20 years.

It is apparent, then, that the trends for new semiconductor chip packaging are increasing the number of package I/Os. Area array packages for high- I/O semiconductors have emerged to minimize package size and enhance package electrical performance (i.e., lower lead inductance). The impact of this will be pressure on PCB fabricators to minimize linewidth and space in order to escape from high- I/O area array packages or direct chip attach (DCA) semiconductors. In 1986, for PCB interconnects, 6-mil lines and spaces were nominal; in 1992, 8-mil lines and spaces were nominal; in 1995, 6-mil lines and spaces were nominal, and in 2000 4-mil lines and spaces are nominal to meet the interconnect requirements of commercial hand-held electronics products.

To meet the needs for a finer-pitch circuit board technology for ball grid array (BGA) packages, chip-scale packages (CSPs), and high-density circuit cards, a new circuit board

**FIGURE 3.3** Packaging trends show the area efficiency of array package concepts over a period of 20 years.

technology called high-density interconnect, capable of 1.58-mil (40- $\mu\text{m}$ ) lines and spaces have been developed.

### 3.1.2 Electronic Packaging Issues and Concerns

Electronic packaging begins where circuit design leaves off.

**3.1.2.1 Physical Design and Packaging Issues.** The issues involved in electronic physical design and packaging are as follows:

- Selection of appropriate electronic components (i.e., semiconductors, discrete, and passives)
- Mechanical layout and assembly of components, interconnectors, and cases
- Production engineering/technology
- Electrical parameters of interconnects (controlled-impedance design, cross talk, clock skew, signal propagation delay, electromagnetic interference for RF circuits, etc.)
- Thermal conditions (heat dissipation, cooling, etc.)

**3.1.2.2 Digital Circuit Design Considerations.** Digital circuits should be able to do the following:

- Transfer a complete logic swing in shortest time
- Have the interconnect characteristic impedance designed to equal the load impedance
- Have characteristic impedance that is purely resistive to minimize reflections
- Accommodate clock skew

For the interconnection of digital semiconductor devices, a major issue that must be considered is clock skew, which results from varying the length of clock lines and is a major design consideration for high-speed products.

**3.1.2.3 Analog Circuit Design Considerations.** Analog circuits should be able to do the following:

- Maximize power transferred from input to output
- Make the driver impedance a complex conjugate on the transmission line

**3.1.2.4 Power Issues for Silicon Semiconductors.** The following items are power considerations for silicon semiconductors:

- Transistor-transistor logic and complementary metal oxide semiconductor (CMOS) power dissipation depend on frequency and increase dramatically at high frequencies.
- Drain of an emitter collector logic device is independent of frequency for a given load.
- Resistance loading drains the output capacitor of CMOS circuitry.
- Terminating CMOS circuits to control reflection imposes a power penalty.

Gallium arsenide (GaAs) semiconductors are now technologically competitive with silicon,<sup>2</sup> especially for high-speed logic applications. For GaAs logic, power dissipation is independent of frequency, and GaAs circuit operation is unaffected by power supply voltages down to about 1 V.

**3.1.2.5 RF Semiconductors.** GaAs bipolar CMOS and silicon germanium are semiconductor technologies now being used in RF circuits of many wireless products. Special attention

is required in the packaging of RF components to control the electrical parasitics, the thermal resistance for components such as power amplifiers, etc.

### 3.1.3 Requirements for Electronic Systems

The requirements for electronics systems and products driven by semiconductor technology developments are as follows:

1. The advances in integrated semiconductor technology mean products operate at higher speeds and have higher performance and greater functionality.
2. The reliability and quality of products are givens and are expected to be built in at no cost premium.
3. The volume (i.e., size) of the electronics products is diminishing, and is constrained only by ergonomic requirements and the ability to dissipate heat (i.e., power).
4. The costs of the components and assembly are expected to continuously decrease with time.
5. The time to market impacts all of the preceding items.

## 3.2 SINGLE-CHIP PACKAGING

Prior to 1980, the semiconductor package predominately used was the dual inline package (DIP). The package is rectangular in shape with leads on a 0.100-in pitch along the long sides of the package.

Figure 3.4 shows the various semiconductor formats and package trends. The packages on the left side of Fig. 3.4 are essentially perimeter I/O packages—i.e., DIPs, quad flat packages (QFPs), plastic leaded chip carriers (PLCCs, tape automated bonding (TAB), etc. The package types on the lower right side of Fig. 3.4 represent area array packages such as pin grid array (PGA) packages (an array of pins attached to the package base for electrical connection), land grid array packages (an array of conducting pads on the package base for electrical connection, sometimes called pad array carriers [PACs], or, when the lands have reflowed solder balls attached, ball grid array [BGA] packages), and multichip modules. The pitch of the I/Os of DIPs and PGA packages is 0.1 in, while the I/O pitches of the balance of the parts

FIGURE 3.4 Integrated circuit packaging trends.

are 0.060 in or less (i.e., 0.050 in, 0.5 mm, 0.4 mm, 0.3 mm). Array-type packaging concepts have emerged to provide higher package electrical performance and/or lower packaging densities (package area/die area).

### 3.2.1 Dual Inline Packages (DIPs)

Figure 3.5 shows the configuration of a DIP. DIPs are available with a cofired ceramic body with the leads brazed along the long edges or in a postmolded construction where the die is bonded to a lead frame and gold wires interconnect the chip to the lead frame leads prior to molding of a plastic body around the lead frame. DIPs are limited to 64 or fewer I/Os.

FIGURE 3.5 Dual inline package.

### 3.2.2 Leadless Ceramic Chip Carriers

To improve the form factor, packages for commercial and military applications were developed called leadless ceramic chip carriers, consisting essentially of the cavity portion of the ceramic hermetic DIP (see Fig. 3.6) with solderable lands printed onto the bottom of the leadless ceramic chip carrier package. These parts were assembled on ceramic substrates and used in both military and telecommunications products. Almost concurrently, leaded versions of the leadless packages begin to appear. The pitches of the leadless parts were 0.040 and 0.050 in, while the leaded parts were on a 0.050-in pitch. Reference 3 discusses these developments in detail. By 1980, thrust-to-quad surface-mount packaging had begun, with the emphasis on leaded plastic quad packages.

Reference 4 shows that by 1993 there was a dramatic swing away from through-hole-mounted parts (i.e., DIPs) to surface-mount packages. In 1993, 50 percent of the semiconductor

FIGURE 3.6 Leadless ceramic chip carrier.

packages fabricated were through-hole-mounted DIPs. By 2000, this percentage dropped to 30 percent, and by 2005 it is projected to drop to only 15 percent.

### 3.2.3 Plastic Quad Flat Package (PQFP)

The driver for the surface-mount plastic packages has been the development of the plastic quad flat package (PQFP), which consists of a metal leadframe with leads emanating from all four sides. The leadframe is usually copper, to which the semiconductor die is “die bonded” (usually epoxy die bonded). The I/Os of the die are connected by wire bonds to the leadframe leads. The conventional method of wire-bonding is thermosonic gold ball wedge bonding. A plastic body is then molded around the die and the leads are trimmed and formed. Figure 3.7(a) shows a cross-sectional view of a PQFP.

PQFPs have their leads formed in a gull-wing fashion (see Fig. 3.7), while PLCCs have their leads in the shape of a J, which are formed (i.e., folded) underneath the package.

Figure 3.8 shows the lead pitch and pin count limit versus QFP size and lead pitch. QFPs are in production and readily used in the assembly of product with 0.5-mm pitch. Based on molding capability and impact of lead length on electrical performance,

FIGURE 3.7 Surface-mount plastic package types.

a molded body 30 mm on a side is thought to be the practical limit. QFPs with 0.5-mm pitch based on the preceding are limited to around 200 I/Os. QFPs with 0.4-mm pitch have been implemented.

FIGURE 3.8 Lead pitch and pin count limit vs. QFP size and lead pitch.

Figure 3.7 shows the variety of surface-mount plastic packages that have been developed based on PQFP technology.

Ceramic and plastic QFPs, as well as PLCCs, are used to package gate array and standard cell logic and microprocessors. Small-outline IC and small-outline J-lead packages are used to package memory (SRAM and DRAM) as well as linear semiconductors. Pin count for all package types is limited only by molding capability and the demand for ever thinner molded packages.

### 3.2.4 Pin Grid Array (PGA) and Pad Array Carrier (PAC)

Consider the impact of using a perimeter I/O package versus an area array package. Figure 3.9 illustrates the differences between a perimeter array package (leadless chip carrier) and an area array package (PAC). Figure 3.10 shows the relation between the package area versus I/O for perimeter and area array packages. It is clear from Fig. 3.10 that for semiconductors with more than 100 I/Os, PGA and PAC packages have become increasingly attractive for packaging very-large-scale semiconductor ICs and ultra-large-scale semiconductor ICs. The scalable limit is determined only by fatigue issues of the solder connection or joint.

FIGURE 3.9 Perimeter I/O package vs. area array package.

FIGURE 3.10 PAC packaging efficiency

#### 3.2.4.1 Perimeter Array I/O Package Advantages and Disadvantages

- Perimeter array I/O packages at 0.050-in pitch can be readily surface-mount assembled. Both 0.4-mm pitch perimeter I/O QFPs and 0.3-mm pitch perimeter I/O QFPs are now in manufacture. Reviewing Fig. 3.8, which shows QFP size versus lead pitch and pin count, it is apparent that the usefulness of QFPs is limited to around 400 I/Os.
- There still is a controversy in the packaging and assembly community as to whether 0.3-mm pitch QFPs, particularly with a large number of I/Os, are a high-throughput, high-assembly-yield part due to the fragility of the lead (0.015 mm wide) and the possibility of solder shorts between leads.

**3.2.4.2 Pad Array and BGA Packages.** This disconnect is being addressed first by pad array and BGA package technology. References 5 and 6 provide details of this emerging technology, particularly as it relates to low-cost plastic array packages with reflowed solder balls attached to the package array I/Os. Figure 3.11 shows a ceramic BGA (CBGA) and Fig. 3.12 shows a cross section of the plastic BGA.

**FIGURE 3.11** Ceramic ball grid array.

**FIGURE 3.12** Ball grid array cross section.

The advantage of ball grid array packages (ceramic or plastic) include the following:

- The package offers a high-density interconnect. Pad array pitches of 1.27, 1.0, 0.8, and 0.5 mm are now commercially available.
- The packages have achieved six-sigma soldering (demonstrated for 1.27- and 1.00-mm I/O pitches) because of the large volume of solder on the I/O pad.
- The package is a low-profile part (package thicknesses as low as 1 mm are now available).
- The package has superior electrical performance in that the total lead length is short, controlled impedance interconnects can be designed in, and low-dielectric constant and low-loss materials can be used for the substrate.
- The package depending on the design has the potential for superior thermal performance.
- The package concept is extendable to multichip packages (MCPs).

Table 3.2 gives the expected ranges of I/O for BGA packages for high-end microprocessors and for dies used in portable products. In 2000, approximately 60 percent of all BGA packages

had 1.27- or 1.00-mm pitch and the balance had 0.8- or 0.5-mm pitch. By 2004, 60 percent of all BGA packages will have 0.8- or 0.5-mm pitch, with a small number having less than 0.5-mm pitch.

**TABLE 3.2** BGA Pin Counts

Year	2001	2005	2010
Pin count, high-end logic	700–1000	1000–1900	1200–4000
Pin count, portable products	256	312	360

The area efficiency of BGA packages that have a relatively low pad count (i.e., less than 140) has increased in the last several years. This new form of the BGA package, called chip-scale package (CSP), has an area efficiency of around 80 percent (i.e., 80 percent of the package area comprises the silicon die area). The pad pitch on CSPs range from 0.8 to 1 mm. CSPs should be considered a variant of the BGA package technology. Figure 3.13 shows a typical CSP package.

## Amkor Tape CSP

**FIGURE 3.13** Typical CSP technology. (Courtesy of Amkor Inc.)

A new and smaller package called a wafer-scale package (WSP) has been developed. Figure 3.14 shows such a package. The area efficiency of this package is 100 percent (i.e., 100 percent of the package area comprises the silicon die area). A WSP is a package where all the packaging processes are completed on the silicon wafer, including application of the I/O solder balls. The WSP has relatively low I/O count and has pad pitches ranging from 0.8 to 1 mm. Generally, a redistribution of the chip I/Os uniformly over the die area is required to obtain these pitches. The WSP requires no chip under encapsulation, as is required by direct chip attach (DCA), discussed in Sec. 3.2.5.

**FIGURE 3.14** Wafer-scale package. (Courtesy of Flipchip Technologies.)

### 3.2.5 Direct Chip Attach (DCA)

The next step down from area array packages is DCA. The methods of attaching a semiconductor die directly to an interconnect board (PCB, multilayer ceramic, etc.) are:

- Die bond/wire-bond
- TAB
- Flip-chip bonding

An exhaustive discussion of wire-bond, TAB, and controlled-collapse chip connection (C4) or solder-bumped flip-chip-to-board interconnect technology can be found in Chap. 6 of Ref. 7. Figure 3.15 illustrates these chip interconnect methodologies, which will be discussed in the following text.

**3.2.5.1 Die Bonding to Printed Circuit.** The preferred method of die bonding and wire-bonding is epoxy die bonding to the interconnect (i.e., PCB or multilayer ceramic) and gold ball-wedge wire-bonding. One of the advantages of gold ball-wedge wire-bonding is that a wedge bond can be performed on an arc around the ball bond. This is not true for wedge-wedge wire-bonding.

Wire bonds can be made with wire diameters as small as 0.8 mil. Thermosonic ball-wedge bonding of a gold wire, shown in Fig. 3.15(e), is performed in the following manner:

1. A gold wire protrudes through a capillary.
2. A ball is formed over the end of the wire by capacitance discharge or by passing a hydrogen torch over the end of the gold wire.

**FIGURE 3.15** DCA interconnect methodologies: (a) die bond/wire-bond module; (b) TAB module; (c) flip TAB module; (d) flip-chip module; (e) thermosonic gold wire-bonding; (f) TAB bonding; (g) flip-chip bonding.

3. Bonding of the ball is accomplished by simultaneously applying a vertical load to the ball bottomed out on the die bond pad while ultrasonically exciting the capillary (the die and substrate are usually heated to a nominal temperature).
4. The capillary is moved up and over to the substrate or lead bond pad, creating a loop, and, under load and ultrasonic excitation, a bond is made.
5. The wire is clamped relative to the capillary and the capillary moves up, breaking the wire at the bond.

Die bond and wire-bond attach suffer from the problem that this method of chip attach is difficult to repair, particularly if the chip is encapsulated.

**3.2.5.2 Tape-Automated Bonding (TAB).** TAB, shown in Fig. 3.15(f), is more expensive than wire bonding and may require a substantial fan-out from the die to make the outer lead bond. TAB is a process in which chemically etched, prefabricated copper fingers, in the form of a continuously etched tape consisting of repetitive sites, are simultaneously bonded using temperature and pressure to gold or gold-tin eutectic bumps that are fabricated on the I/Os of the die. The outer leads of the TAB-bonded die are excised and simultaneously bonded to tinned pads on the interconnect, using temperature and pressure.

**3.2.5.3 Solder-Bumped Dies.** The use of solder-bumped dies for packaging electronic systems was pioneered by IBM and was called controlled-collapse chip connection (C4) by IBM. The solder bump composition of the C4 die is approximately 95Pb/5Sn. The C4 dies in the IBM application were attached to multilayer ceramic substrates by reflow soldering, using a flux that required cleaning after reflow. The initial IBM application of C4 technology was for high-end computer packaging. Flip-chip attach shown in Fig. 3.15(g), where the die I/Os are solder bumped (usually with 95Pb/5Sn or eutectic Pb/Sn solder) and the chip reflow is attached to its interconnect, has now emerged as a viable packageless technology for consumer commercial products. For the DCA technology, the PCB flip-chip lands are usually solder-finished with a eutectic Pb/Sn solder. A no-clean flux is used for DCA soldering. Once the chip has been solder-attached, it is underencapsulated to provide moisture protection and to enhance the thermal cycling performance of the assembled die. References 8 to 10 discuss some of the emerging developments for direct attach of solder-bumped die to PCBs for commercial product applications. Figure 3.16 shows the DCA application discussed in Ref. 10. In this application, the CBGA packaged microprocessor was solder-bumped and direct chip attached to illustrate the potential savings in PCB real estate.

**FIGURE 3.16** DCA applications. The microprocessor on the left is in BGA, while the microprocessor on the right is attached by solder bumps to show potential area savings.

### 3.3 MULTICHIP PACKAGES

MCPs have emerged as a packaging option where performance is an issue or where interconnect area for connecting packaged ICs is at a premium. The performance issue is one of increasing semiconductor performance and the impact of the interconnect medium on the performance of the assembled die. The consequence of this is that the interconnects can no longer be considered to provide an instantaneous electrical connection. It can be shown that for copper conductors on polyimide at a clock frequency of 200 MHz, the maximum allowable length of interconnect is 170 mm, or about 6.8 in. As a reference point, the clock speed for the DEC ALPHA RISC microprocessor was 200 MHz or better in 1995. The clock speed of the Pentium III microprocessor is 500 MHz, and microprocessors with 1 GHz clock speeds are commercially available.

#### 3.3.1 Multichip Versus Single-Chip Packages

MCPs for memory have found broad application in personal computer and laptop computer products. Multiple memory dies (packaged or unpackaged) are assembled on a rectangular interconnect (PCB or multilayer ceramic) with I/Os along one rectangular edge. Such a package is called a single inline package (SIP). The I/Os of the SIP can have DIP leads assembled on them for through-hole attachment onto PCB, or they can have lands on the package to mate with a suitable connector. For through-hole-mounted SIPs, the leads are usually on a 0.100-in pitch. Memory packaged in system-on-a-package or thin system-on-a-package or small-outline J-lead packages are assembled onto SIPs whose substrate is a PCB in appropriate multiples to offer enhanced memory capability. DCA or memory die is also possible. Figure 3.17 shows several SIP configurations. Figure 3.17(a) shows an early version of a SIP using a ceramic substrate and leadless ceramic chip carriers with soldered-on leads. Figure 3.17(b) shows a typical version of an SIP to mate with an SIP-type connector.

(a)

(b)

FIGURE 3.17 SIP configurations.

### 3.3.2 MCPs Using Printed Circuit Technology

MCPs using PCB technology, but using leads on the substrate, are also being implemented to provide improved product functionality and board space savings. Figure 3.18 shows the concept of the lead-on-substrate MCP. The leads to the substrate can be fabricated integrally with the board during the PCB fabrication or can be soldered on using a suitable high-temperature solder. The lead-on-substrate MCPs can be postmolded or cover-coated with a suitable encapsulant.

**FIGURE 3.18** LOS printed circuit MCP.

The lead-on-substrate MCP could also be implemented using a cofired ceramic package with the leads brazed on and finished by cover coating with a suitable encapsulant or hermetic sealing of the assembled ICs. Chapter 7 of Ref. 7 gives a detailed discussion of the cofired multilayer ceramic package manufacturing processes.

### 3.3.3 MCPs Using Organic Substrates

The more prevalent form of MCPs uses a multilayer organic interconnect built on a substrate such as silicon, alumina ceramic, or metal composite. The dielectric films are patterned serially one on top of another to produce a multilayer interconnect. The dielectric of choice is polyimide with thin-film copper conductors. The technology for the interconnect in question uses processes and manufacturing equipment initially developed for semiconductor manufacture. This technology has a 1-mil line and space capability. The packages can have the cavity facing up (facing away from the PCB) or down (facing the PCB) if a heat sink is required for heat dissipation.

Figure 3.19 shows wire-bonded die on a silicon substrate packaged in a premolded QFP and a ceramic QFP. A premolded QFP is a lead frame about which a plastic body has been molded and which contains a cavity for a die or a substrate. The method of interconnect from the silicon substrate to the package is wire-bonding. As shown in Fig. 3.15, bare die can be attached to the silicon substrate by die/wire-bonding, TAB bonding, or flip-chip bonding. As with the lead-on-substrate technology, the I/O format for the QFPs that house the multichip substrate follows the standards for QFP packages.

FIGURE 3.19 MCP example.

### 3.3.4 MCP and PGA

PGA packages can also be used as MCPs containing the type of substrate shown in Fig. 3.19. The PGA packages can have their cavity facing up (facing away from the PCB) or down (facing the PCB) if the package requires a heat sink for power dissipation. The pitch of the pins of the PGA is usually 0.1 in.

### 3.3.5 Multichip Stacked-Die Packages

A new form of MCP is emerging at the time of this writing. The packaged dies are stacked one on top of each other and are interconnected generally by wire bonds. The dies are thinned in wafer format to thicknesses of 6 mil or less. Figure 3.20 shows the various formats. The substrates for the multichip stacked-die packages can be tape, multilayer organic (FR-4, FR-5, etc.), multilayer organic with high-density interconnect layers, or multilayer ceramic. The preferred package format is a BGA. The initial application of stacked die has been to incorporate memory with logic dies rather than integrate logic and memory on a single silicon die.

### 3.3.6 MCP and Known Good Die

One of the issues in the application of MCP technology is the availability of known good die. Clearly considering that, for most dies, the package die test yield after wafer test runs

**FIGURE 3.20** Formats for multichip stacked die packages.

somewhere around 95 percent, the MCPs are limited to perhaps five IC dies per package at best. The limitation is the resultant yield loss of a finished multichip module package. As an example, for a two-die MCP where each die has an assembled yield of 90 percent the MCP yield would be 81 percent (i.e.,  $0.9^2$ ) and for a four-chip MCP the yield would be 65.6 percent (i.e.,  $0.9^4$ ).

### 3.3.7 System-in-a-Package

An enhanced form of MCP called system-on-a-package or system-in-a-package has emerged. This package incorporates some or all of the multichip packaging technologies previously discussed. Figure 3.21 shows all of the various packaging features that make up a system-on-a-package or system-in-a-package. One feature of this package concept is that it includes not only silicon die but all the passives, etc., required to provide a system function. Passives (i.e., resistors, capacitors, and inductors) can be assembled on the substrate or can be integrated into the substrate itself (i.e., embedded passive substrate technology). Reference 11 provides a detailed overview of the system-on-a-package or system-in-a-package concept. Another example of this concept is the RF front-end HiperLAN module shown in Fig. 3.22.

## 3.4 OPTICAL INTERCONNECTS

As the performance of semiconductors increases, as measured by clock frequency, the allowable length of interconnect that does not degrade the device performance decreases. The emergence of the Internet and the need for ever increasing bandwidth has become the

(a)

(b)

  - 2 wirebonded GaAs discretes

**FIGURE 3.22** Example of system-in-a-package.

major driver for optical component and interconnect technology development. For wave-division multiplexing and Ethernet systems, we have reached the copper bandwidth limit of 5 Gbs.

### 3.4.1 Components and Packages

The demand for increased bandwidth is being driven closer to the end user (i.e., residence or desktop). The issues facing low-cost optoelectronic physical designs are (1) low-cost assembly/processes and low-cost packages for optoelectronic components and (2) the capability for standard automated board assembly of all optoelectronic parts. Figure 3.23 shows a variety of package types used to package light emitters and detectors. The packages are generally of the TO header type or the butterfly DIP or through-hole-mounted DIP type. In general the packages are hermetic. The through-hole-mounted DIP and the butterfly DIP packages are most often used to package edge-emitting lasers. An example of a fiber pigtailed butterfly DIP packaged edge-emitter laser is shown in Fig. 3.24.

**FIGURE 3.23** Package types used to package light emitters and detectors.

**FIGURE 3.24** DIP laser 0/7.

### 3.4.2 Advantages of Optical Interconnects

The advantage of optical interconnects are as follows:

- The signal propagation is independent of the bit rate (up to 20,000 Gbits/s)
- The component is immune to electromagnetic interference and cross talk
- The optical signals can pass through one another (optical noninteraction)
- The components lend themselves readily to multiplexing

Advances in optoelectronic devices are leading to active consideration of local optical signal distribution to:

- Reduce the pin count of packages for complex very-large-scale semiconductor IC chips by replacing I/O complexity with bandwidth
- Carry very-high-bit-rate signals in hybrid circuits and PCB assemblies
- Allow highly complex interconnections to be achieved without the cost and difficulties of a metal-based backplane

## 3.5 HIGH-DENSITY/HIGH-PERFORMANCE PACKAGING SUMMARY

---

Where high performance and a high level of interconnects are required, MCPs and multichip modules have emerged as one packaging idea that can provide the performance required. In addition, fiberoptic transmitters and receivers are now commercially available to provide high-performance offboard optical interconnects in place of a hard-wired backplane interconnect using standard PCB technology and cabling. These fiberoptic transmitters and receivers generally use hermetic and nonhermetic custom DIP package formats for packaging. With advances in optoelectronic semiconductors, onboard optical interconnects are also being investigated and demonstrated. Reference 12 discusses one such demonstration of onboard optical interconnects where a polyimERIC optical waveguide, including branch and cross-circuits, was fabricated in the polyimide dielectric of a multilayer copper polyimide silicon substrate. Optical waveguide technology that is embedded in PCBs is now being developed.

## 3.6 ROADMAP INFORMATION

---

The NEMI *Year 2000 Roadmap*<sup>13</sup> is a good source of detailed roadmap information for IC packaging, PCB technology, optoelectronics, and so on.

## 4.1 INTRODUCTION

---

Packages that contain electronic devices such as integrated circuits (ICs) must, at a minimum, perform the following four basic functions:

- Provide for electrical interconnection (signal, power, and ground) between the various components in the package
- Offer mechanical, electrical, and environmental protection for the devices it contains
- Provide sufficient input/output connections to allow fan-out with other parts of the electronic system of which it is a part
- Provide for dissipation of heat that may be generated by the electronic devices contained within the package when the system is powered

In the simplest terms, an electronic package must provide for circuit support and protection, power distribution, signal distribution, and heat dissipation. These basic requirements must be met if a package contains a single IC, a multiple number of ICs, or a combination of ICs and passive devices.<sup>1</sup>

Driven by the desire, and need, to make electronic systems smaller, faster, cheaper, and less power hungry, semiconductor technology continues its relentless efforts on increasing component and interconnect density, input/output (I/O) capability, and power dissipation, which, in turn, places increasing demands on packaging technology.<sup>2</sup> These advances in ICs drive packaging technology by increasing the number of I/O connections, the operating speeds, and the thermal dissipation requirements. Furthermore, systems packaging interconnections must accommodate passive components required for electromagnetic interference (EMI) reduction, filter circuits, terminations, and impedance matching.<sup>3</sup> Consequently, for high-performance ICs,

the package will continue to play an increasingly role in determining performance and cost of the IC. As a result, packaging technologies must continue to improve on the protection provided for the IC, the handling of thermal dissipation, and the routing of more and more signal interconnections, as well as power and ground distribution, through smaller and smaller spaces.<sup>4</sup> Many packages include passive devices in the form of integral passives. The advent of micro-electro-mechanical systems (MEMS), micro-opto-electro-mechanical systems (MOEMS), and even biological packages and applications has further added to the already high demands on packaging. Optoelectronic packages contain not only semiconductor devices but also optical components, such as optical fibers, lens assemblies, and, depending on the application, elements, such as optical multiplexers/demultiplexers. MEMS and MOEMS both include tiny moving parts inside the package. In view of the increased scope, *advanced packaging* is probably a more appropriate terminology than simply *electronic packaging*.

Over the past decade or two, semiconductor technology has evolved to the point where packaging cannot be considered as an afterthought in device design and manufacturing. The package plays an increasingly more integral, sometimes decisive role in the performance of the semiconductor device or devices it contains. The International Technology Roadmap for Semiconductors (ITRS) addresses this fact,<sup>5</sup> stating the following in its assembly and packaging section: “There is an increased awareness in the industry that assembly and packaging is becoming a differentiator in product development. Package design and fabrication are increasingly important to system applications. It is no longer just a means of protecting the integrated circuit (IC), but also a way for the systems designer to ensure form fit and function for today’s product—spanning consumer products to high-end workstations.” Although the definition of high-density packaging varies across the interconnect pitch to a package that has to be code-designed with the chip, it is understood that high-density packaging is and will continue to be a requirement for high-performance ICs and systems.<sup>3</sup> Figure 4.1 shows the evolution of what have been termed advanced packaging technologies for the past few years in terms of system-level packaging efficiency. It is anticipated that system-on-a-chip (SOC) and system-on-a-package (SOP) technologies will dominate advanced packaging for the next several years.

FIGURE 4.1 Evolution of system-level packaging efficiency.

## 4.2 LEAD-FREE

A new requirement on packages—that of lead-free solder—has initiated a tremendous amount of developmental effort in the past few years. This effort stems from the requirement of packages exported to the European Union (EU) market, to pass Restriction of Hazardous Substances (RoHS) compliance requirements set forth in the Directive 2002/95/EC of the

European Parliament.<sup>6</sup> Origins of the RoHS requirements stem from the need to restrict the use of specific materials found in electrical and electronic products due to their hazardous nature, the risk posed to the environment, their ability to pollute landfills, and the risk posed during its use in component manufacturing and recycling.

The substances banned under RoHS requirements and its maximum allowable trace values are as follows:

- Lead: 0.1 percent by weight (1,000 ppm)
- Cadmium: 0.01 percent by weight (100 ppm)
- Mercury: 0.1 percent by weight (1,000 ppm)
- Hexavalent chromium: 0.1 percent by weight (1,000 ppm)
- Polybrominated biphenyls (PBB) and polybrominated diphenyl ethers (PBDE): 0.1 percent by weight (1,000 ppm) combined

Two other related but different terms sometimes used in this context are the “lead-free” and “green.” RoHS is clearly more than “lead-free,” but “green” includes absence of antimony (Sb) and halogens (chlorine, bromine, and iodine). However, the eutectic tin-lead solder (Sn63%–Pb37%, or SnPb for short) cannot be used in any of the preceding. This single requirement is bringing about a paradigm shift to the world of advanced packaging. The SnPb solder has been in use in the electronics and related industry for about three decades now. During this time, the entire infrastructure related to package manufacture—beginning from the assembly materials such as substrates, flux, and underfill, and in case of flip-chip, wafer bumping—equipment such as substrate bake and solder reflow ovens and the package reliability requirements such as the JEDEC standards have been centered around the SnPb solder. Changing the requirement to now eliminate Pb from electronic packages translates to a change in all of the preceding. This change stems from an inherent difference in the physical and metallurgical properties—and hence, the processibility and reliability of the two solder materials. SnPb is an eutectic composition of its two parent elements, and has a melting temperature of 183°C. Lead-free solder alloys, almost regardless of their type and composition, have a higher melting point. Further, most of the lead-free compositions are not eutectic in nature, meaning that they do not melt at one temperature. Instead, such compositions have a softening range of temperature. Additionally, the higher melting/softening temperature imposes additional requirements on the assembly materials and on the assembly process. For example, because of the higher solder reflow temperatures for Pb-free solders, the substrates must be able to maintain their integrity and withstand a higher temperature. The flux used in the flip-chip assembly process now needs to be more aggressive in order to be effective on Pb-free solders and must not burn off at higher temperatures that correspond to the higher melting temperatures of Pb-free solders, while simultaneously leaving behind a residue that is not corrosive. The underfill also needs to be suitably selected so that its chemistry is compatible with the flux residue.

Additional challenges are due to the fact that it is difficult to change all components on a system, all at a time, to lead-free. Consequently, the industry must cope with a scenario where a system has mixed metallurgy—partly SnPb based and the others Pb-free—on the system boards.

### **4.3 SYSTEM-ON-A-CHIP (SOC) VERSUS SYSTEM-ON-A-PACKAGE (SOP)**

---

For decades, the most efficient way to add more functions to an electronic system has been to integrate more functions on a chip either by reducing minimum line width, increasing the size of the chip, or both. Recently, however, it is beginning to be recognized that on-chip integration poses several practical challenges as the die size grows to increasing proportions. With increasing die size, the die-per-wafer yield at the wafer fabrication starts going down, partly due to the increased complexity, but also due the challenges in the wafer manufacturing processes.

To complicate the problem further, off-chip interconnects are beginning to contribute to the challenge of SOC integration. What this means is that interconnects, and not the ICs, are dominating, and often limiting, the system performance and increasing its cost.<sup>7</sup> Consequently, there is mounting support for moving interconnects off the chip and onto the package.<sup>8</sup>

#### 4.3.1 System-on-a-Chip (SOC)

There are many reasons why semiconductor manufacturers continue to push on-chip integration of a system.<sup>9</sup> The reason most often cited is that on-chip integration allows faster interconnection between circuit components simply because of the shorter distances involved. However, it has been pointed out that this may not be the case for all designs. For example, on a large digital IC running at a high clock frequency, a signal traveling on a global interconnection trace may take dozens of clock cycles to reach its destination. In such a case, dividing the device into smaller dice and using high-density interconnects on a package substrate can actually be faster.<sup>10</sup>

Another reason for continuing with on-chip system integration is to avoid the configuration of a multichip package (MCP) because, historically, packages containing a system composed of a multiple number of chips have been larger than those containing a single-chip system.

Although designers will continue to be pressured to integrate as much functionality onto a single chip as possible, there are many factors that must be considered when deciding if SOC is the right approach to the design of an electronic system. Furthermore, as minimum geometries continue to shrink and chip sizes continue to increase due to the incorporation of additional functionality, a point may be reached where it becomes economically impractical, if not impossible, to fabricate SOC. At this point, SOP may provide the only practical alternative to SOC. Now that chip and package are starting to be codesigned, an opportunity exists to develop capabilities for designing the SOP solutions that would cost less and perform better than SOP solutions.<sup>11</sup> Figure 4.2 provides a list of some of the challenges that must be addressed if SOC is to become the standard approach to electronic system integration.

SOC Challenges	SOP Challenges
Fundamental: latency, SiO <sub>2</sub> insulation	Design: High speed digital, optical analog, RF
Process complexity	Large-area intelligent manufacturing, cost/yield
SOC design and test	Thermal management
Wafer fab costs and yields	Testing and reliability
Intellectual property for integrated functions	High performance for low cost fab

**FIGURE 4.2** Issues that must be addressed prior to full-scale implementation of SOC and SOP.

#### 4.3.2 System-on-a-Package (SOP)

The definition of SOP depends on what is considered to be a system. In fact, much of what is referred to today as an electronic system is in reality a subsystem, meaning that it does not perform an autonomous electronic function. Consequently, SOP has multiple definitions. For example, some consider a multiple number of logic and memory ICs in a single package as an SOP. On the other hand, if the SOP does not contain analog peripheral device drivers, one might argue that the package really doesn't contain a system. Additionally, complete systems usually contain passive devices in addition to the ICs. Passive devices are required to make systems work, and if an entire system is to be placed in a package, then the required passives must go in as well,<sup>3,11</sup> making it what is often referred to an MCM.

Area array packaging is becoming an enabling technology for addressing the needs of customized SOP solutions in order to reduce size, weight, and pincount at the second level of interconnection.<sup>12</sup> This type of packaging technology includes pin grid array (PGA), ball grid array (BGA), and chip-scale packages (CSP), with BGA playing the largest role, primarily

**FIGURE 4.3** Future trends of IC, packaging, and system technologies as envisioned by personnel of the Packaging Research Center at The Georgia Institute of Technology. (Drawing provided courtesy of the Packaging Research Center, the Georgia Institute of Technology.)

because of its versatility. Compared to conventional leaded packages, BGA packages exhibit improved electrical performance due to a shorter distance between the IC and the solder balls, improved thermal performance by the use of thermal vias or heat dissipation through power and ground planes, reduced handling related lead damage, and increased manufacturing yields due to their self-alignment feature.<sup>15</sup> In fact, BGA has been one of the biggest contributing factors to the proliferation of mobile phones and other wireless communication systems. However, even with the advantages created by area-array packaging, performance, reliability, and cost requirements are challenging currently available area-array electronic package design, primarily by because of materials issues<sup>14</sup> Fig. 4.3 provides an overview of IC, packaging, and system trends that are anticipated for the year 2007 and beyond.

#### 4.4 MULTICHIP MODULES

Just as the name implies, MCM technology mounts multiple, unpackaged ICs (bare die), along with signal conditioning or support circuitry such as capacitors and resistors, to form a system, or a subsystem on a single substrate.<sup>1</sup> In fact, in the late 1980s and early 1990s, MCMs were considered to be the ultimate interconnect and packaging solution, capable of meeting every challenge of the electronics industry. This technology placed ICs in close proximity to each other, thereby enhancing system performance by reducing interconnect delay.<sup>15</sup>

Size is often the primary driver for MCM-based systems. The typical multicomponent discrete assembly provides a silicon-to-board efficiency of <10 percent (actual total die area versus the total printed circuit board area). MCM technology can often increase the silicon-to-board efficiency to 35 or 40 percent with chip and wire assembly processes, and to 50 percent or higher with some of the higher-density processes.<sup>16</sup> Thus, with reduced size and weight, MCMs offer a practical approach to reducing overall system size while providing enhanced performance due to a reduction in the interconnect distance between chips.<sup>1</sup> Multichip modules typically use three to five times less board area than their equivalent discrete solution.<sup>16</sup>

Since a multichip module is, by definition, a single substrate containing two or more ICs, it is unlikely that they are a thing of the past. Instead, they have been renamed from MCMs to MCPs, few chip packages (FCPs), or other similarly descriptive names. These packaging solutions usually contain from about two to six ICs that are packed onto an inexpensive laminate substrate. Although they are multichip modules, they may be called something else. Intel refers to its two-chip package as a CSP, although in fact it is an MCP or MCM.<sup>17</sup> Interestingly, some still believe that when time is an important consideration while reaching the market with a low-cost and reliable product, multichip solutions win. On the other hand, others believe that it's only a matter of time before SOCs take over completely and multichip packaging will not be necessary, and they view multichip solutions only as stopgaps.<sup>18</sup> Nevertheless, regardless of their nomenclature, laminate based multifunctional packages are among the key package types in the industry.

## 4.5 MULTICHIP PACKAGING

In general, an MCP is any package that contains more than one die. Low-cost solutions to multichip packaging are available for high-volume applications.<sup>11</sup>

Advanced electronic packaging technologies have historically been limited to applications in high-performance products such as supercomputers. Today, they are being moved into lower-cost products through the use of chip-on-board (COB), BGA, or land grid array (LGA) for second-level interconnect assembly, and surface-mount technology (SMT) mass production equipment. Prismark's December 2005 *Report on Semiconductor and Packaging* found that laminate packages constitute 47 percent of the overall packaging volumes followed by lead-frame packages at 39 percent.

Improvement in the silicon efficiency of MCM designs can be accomplished by packaging ICs onto very-thin, compact, and lightweight microcarriers using BGA or LGA connections, such as those shown in Fig. 4.4. Because of the development of lower-cost materials (i.e., low-cost

**FIGURE 4.4** Photograph showing three different BGA packages and one LGA package: in the top-left, 1,600-pin FCBGA (1.0 mm pitch, ceramic substrate); in the top-right, 1,140-pin FC-LGA (1.0 mm pitch, build-up substrate); in the bottom-left, 768-pin TAB-BGA (1.0 mm pitch); and in the bottom-right, 672-pin EBGA (1.27 mm pitch). (Photograph provided courtesy of Fujitsu Microelectronics, Inc.)

photosensitive materials), large-area processing (as practiced in the fabrication of displays), large-area lithography, and low-cost metallization processes as practiced in printed wiring board (PWB) fabrication, economically viable multichip packaging is realistic.<sup>19</sup>

#### 4.5.1 Few Chip Packaging (FCP)

An increasing number of companies are embracing FCP for technical and business reasons. Although these FCPs are virtually indistinguishable from their single-chip packages, they are a radical departure from the MCMs of the early 1990s. Instead of 10 to 20 die, today's FCPs typically contain two to five die mounted on a laminate substrate in a BGA package. This rebirth can be attributed, at least in part, to improved bare die testing and handling, along with the availability of low-cost, high-performance laminate substrates. Furthermore, there is a growing trend to use FCP as an alternative to SOC, resulting in a system-in-a-package (SIP). This approach is also referred to as SOP.

#### 4.5.2 Chip-Scale Packaging (CSP)

CSP was introduced in Japan in the early 1990s and in the United States soon thereafter as a less expensive alternative to MCMs.<sup>20</sup> According to IPC/JEDEC J-STD-012 definition, CSP is a single-die, direct-surface mountable package with an area of no more than 1.2 times the original die area. CSPs come in many forms—wire-bonded, flip-chip, leaded, and BGA. A typical wire-bonded CSP packaging process (Fig. 4.5) starts with the attachment of the die on

**FIGURE 4.5** Schematic of a wire-bonded CSP.

an interposer using an epoxy. Wire-bonding is then performed from the I/O pads of the die to the interposer. These wirebonds must be as low and as close to the die as possible to achieve the minimized package size. A plastic transfer molding process is used to encapsulate the die. Finally, solder balls are formed on the bottom of the interposer. In flip-chip CSPs, the solder-bumped die is bonded onto the interposer as shown in Fig. 4.6. The area-array version of CSPs, also known as fine-pitch ball grid assemblies (FPBGAs), is now widely used in many portable and telecommunication products.

**FIGURE 4.6** Schematic of a flip-chip CSP.

**FIGURE 4.7** Photograph of several chip-size packages. On the left are logic CSPs:

Row 1: 352-pin TAB-BGA (0.80 mm pitch)

Row 2: 288-pin FBGA (0.5 mm pitch)

Row 3: 48-pin BCC (0.5 mm pitch)

Row 4: 16-pin BCC (0.65 mm pitch)

On the right are memory CSPs:

Row 1: 60-pin  $\mu$ BGA (0.8 mm pitch)

Row 2: 46-pin SON (0.5 mm pitch)

Row 3: 48-pin FBGA (0.8 mm pitch)

Row 4: 16 M bit flash memory chip

*(Photograph provided courtesy of Fujitsu Microelectronics, Inc.)*

CSPs have smaller size, lesser weight, and improved electrical performance. CSPs offer the same space and material savings and short signal paths as direct chip attach (DCA) methods such as COB and flip-chip-on-board (FCOB) offer. The advantages of using a chip-scale package over DCA are easier handling, more protection for the chip, and simpler board assembly. Figure 4.7 shows a selection of commercially available CSPs. CSPs are somewhat limited to use in moderate I/O ICs.<sup>20</sup>

### 4.5.3 Wafer-Level Packaging (WLP)

Wafer-level package is defined as an IC package completely fabricated at the wafer level and assembled with standard SMT. Alternatively, a wafer-level package can be defined as the package in which the die and “package” are fabricated and tested on the wafer prior to singulation. Significant reductions in cost and device form factor can be achieved with WLP, while at the same time increasing the electrical performance. Wafer-level packaging was first investigated by Sandia National Laboratories and Fujitsu in the mid-1990s. Since then, WLP technology has been applied to flash and dynamic random access memory (DRAM) devices. However, widespread market adoption of WLPs has yet to occur. A WLP is not the

optimal package for high I/O devices because of the limitations of the SMT assembly process and the wiring constraints of the printed circuit board (PCB) to which it is mounted. WLPs are typically used in devices that are small, with 2 to 36 bumps, such as in power metal-oxide semiconductor field effect transistors (MOSFETs), electronically erasable read-only memory (EEPROM), small logic devices, and transient voltage suppressors. Cellular phone market consumes more than 90 percent of all WLPs produced today. This is because WLPs enable the small form factor and increased functions desired in modern cellular phones. However, there are indications that higher-end DDR2 and DDR3 DRAM devices will be able to take advantage of the benefits offered by WLPs. Several factors must be addressed in adopting WLPs. These factors include I/O density, reliability, burn-in, assembly processes, and cost. It is important to remember that a WLP is not the ultimate package for certain devices.

The benefits of wafer-level packaging can be summarized as follows:

- Smallest IC package size, as it is truly CSP
- Lowest cost per I/O because the interconnections are all done at the wafer level in one set of parallel steps
- Lowest cost of electrical testing, as this is done at the wafer level
- Lowest burn-in cost, as burn-in is done at the wafer level
- Elimination of underfilling with organic materials around the solder joint
- Enhancement of electrical performance because of the short interconnections

According to the latest ITRS roadmap, the pitch of area-array packages is expected to decrease to 100  $\mu\text{m}$  by 2009. Simultaneously, the electrical performance of these interconnections needs to be improved to support data rates in excess of 10 Gbps, while guaranteeing thermomechanical reliability and lowering the cost. These requirements are thus challenging, requiring innovative interconnection designs and technologies. To meet these challenges, nano wafer-level packaging that uses nano materials and structures to bring about unprecedented advances in electrical, mechanical, and thermal properties in the chip-to-package interconnections is being investigated.<sup>21,22</sup>

#### 4.5.4 Three-Dimensional (3-D) Packaging

Another type of multichip packaging gaining wider acceptance is stacked die packaging.<sup>23, 24, 25</sup> At the present time, most packaging of this type is in the form of stacked memory in CSPs, and the stacking is done only to save space. However, it is a growing trend that can be applied to any electronic system where volume density is of concern. Stacked die packaging is illustrated in the top view of Fig. 4.8, while the bottom view shows how packaged devices can be stacked.

The advantages of stacked die packaging are further enhanced by using thinned die. Thinning die has the potential of enhancing first-level interconnect reliability while minimizing the increase in vertical profile. A silicon die with a thickness  $<100 \mu\text{m}$  is quite flexible and can relieve stresses induced by packaging and coefficient of thermal expansion (CTE) mismatch.<sup>26</sup>

The latest in IC packaging is a stacked ball grid array (SDBGAs) package for the communication market. It is used to stack various ICs in one package with the resulting savings in real estate on the motherboard and manufacturing cost. Compared to conventional packages, an area savings of up to 70 percent can be realized. Popular SDBGAs sizes range from 8 mm  $\times$  8 mm to 14 mm  $\times$  14 mm and a pin count between 80 and 140. The total package height is typically about 1.4 mm.

**FIGURE 4.8** Drawings illustrating 3-D packaging: at the top, die (or chip) stack packaging; at the bottom, package stacking.

**4.6 ENABLING TECHNOLOGIES**

The end application and the electrical, thermal, and reliability performance demands it presents on the package often dictate the choice of assembly materials, assembly process, and package test technologies. For packages that involve multiple die or components, the need for known good die cannot be overemphasized. Applications such as cell-phones, where the available space has a premium but which demands an increasing functionality, may require enabling technologies such as wafer thinning along with stacked die or stacked package. However, in view of the relatively small product lifetime, the reliability requirements may be somewhat more forgiving than those for a server application, wherein the long product lifetime, large body size, high electrical signal speeds, and high power dissipation pose a different set of challenges. This section will review some of the key enabling technologies required across different application spaces and will also discuss the resulting impact of lead-free requirements.

**4.6.1 Known Good Die (KGD)**

When an electronic system is fabricated or an electronic component is assembled, KGD considerations play a very important role in minimizing waste, optimizing the material, and

infrastructural resources, and keeping the costs low.<sup>27,28</sup> Packaging and test combined, especially that for high-performance devices, form a higher fraction of the total device cost today than it did a few years ago. Consequently, it makes even more sense to weed out the known reject die and not let it into the assembly process. By doing so, the manufacturer can control the overall cost of packaging while simultaneously using the assembly equipment time only for known good subcomponents. This requirement directly translates into a need for developing adequate test and probe technologies that are suitable for flip-chip as well as wire-bond devices. Shrinking pad pitches and narrowing geometries require the development of advanced wafer probe technologies.

#### 4.6.2 Chip Thinning

As noted in a previous section, one approach to increasing the functional density of an electronic system is to stack ICs vertically. Reducing the thickness of the chips allows for more chips to be stacked within a package, thereby substantially increasing the functional density. In addition to increasing the functionality per unit area of substrate (module), thinning chips also improves their thermal performance, results in a more mechanically reliable device, allows for flexibility so they can conform to a curved surface, and relieves stress induced on a chip due to packaging.<sup>26,29</sup> Thinning chips can result also in an improved electrical performance in view of the reduced signal path across two or more chips. However, this is not necessarily always the case, as cross-talk and interference across the chips can also increase due to the reduced distance, thereby potentially degrading the electrical performance. Decoupling capacitors may be needed for adequate isolation; however, a more detailed electrical analysis is beyond the scope of this chapter.

Four techniques that are primarily used for wafer thinning are mechanical grinding, chemical mechanical polishing (CMP), atmospheric downstream plasma (ADP, sometimes used with wet etching), and dry chemical etching (DCE). Factors to be considered when selecting the appropriate thinning technique include the throughput of the time taken to thin a wafer, quality, and defect density in the resulting thinned surface, and cost. Due to its high material removal rate, mechanical grinding continues to be the most popular method for wafer thinning. However, this technique also introduces to the thinned surface a significant amount of mechanical damage that needs to be removed. This is achieved by fine grinding or through CMP, which relies on chemically assisted mechanical polishing of the wafer surface. CMP can deliver very flat and defect-free wafer surface, however, the material removal rate is small—of the order of a few micrometers per minute. Thicknesses routinely achieved vary from 50 to 100  $\mu\text{m}$ , although thicknesses as small as 15 to 25  $\mu\text{m}$  (silicon is flexible in this thickness range) have been demonstrated.<sup>30</sup> Figure 4.9 is a photograph of a silicon wafer that has been thinned to approximately 50  $\mu\text{m}$  using a plasma process that causes bending of the wafer.

**FIGURE 4.9** Photograph of a silicon wafer that has been thinned to approximately 50  $\mu\text{m}$  by plasma etching. Warpage was caused by the wafer thinning process. (Photograph provided courtesy of Materials and Manufacturing Research Laboratories, University of Arkansas, Fayetteville AR.)

#### 4.6.3 Lead-Free Chip Attach Processing

Packaged devices require a larger amount of real estate as compared to the die due to the requirement for a substrate (or “chip carrier”).<sup>31</sup> Substrates provide electrical connections from the die bond pads to the external world. Bare die attachment eliminates the need for a

substrate, thereby saving valuable module space and reducing interconnect distance, but such system configuration can increase the risk of reliability performance of the system. Direct die attachment can be accomplished by conventional die attach/wire bonding, tape-automated bonding (TAB), and flip-chip processes.

Lead-free requirements impose the following additional requirements:

- Use of suitable lead-free materials in the assembly bill-of-materials
- Compatibility of these materials with lead-free processing temperatures

Performance of the package moisture sensitivity level (MSL) can be impaired by the higher temperature compatibility arising from lead-free requirements.

**4.6.3.1 Wire Bond.** For most part, transition to lead-free of a wirebond package on a component level is relatively straightforward. Through the use of gold wires, the first level interconnect is already lead-free. Further, most of the metal lead-frame-based packages are lead-free-compliant as long as the mold compound or the die-attach materials are free of lead or similar components and are able to withstand the higher temperatures seen by the package during component reflow. BGA-based wirebond packages, on the other hand, additionally need use of lead-free BGA balls on the package to make it compatible with lead-free requirements.

**4.6.3.2 Tape-Automated Bonding (TAB).** TAB is rather expensive because it requires a custom tape for each different IC and its construction requires a significant amount of processing. Furthermore, the assembly process is equipment-intensive because of testing of the IC while it is mounted on the tape, excising the IC from the tape and shaping (forming) its leads prior to mounting it onto a substrate, requiring a custom die for gang bonding. However, it is attractive because it provides the opportunity to perform burn-in and die testing prior to final assembly. The TAB process is schematically illustrated in Fig. 4.10.

TAB packages are usually naturally lead-free at the component level. Assembly to the application board does require lead-free solder along with a requirement for the package to be able to withstand the high temperatures associated with lead-free processing.

**4.6.3.3 Flip-Chip Bonding.** The flip-chip assembly technique is one of the important techniques of die attach to either the carrier (substrate) or directly to the board usually employing either solder bumps or z-axis conductive polymers. Another common mode of attaching silicon dice in the flip-chip configuration is stud bumping, where a gold wire is used in a similar fashion as in wirebonding, but the wire is truncated after establishing contact to the die pads. The resultant stud is then flattened using a coining process. The original flip-chip assembly, pioneered by IBM, eliminates all the packaging area that is not occupied by the die itself, generally resulting in the smallest footprint and the lowest profile. However, wire-bonded devices can be back-ground to reduce the overall package thickness. It is not trivial to perform a similar back-grinding operation on flip-chip devices for two reasons. First, the bumping process prefers to use full thickness wafers due to breakage concerns, and second, it is extremely difficult to back-grind bumped wafers.

In general, flip-chip assemblies can use either grid arrays or peripheral pads for I/O connection at pitches between 0.1 and 0.65 mm, but are limited mostly by routing constraints through substrate manufacturing capabilities. Consequently, most flip-chip devices in production today use a solder bump area-array pitch in the range of about 0.15–0.25 mm. Of all the techniques available, flip-chip assembly offers the highest packaging density and there is increased use of flip-chip attachment. Consequently, many bumping contractors also offer redistribution services. Although redistribution is done on the chip (actually on the wafer), it is considered a packaging operation.

Additional requirements presented by the need for lead-free, RoHS-compliant, “green” packages call for lead-free solder bumps. Devices that use gold stud bumps previously referenced are

FIGURE 4.10 Schematic of the TAB process.

already lead-free; however, stud bumping is typically limited to a smaller die and those with a small number of I/O count requirements (note that I/O here refers to the total number of connections required across the die and the carrier/substrate). Furthermore, the stud-bump-based lead-free solution has its challenges due to the serial nature of the stud-bumping and die-attach processes. Consequently, a lot of effort continues to go into the development of lead-free solder-based wafer bumping. Lead-free wafer bumping is discussed in more detail in the next section.

**4.6.3.4 Wafer Bumping.** Wafer bumping is a wafer-level packaging technology that uses solder bumps to form interconnects between the integrated circuit (IC or chip) and the actual package. To create a solderable site with an electromigration barrier, the manufacturer usually first deposits an under-bump metallurgy (UBM) of electroless nickel and gold directly onto the I/O pad of the IC. Other typical UBM consists of a 20–50 nm of evaporated chromium acting as contact and adhesion layer, a diffusion barrier of 100–200 nm of Cr:Cu, a conductive layer of 0.4–0.6  $\mu\text{m}$  of copper, and finally an optional oxide protector of about 100 nm of gold. This is followed by the placement of solder—either by evaporation, electroplating, or screen printing—onto each I/O site and a thermal reflow to form a solder ball as shown in Fig. 4.11.

**FIGURE 4.11** Schematic of a solder bump and underlying metallurgy.

Flip-chip ball grid array (FCBGA) is a package type that uses solder bumping to yield area-array interconnection. Area-array interconnection ensures signal and power/ground integrity far more superior to conventional peripheral wire-bonding interconnection due to elimination of wirebond inductance and a lower electrical resistance. Solder bumping enables the realization of CSPs. CSPs are well accepted in handheld consumer products such as cellular phones and PDAs, since the package size is of vital importance. However, the ultimate package is a true chip size package, the wafer-level CSPs (WL-CSP). WL-CSP is predicted to enjoy the highest continuous aggregated growth rate (CAGR) of more than 20 percent since it enables high-performance microprocessor chip (MPU), application-specific integrated circuit (ASIC), and memory devices for the high-end computing and networking markets. Bumped die for FCOB assembly is common in electronic manufacturing due to the saving in the printed circuit board real estate.

There are three primary wafer-bumping processes for solder placement: screen printing, electroplating, and evaporation. All these processes have been used in production, but bump pitch, I/O count, start-up cost, and production volume are critical criteria that dictate which process is best for a particular solder placement. Evaporation of solder requires substantial investment in capital equipment since it is performed in a high-vacuum environment. Electroplating of solder yields a finer solder bump pitch, but it is primarily limited to solders with binary alloys such as SnAg and SnCu. Screen printing of solder is the most cost-efficient for solder bump pitch greater than 120  $\mu\text{m}$ .<sup>32</sup>

Solder bumps must undergo a reflow process to create the solder bump structure shown in Fig. 4.11 as a result of its surface tension. Since the composition of the solder may be high-lead, eutectic, or lead-free, the equipment and processes must be capable of handling a wide range of temperature profile variations while maintaining a tight thermal uniformity within each process profile. A typical reflow process undergoes five transitions: pre-heat, flux activation, soak, reflow, and cooldown. The purpose of the pre-heat is to evaporate solvents from the solder paste. A slow thermal ramp-up rate prevents damage due to thermal shock. The time and temperature to evaporate the solvents depends on the solder paste that is applied. As the temperature is ramped up, the flux reacts with the oxide and contaminants on the surfaces to be joined. The time and temperature should be long enough to allow the flux to clean these surfaces fully, but not so long that the flux may be exhausted before soldering takes place. The soak temperature should be approximately 20–40°C below the peak reflow temperature.

Time and temperature depend on the mass and solder materials. During reflow, the assembly is briefly brought to the temperature sufficient to reflow the solder. After reflow, a gradual cooling should be used to prevent thermal shock. Gradual cooling produces a finer grain structure and fatigue-resistant solder joint. During reflow process, care must be exercised to prevent the formation of oxides that degrade subsequent processes. A nitrogen-with-flux or hydrogen-flux-free reflow process has been used to control oxide formation.

There is a trend in the industry toward smaller area-array packages with lead-free bump sizes in the range of 10–15  $\mu\text{m}$ . Metal bumps, including gold, copper, and nickel, are lead-free wafer bumping.<sup>33</sup> In addition, gold and copper have a greater mechanical shear strength compared to lead solders. This helps to relieve residual stresses caused by the mismatch of the CTE between the chip and printed-circuit board materials, and hence strengthens the bump connections.<sup>34</sup>

Gold stud bumps are formed by a modified wire bonder that uses thermosonic energy (150–200°C) to first attach a gold bondwire to the die bond pads and then shear the top of the gold wire without leaving a tail.<sup>35</sup> To achieve a uniform bump height, the gold studs may be flattened or “coined” by pressing any remaining wire tail to the ball or shearing it off. This yields a planar, flat-top gold bump that does not require any coining in a single-step process.

Copper is another candidate material for wafer bumping. Compared to gold, copper costs less but has a good electrical and heat-dissipating performance due to its low electrical resistivity and high thermal conductivity.

Copper studs can be created by bonding a copper bondwire directly onto the aluminum bonding pads on a wafer using a thermosonic bumping machine. However, the ultrasonic power and bonding force required for copper studs are generally higher than those for the gold studs due to the hardness of copper. Also, a reducing gas, usually 5 percent hydrogen in nitrogen, is blown over the end of the copper wire during formation of the ball to prevent oxidation of copper. Copper bumping has many advantages over solder and gold bumping in terms of increased electrical and mechanical performance and reduction of material cost; however, it is relatively new to the flip-chip industry.

**4.6.3.5 Chip-on-Board (COB).** In COB assembly, a back of a bare (unpackaged) IC is attached directly onto a PWB, wire-bonded, and then encapsulated with a polymer. The die bondpad pitch is generally in the range of about 0.175–0.25 mm and IC placement must be very accurate. For many applications requiring miniaturization, and especially those where space is limited, COB assembly can be the most cost-effective packaging option. It is a mature technology and offers high packaging density, low packaging cost, and fast signal speed because the dies are wire-bonded directly onto a board.<sup>36</sup> The photograph in Fig. 4.12 shows details of a COB-mounted power diode. Usually, as a final step, a glob top is deposited onto the chip to serve as passivation and protection.

**FIGURE 4.12** Photograph of chip-on-board. (A COB assembly).

**4.6.3.6 Passive Devices: Surface-Mount Components.** Since the invention of the IC, almost continuous progress has been made in creating a given functionality in a smaller area. Unfortunately, surface mount (SM), discrete passive (DP) component size, which has seen continuing size reductions from 0805 components (80 mils  $\times$  50 mil or 2 mm  $\times$  1.25 mm) to 0201 components (20 mil  $\times$  10 mil or 0.5 mm  $\times$  0.25 mm) with preliminary work being done on 0105 components (10 mil  $\times$  5 mil or 0.25 mm  $\times$  0.125 mm), has not shrunk accordingly. Furthermore, increasing numbers of DPs are required in newer electronic systems. Consequently, DPs can occupy significant substrate area. In fact, system substrates are now dominated by

individually placed DP components. The key challenges presented by DPs are their fairly constant physical size, their increasing numbers, the cost of individual handling and attachment, the parasitic effects of their associated electrical connections, the reliability of solder joints, and the wide range of required values.<sup>3,37,38</sup> Thus, they continue to pose challenges for miniaturization of electronic systems, particularly for the wireless and consumer markets.

Lead-free requirements pose manufacturing challenges, not only in package assembly but also in areas of component manufacturing assembly and of lead-free assembly.

**4.6.3.7 Passive Devices: Integrated Passive Components.** Recently, much attention has been directed toward the use of integrated passive (IP) devices (also referred to as embedded or integral passive devices). IPs are located within the substrate and are formed during the fabrication of the substrate. Consequently, they require processing steps in addition to those that provide only interconnection. There are no external leads to be individually attached because all IPs are connected to metallizations within the substrate, whether it is laminate, ceramic, or any other material. They do not compete with ICs for surface space, but may complicate routing within inner substrate layers. They have no casing or packaging of their own to contribute weight and volume to the system. The lead length between the IP and an interconnect is usually only mils. Also, since the IP is typically a planar structure, there is much less parasitic inductance, capacitance, and resistance compared to DPs. Furthermore, IPs eliminate pick-and-place operations and two solder joints. A shortcoming of IPs is the fact that they cannot be tested individually so the yield of the IPs directly impacts the yield of the substrates. The arguments for changing to IPs include reduced cost, smaller system size, better electrical performance, and improved system reliability. Figure 4.13 shows schematically the difference between discrete passives, located on the surface of a substrate, and integrated passives, which are located below the surface of a substrate.

**FIGURE 4.13** The physical transition from discrete passives (top) to integrated passives (bottom).

Thin-film passive components rely on deposition and photolithography to define conductive, resistive, and dielectric materials physically that produce a desired electrical response.<sup>3</sup> Integrated resistors are fabricated by depositing and patterning a layer of thin-film or thick-film

**TABLE 4.1** Characteristics of Typical Tantalum Nitride and Nichrome Resistors

Resistor material → characteristic ↓	Tantalum nitride	Nichrome
Sheet resistance	20–150 Ω/□ 100 Ω/□ (typical)	25–300 Ω/□ 100–200 Ω/□ (typical)
Sheet resistance tolerance	±10% of nominal value	±10% of nominal value
Temperature coefficient of resistance	–75 + 50 ppm/°C (typ.) 0 ± 25 ppm/°C (anneal)	0 + 50 ppm/°C 0 + 25 ppm/°C (anneal)
Resistor drift (1000 h at 150° in air)	<1000 ppm	<1000 ppm (anneal) <200 ppm (sputter/ann.)
Resistor tolerance after anneal and laser trim	±0.10% standard ±0.03% (bridge trim)	0.10%

resistive material in series with an interconnect line on an insulating substrate. Table 4.1 gives some characteristics of typical tantalum nitride and nichrome resistors.

The integration of capacitors into interconnect substrates is largely driven by three applications: decoupling of ICs from power supplies, analog functions such as those in radio frequency (RF)/wireless, and termination of transmission lines. A wide variety of dielectric materials can be used to build integrated capacitors. There are two broad classifications of dielectrics—paraelectrics and ferroelectrics—and they have very distinct electrical properties, the most significant being the dielectric constant. Some of the dielectric materials that can be used to fabricate integrated capacitors are listed in Table 4.2, along with their composition and dielectric constant.

**TABLE 4.2** Dielectric Material Candidates for Application in Integrated Capacitors

Material	Composition	Dielectric constant	Paraelectric (P) or Ferroelectric (F)
Silicon monoxide	SiO	4.5–6.8	F
Silicon dioxide	SiO <sub>2</sub>	4–5	F
Silicon nitride	Si <sub>3</sub> N <sub>4</sub>	6–7	F
Silicon carbide	SiC	20–45	F
Aluminium oxide	Al <sub>2</sub> O <sub>3</sub>	6–10	F
Aluminium nitride	AlN	8–10	F
Tantalum oxide (a)	Ta <sub>2</sub> O <sub>5</sub>	25	F
Tantalum oxide (h)	Ta <sub>2</sub> O <sub>5</sub>	50	F
Titanium oxide	TiO <sub>2</sub>	10–100	F
Diamond-like-carbon	sp <sup>2</sup> and sp <sup>3</sup> carbon	4–6	F
BCB	Organic	2.7	F
Polyimide	Organic	3–4.5	F
Barium strontium titanate	BaSrTiO <sub>3</sub>	up to 1000	P
Lead zirconate titanate	PbZr <sub>x</sub> Ti <sub>1-x</sub> O <sub>3</sub>	up to 2000	P
BPZT	Ba <sub>0.8</sub> Pb <sub>0.2</sub> (Zr <sub>0.12</sub> Ti <sub>0.88</sub> )O <sub>3</sub>	up to 3000	P
Barium titanate	BaTiO <sub>3</sub>	up to 5000	P

Integrated inductors are the easiest of the IPs to fabricate since they are usually spirals of the conductor material. Also, since inductors are magnetic devices, they pose an integration problem not shared by resistors and capacitors: They perform best when there is a sufficient volume of space to allow their magnetic fields to be unimpeded by other structures. As a

result, there is a “keep-away” distance required for inductors in order to avoid loss of inductance relative to an isolated structure and to prevent interference with nearby signal lines and ground planes from the inductor’s field.

The easiest way to fabricate integrated inductors is simply to form a spiral out of the interconnect material, typically one to eight turns with a total outer diameter of about 0.2 mm, which provides an inductance of around 1–40 mH.<sup>3</sup>

#### 4.6.4 Hybrid SnPb- and Pb-free Systems

In an ideal world, the transition from SnPb to Pb-free could happen overnight. However, in reality, the transition is not likely to happen instantly; instead, this is expected to occur over a period of at least 6 to 12 months. During this time, SnPb and lead-free alloys are likely to coexist on the same printed circuit board assembly (PCBA), which poses potential issues with component soldering and reliability.

When a BGA with lead-free solder is reflowed with SnPb solder paste on the motherboard using a SnPb reflow profile, the lead-free solder balls stay virtually in an unmolten state. However, the lead in the eutectic tin-lead solder paste can diffuse through the grain boundaries in the lead-free BGA solder ball, the extent of which depends on several factors such as the maximum reflow temperature and the time during which this temperature stays over the melting temperature of SnPb solder. This can result in potential solder joint reliability issues, as the Pb-rich grain boundaries have a higher risk of microcracks, which can lead to solder opens.

The industry is also exploring benefits of an approach called backward-compatibility, where the component termination is lead-free, but the on-board solder is Pb containing solder—eutectic SnPb in many cases. Such a joint is neither Pb-free nor RoHS-compliant, but can allow for the component supplier to deliver lead-free components while letting the customer keep the assembly materials and reflow profiles mostly constant.

## 4.7 ACKNOWLEDGMENT

---

The first version of this chapter was written for the fifth edition of this handbook by Drs. Simon Ang, Fred Barlow, William Brown, and Tarak A. Raikar.

# TYPES OF PRINTED WIRING BOARDS

---

**Dr. Hayao Nakahara**

*N.T. Information Ltd., Huntington, New York*

---

## 5.1 INTRODUCTION

---

Since the invention of printed wiring technology by Dr. Paul Eisner in 1936, several methods and processes have been developed for manufacturing printed wiring board (PWBs) of various types. Most of these have not changed significantly over the years; however, some specific trends continue to exert major influences on the types of PWBs required and the processes that create them:

1. Computers and portable telecommunications equipment require higher-frequency circuits, boards, and materials, and also use more functional components that generate considerable amounts of heat that need to be extracted.
2. Consumer products have incorporated digital products into their design, requiring more functionality at ever-lower total cost.
3. Products for all uses continue to get smaller and more functional, driving the total circuit package itself to become more dense, causing the PWBs to evolve to meet these needs.

These trends have led to the larger use of nonorganic base substrates, such as aluminum and soft iron. In addition, alternate ways to create boards have been developed. These will be discussed in this chapter, along with the traditional board structures and processes. The terms *printed wiring board*, *PWB*, and *board* will be used synonymously. Also, the words *laminate*, *substrate*, and *panel* will be used interchangeably.

---

## 5.2 CLASSIFICATION OF PRINTED WIRING BOARDS

---

PWBs may be classified in many different ways according to their various attributes. One fundamental structure common to all of them is that they must provide electrical conductor paths which interconnect components to be mounted on them.

### 5.2.1 Basic PWB Classifications

There are two basic ways to form these conductors:

1. *Subtractive:* In the subtractive process, the unwanted portion of the copper foil on the base substrate is etched away, leaving the desired conductor pattern in place.
2. *Additive:* In the additive process, formation of the conductor pattern is accomplished by adding copper to a bare (no copper foil) substrate in the pattern and places desired. This can be done by plating copper, screening conductive paste, or laying down insulating wire onto the substrate on the predetermined conductor paths.

The PWB classifications given in Fig. 5.1 take into consideration all these factors, i.e., fabrication processes as well as substrate material. The use of this figure is as follows:

- Column 1 shows the classification of PWBs by the nature of their substrate.
- Column 2 shows the classification of PWBs by the way the conductor pattern is imaged.
- Column 3 shows the classification of PWBs by their physical nature.
- Column 4 shows the classification of PWBs by the method of actual conductor formation.

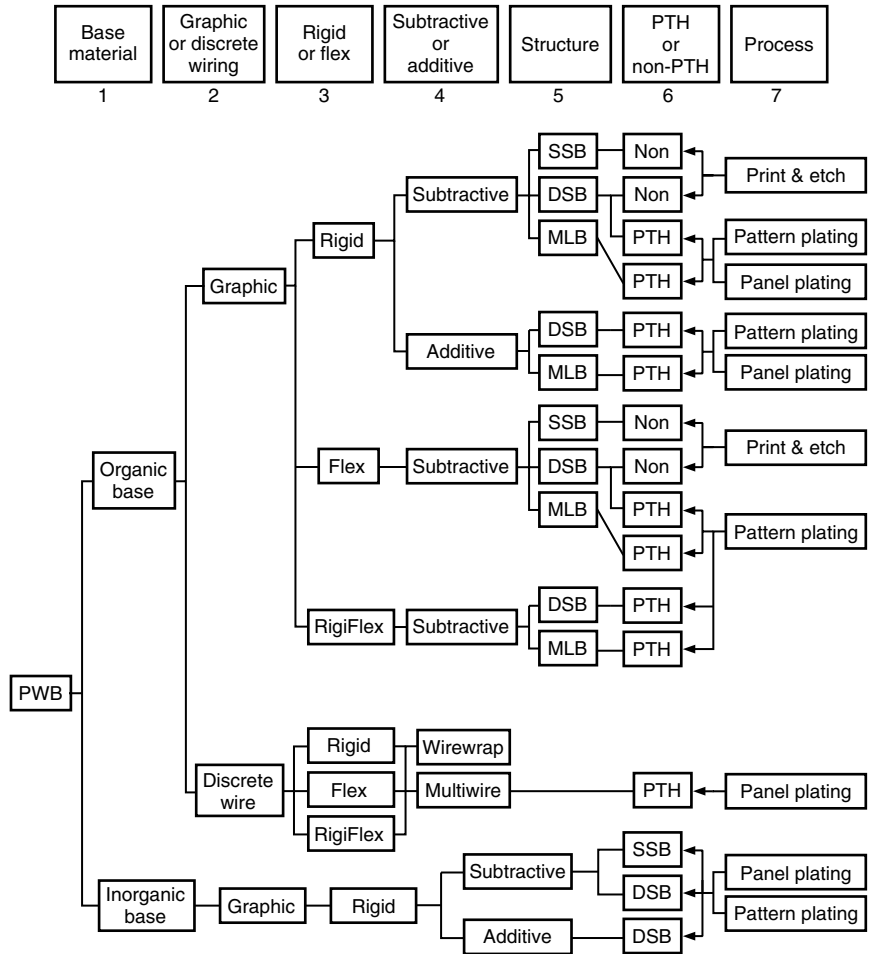

FIGURE 5.1 Classification of printed wiring boards.

- Column 5 shows the classification of PWBs by the number of conductor layers.
- Column 6 shows the classification of PWBs by the existence or absence of plated-through-holes (PTHs).
- Column 7 shows the classification of PWBs by production method.

### 5.3 ORGANIC AND NONORGANIC SUBSTRATES

---

One of the major issues that has arisen with the ever-higher speed and functionality of components used in computers and telecommunications is the availability of materials for the PWB substrate that are compatible with these product and process needs. This includes the stresses on substrate material created by more and longer exposure to soldering temperatures during the assembly process, as well as the need to match the coefficient of thermal expansion for components and substrate. The resultant search has found new materials, both organic and nonorganic based. The details of these materials are explained in Chaps. 6 through 11, but this outlines the basic character of the two types of substrate.

#### 5.3.1 Organic Substrates

Organic substrates consist of layers of paper impregnated with phenolic resin or layers of woven or nonwoven glass cloth impregnated with epoxy resin, polyimide, cyanate ester, BT resin, etc. The usage of these substrates depends on the physical characteristics required by the application of the PWB, such as operating temperature, frequency, or mechanical strength.

#### 5.3.2 Nonorganic Substrates

Nonorganic substrates consist mainly of ceramic and metallic materials such as aluminum, soft iron, and copper-invar-copper. The usage of these substrates is usually dictated by the need of heat dissipation, except for the case of soft iron, which provides the flux path for flexible disk motor drives.

### 5.4 GRAPHICAL AND DISCRETE-WIRE BOARDS

---

Printed wiring boards may be classified into two basic categories, based on the way they are manufactured:

1. Graphical
2. Discrete-wire

#### 5.4.1 Graphical Interconnection Board

A *graphical PWB* is the standard PWB and the type that is usually thought of when PWBs are discussed. In this case, the image of the master circuit pattern is formed photographically on a photosensitive material, such as treated glass plate or plastic film. The image is then transferred to the circuit board by screening or photoprinting the artwork generated from

the master. Due to the speed and economy of making master artwork by laser plotters, this master can also be the working artwork.

Direct laser imaging of the resist on the PWB can also be used. In this case, the conductor image is made by the laser plotter, on the photoresistive material, which is laminated to the board, without going through the intermediate step of creating a phototool. This tends to be somewhat slower than using working artwork as the tool and is not generally applied to mass production. Work continues on faster resists, as well as exposure systems, and this method will undoubtedly continue to emerge.

#### 5.4.2 Discrete-Wire Boards

Discrete-wire boards do not involve an imaging process for the formation of signal conductors. Rather, conductors are formed directly onto the wiring board with insulated copper wire. Wire-wrap® and Multiwire® are the best known discrete-wire interconnection technologies. Because of the allowance of wire crossings, a single layer of wiring can match multiple conductor layers in the graphically produced boards, thus offering very high wiring density. However, the wiring process is sequential in nature and the productivity of discrete-wiring technology is not suitable for mass production. Despite this weakness, discrete-wiring boards are in use for some very high density packaging applications. See Fig. 5.2 for an example of a discrete-wiring board.

FIGURE 5.2 Example of discrete-wiring board.

## 5.5 RIGID AND FLEXIBLE BOARDS

Another class of boards is made up of the *rigid* and *flexible* PWBs. Whereas boards are made of a variety of materials, flexible boards generally are made of polyester and polyimide bases. *Rigi-flex boards*, a combination of rigid and flexible boards usually bonded together, have gained wide use in electronic packaging (see Fig. 5.3). Most rigi-flex boards are three-dimensional

**FIGURE 5.3** Rigi-flex printed wiring board.

structures that have flexible parts connecting the rigid boards, which usually support components; this packaging is thus volumetrically efficient.

## 5.6 GRAPHICALLY PRODUCED BOARDS

---

The majority of boards produced in the world are graphically produced. There are three alternative types:

1. Single-sided boards
2. Double-sided boards
3. Multilayer boards

### 5.6.1 Single-Sided Boards (SSBs)

Single-sided boards (SSBs) have circuitry on only one side of the board and are often referred to as print-and-etch boards because the etch resist is usually printed on by screen-printing techniques and the conductor pattern is then formed by chemically etching the exposed, and unwanted, copper foil.

**5.6.1.1 Typical Single-Sided Board Materials.** This method of board fabrication is generally used for low-cost, high-volume, and relatively low functionality boards. In the Far East, for example, the majority of SSBs are made of paper-based substrates for lowest cost, with the most popular grade of paper-based laminate being XPC-FR, which is a flame-retardant phenolic material that is also highly punchable. In Europe, FR-2 grade paper laminate is the most popular substrate for SSBs because it emits less odor than XPC-FR when placed in high-voltage, high-temperature environments, such as inside a television set chassis. In the United States, CEM-1 material, which is a composite of paper and glass impregnated with epoxy resin, is the most popular substrate for SSBs. While not as low cost as XPC-FR or FR-2, CEM-1 has gained popularity because of its mechanical strength and also because of the relative unavailability of paper phenolic laminates.

**5.6.1.2 Single-Sided Board Fabrication Process.** Given the emphasis on cost and low complexity, SSBs are generally produced in highly automated, conveyORIZED print-and-etch lines, using the following basic process flow.

- Step 1:* Cut substrate into appropriate panel size by either sawing or shearing.
- Step 2:* Place panel in loader which feeds them into the line.
- Step 3:* Clean panels.
- Step 4:* Screen panel with ultraviolet curable etch-resist ink.
- Step 5:* Cure the etch-resist ink.
- Step 6:* Etch exposed copper.
- Step 7:* Strip the resist.
- Step 8:* Apply solder resist.
- Step 9:* Screen legend.
- Step 10:* Form holes by drilling or punching.
- Step 11:* Test for shorts and opens.

The conveyor speed of automated print-and-etch lines ranges from 30 to 45 ft/min. Some lines are equipped with an online optical inspection which enables the elimination of the final electrical open/short test.

As previously noted, after the conductor pattern is generated in the print-and-etch line, holes for component insertion are formed on the panel by punching when the panel is made of paper-based substrate, but must be formed by drilling when the panel is made of glass-based substrate.

**5.6.1.3 Process Variations.** In some variations, the conductor surface of the PWB gets insulated, exposing only pads, and then conductive paste is screened to form additional conductors on the same side of the board, thus forming double conductive layers on a single side.

Most metal-core PWB consumer applications are made of aluminum substrate, which comes as a copper-clad material. PWBs made of such material do not have through-holes, and components are usually surface-mount types. These circuits are frequently formed into three-dimensional shapes.

## 5.6.2 Double-Sided Boards

By definition, double-sided boards (DBs) have circuitry on both sides of the boards. They can be classified into two categories:

1. Without through-hole metallization
2. With through-hole metallization

The category of through-hole metallization can be further broken into two types:

1. Plated-through-hole (PTH)
2. Silver-through-hole (STH)

**5.6.2.1 Plated-Through-Hole Technology.** PTH technology is discussed in some detail in Sec. 5.7; however, some comments are appropriate here.

Metallization of holes by copper plating has been practiced since the mid-1950s. Since PWB substrate is an insulating material, and therefore nonconductive, holes must be metallized first before subsequent copper plating can take place. The usual metallization procedure is to catalyze the holes with palladium catalyst followed by electroless copper plating. Then, thicker plating is done by galvanic plating. Alternately, electroless plating can be used to plate all the way to the desired thickness, which is called *additive plating*.

The biggest change in the manufacturing process of double-sided PTH boards, and also of multilayer boards (MLBs), is the use of *direct metallization* technologies. (See Chap. 30 for full discussion of electroless and direct metallization for through-hole boards.) Here, simply, it eliminates the electroless copper process. The hole wall is made conductive by palladium catalyst, carbon, or polymer conductive film, then copper is deposited by galvanic plating. The elimination of electroless copper, in turn, allows the elimination of environmentally hazardous chemicals, such as formaldehyde, and EDTA, which are two main components of electroless copper-plating solutions.

**5.6.2.2 Silver-Through-Hole Technology.** STH boards are usually made of paper phenolic materials or composite epoxy paper and glass materials, such as CE-1 or CE-3. After double-sided copper-clad materials are etched to form conductor patterns on both sides of the panel, holes are formed by drilling. Then the panel is screened with silver-filled conductive paste. Instead of silver, copper paste can also be used.

Since STHs have a relatively high electrical resistance compared with PTHs, the application of STH boards is limited. However, because of their economic advantage (the cost of

STH boards is usually one-half to two-thirds that of functionally equivalent PTH boards), their application has spread to high-volume, low-cost products such as audio equipment, floppy disk controllers, car radios, remote controls, etc.

### 5.6.3 Multilayer Boards (MLBs)

By definition, MLBs have three or more circuit layers (see Fig. 5.4). Main applications of MLBs used to be confined to sophisticated industrial electronic products. Now, however, they are the mainstream of all electronic devices, including consumer products such as portable video cameras, cellular phones, and audio discs.

**5.6.2.3 Layer Count.** As personal computers and workstations become more powerful, mainframe computers and supercomputers are being replaced in many applications by these smaller machines. As a result, the use of highly sophisticated MLBs, which have layer counts over 70, are being reduced, but the technology to produce them is proven. At the other end of the layer-count spectrum, thin and high-density MLBs with layer counts between 4 and 8 are mainstream. The drive toward thinner MLBs will continue and is made possible by the continuing concurrent advancement of materials and equipment to handle thin core materials.

**5.6.2.4 Via and Via Production Technologies.** As PWBs have had to address the issues of higher speed, higher density, and the rise of surface-mount components that use both sides, the need to communicate between layers has increased dramatically. At the same time, the space available for vias has decreased, causing a continuing trend toward smaller holes, more holes on the board, and the decline of the use of holes that penetrate the entire board, which use space on all layers. As a result, the use of buried and blind vias has become a standard part of multilayer board technology, driven by the need for this increased package density (Fig. 5.4).

One of the immediate issues that arise from these trends is the problems of drilling and the associated cost of this fabrication step. Printed wiring boards, which once were stacked three high on a drilling machine, must be drilled individually, and the number of holes per board has risen, to accommodate the need for vias. This has caused a major problem for fabricators, who find that a lack of drilling capacity is creating a big demand on funds for additional machines, while the cost of drilling continues to increase dramatically. Therefore, alternate methods for creating vias are being developed. These pressures will be ongoing, and therefore the process listed here, or some equivalent, will undoubtedly become more important as the drive to miniaturization continues and drilling individual holes becomes less and less practical.

**FIGURE 5.4** Cross-section multilayer board with buried via holes. Buried vias are built into each of the double-sided boards that make up the final multilayer structure.

These processes have been developed to mass-produce vias without drills.

*Surface Laminar Circuits (SLCs).* The most notable MLB technology developed to form vias is the *sequential* fabrication of multilayers without press operations. This is particularly important for surface blind via holes.

The process for fabricating a board using surface laminar circuits is as follows (see Fig. 5.5):

1. Innerlayer ground and power distribution patterns are formed.
2. Panel receives an oxide treatment.
3. Insulating photosensitive resin is coated over the panel by curtain or screen-coating methods.
4. Holes are formed by photoexposure and development.
5. Panel is metallized by usual copper reduction process (consisting of catalyzing and electroless copper plating or by direct metallization process).
6. Thicker deposition of copper is made by continuation of electroless copper plating or galvanic plating.
7. Circuit patterns are formed by dry film tenting process.

**FIGURE 5.5** Example of surface laminar circuit (SLC) board cross section. (Courtesy IBM Yasu and Ciba-Geigy Limited.)

*DYCOstrate®.* A different approach to small via creation has been taken by Dyconex AG of Switzerland. After ground and power patterns are formed on the panel, and the panel is oxide-treated, polyimide-backed copper foil is laminated on the panel. Holes in the copper are formed by a chemical etching process, and the insulating polyimide material underneath the holes is removed by plasma etching. PWBs made in such a way are called DYCOstrate. In other, similar technologies, different dielectric materials are used, and they are removed by alkaline solutions. The rest of the process is similar to that for SLC; that is, holes are metallized and a thick copper deposition is made by electroless or galvanic plating, and the circuit pattern is formed by a tent-and-etch process (see Fig. 5.5).

*Drilled Vias.* In both SLC and DYCOstrate cases, through-holes can also be made by conventional drilling and plating processes, in addition to the surface blind via holes.

*Cost Impact.* The manufacturing cost of these sequential technologies is not necessarily directly cheaper than conventional MLB technology, which depends on a laminating press operation. However, since the cost of making standard holes in a board can be as high as 30 percent of the total manufacturing cost, and the creation of holes in these processes is comparatively inexpensive, the overall cost for equivalent functionality can be less. In addition, the fine pattern capability for this process is excellent. For example, an eight-layer conventional structure can often be reduced to a four-layer structure, reducing the total cost for the same packaging density.

## 5.7 MOLDED INTERCONNECTION DEVICES

---

Three-dimensional circuit technology was of great interest in the early to mid-1980s. The proponents for this technology, however, realized the mistake of trying to make it directly competitive with conventional flat circuits and have developed a niche where the substrate also offers other functional uses, such as structural support for the product.

Manufacturers of three-dimensional circuits prefer to call them *molded interconnection devices* (MIDs). In many applications of MIDs, the number of components to interconnect the electronic and electrical components can be reduced, thus making the total assembly cost cheaper and the final structure more reliable.

## 5.8 PLATED-THROUGH-HOLE (PTH) TECHNOLOGIES

---

In 1953, the Motorola Corporation developed a PTH process called the *Placir* method,<sup>1</sup> in which the entire surface and hole walls of an unclad panel are sensitized with  $\text{SnCl}_2$  and metallized by spraying on silver with a two-gun spray. Next, the panel is screened with a reverse conductor pattern, using a plating resist ink, leaving metallized conductor traces uncovered. The panel is then plated with copper by an electroplating method. Finally, the resist ink is stripped and the base silver removed to complete the PTH board. One problem associated with the use of silver is the migration caused by silver traces underneath the copper conductors.

The Placir method was the forerunner of the semiadditive process, which is discussed in Chap. 31.

In 1955, Fred Pearlstein<sup>2</sup> published a process involving electroless nickel plating for metallizing nonconductive materials. This catalyzer consists of two steps. First, the panel is sensitized in  $\text{SnCl}_2$  solution, and then it is activated in  $\text{PdCl}_2$  solution. This process presented no problem for metallizing nonconductive materials.

At the same time that Pearlstein's paper was published, copper-clad laminates were starting to become popular. Manufacturers of PWBs applied this two-step catalyzing process to making PTHs using copper-clad laminates. This process, however, turned out to be incompatible with the copper surface. A myriad of black palladium particles called *smads* were generated between copper foil and electrolessly deposited copper, resulting in poor adhesion between the electroless copper and the copper foil. These smads and electroless copper had to be brushed off with strong abrasive action before the secondary electroplating process could begin. To overcome this smad problem, around 1960 researchers began attempting to develop better catalysts; the products of their research were the predecessors of modern palladium catalysts.<sup>3</sup>

The mid-1950s was a busy time in the area of electroless copper-plating solutions. Electrolessly deposited nickel is difficult to etch. But since it adheres somewhat better to the base than does electroless copper, research for the development of stable electroless copper-plating solutions was quite natural. Many patent applications for these solutions were filled in the mid-1950s. Among the applicants were P. B. Atkinson, Sam Wein, and a team of General Electric engineers, Luke, Cahill, and Agens. Atkinson won the case, and a patent<sup>4</sup> teaching the use of Cu-EDTA as a complexing agent was issued in January 1964 (the application had been filed in September 1956).

### 5.8.1 Subtractive and Additive Processes

Photocircuits Corporation was another company engaged throughout the 1950s in the development of chemicals for PTH processes. Copper-clad laminates were expensive, and a major

portion of expensive copper foil had to be etched (*subtracted*) to form the desired conductor pattern. The engineers at Photocircuits, therefore, concerned themselves with plating (*adding*) copper conductors wherever necessary on unclad materials for the sake of economy. Their efforts paid off. They were successful in developing not only the essential chemicals for reliable PTH processes but also the fully additive PWB manufacturing technology known as the CC-4\* process. This process is discussed in detail in Chap. 31.

With the use of  $\text{SnCl}_2$ - $\text{PdCl}_2$  catalysts and EDTA-base electroless copper-plating solutions, the modern PTH processes became firmly established in the 1960s. The process of metallizing hole walls with these chemicals for the subsequent formation of PTHs is commonly called the *copper reduction process*. In the subtractive method, which begins with copper-clad laminates, pattern plating and panel plating are the two most widely practiced methods of making PTH boards. These methods are discussed in the following subsections.

### 5.8.2 Pattern Plating

In the pattern-plating method, after the copper reduction process, plating resist layers of the reverse conductor image are formed on both sides of the panel by screening resist inks. In most fineline boards, photosensitive dry film is used instead. There are some minor variations in the pattern-plating method (see Fig. 5.6):

1. Catalyzing (preparing the nonconductive surface to cause copper to come out of solution onto that surface)
2. Thin electroless copper (0.00001 in) followed by primary copper electroplating; thick electroless copper (0.0001 in)
3. Imaging (application of a plating resist in the negative of the desired finished circuit)
4. Final electroplating copper
5. Solder plating (as etching resist) 0.0002 or 0.0006 in
6. Stripping plating resist
7. Etching of base copper
8. Solder etching (0.0002-in case); solder reflow (0.0006-in case)
9. Solder mask followed by hot-air solder coater leveler if solder etching is used
10. Final fabrication and inspection

Most manufacturers of DSBs with relatively wide conductors employ thick electroless copper plating. However, thin electroless copper followed by primary electroplating is preferred for boards having fine-line conductors, because a considerable amount of surface is brushed off for better adhesion of dry film. This provides a higher reliability for PTHs. Solder reflow boards had been preferred by many customers, particularly in military and telecommunications applications, until the emergence of hot-air solder coater levelers. Although the solder-over-copper conductors protect the copper from oxidization, solder reflow boards have some limitations. Solder mask is hard to apply over reflowed solder, and it tends to wrinkle and peel off in some areas when the boards go through component soldering. A more serious problem is the solder bridging that occurs when the conductor width and clearance become very small.

In step 9, the entire surface of the board except for the pads is covered by solder mask, and then the board is immersed into the hot-air solder coater leveler, resulting in a thin coating of

---

\* CC-4 is a registered trademark of Kollmorgen Corporation.

FIGURE 5.6 Key manufacturing steps in panel plating and pattern-plating methods.

solder over the pads and the hole walls. The operation sounds simple, but it requires constant fine-tuning and maintenance of the hot-air solder coater leveler; otherwise, some holes may become heavily clogged with solder and are then useless for component insertion.

One advantage of the pattern-plating method over the panel-plating method is in etching. The pattern-plating method needs to etch only the base copper. The use of ultrathin copper foil (UTC), which is usually  $\frac{1}{8}$  or  $\frac{1}{4}$  oz thick, offers a real advantage. However, as long as electroplating is used, the pattern-plating method cannot escape from a current distribution problem, regardless of the thickness of the base foils. The panel-plating method by electroplating suffers from the same problem but to a lesser degree. Good current distribution is very difficult to achieve when the boards are not of the same size or type, and particularly if some have large ground planes on the outer faces being plated. When the board has a few holes in an isolated area remote from the bulk of the circuitry, these tend to become overplated, making component lead insertion difficult during assembly. To minimize this current distribution problem, various countermeasures are practiced, such as special anode position, anode masking, agitation, and plating thieves. But none of these offers a decisive solution to the distribution problem, and they are extremely difficult to implement flexibly and effectively in a large plating operation, where a large number of product mixes have to be handled all the time.

Another advantage of the pattern-plating method is its ability to form padless micro-via holes of a diameter ranging from 0.012 to 0.016 in. Micro-via holes enable better usage of conductor channels, thereby increasing the connective capacity of the board.

### 5.8.3 Panel Plating

In the panel-plating method, there are two variations for finishing the board after the panel is plated with electrolytic copper to the desired thickness. In the *hole-plugging* method, the holes are filled with alkaline-etchable ink to protect the hole walls from being etched; this is used in conjunction with screened etch resist. In the other method, called *tent-and-etch* or simply *tenting*, the copper in the hole is protected from etching by covering the hole or tenting with dry film, which is also used as an etch resist for conductors on the panel surface. The simplified sequence of the panel-plating method is as follows (see Fig. 5.6):

1. Catalyzing
2. Thin electroless copper deposition (0.0001 in)
3. Electroplating copper (0.001 to 0.0012 in)
4. Hole plugging with alkaline-resolvable ink; tenting (dry film lamination)
5. Screen-print etching resist (conductor pattern); photoexpose the panel for conductor pattern
6. Etching copper
7. Stripping etching resist
8. Solder mask
9. Solder coater leveler (optional)
10. Final fabrication and inspection

The panel-plating method is ideal for bare copper board. However, it is a difficult way to make padless via holes, which are becoming more popular. Generally, the conductor width of 0.004 in is considered to be the minimum realizable by this method for mass production.

Although the use of the panel-plating method in the United States and western Europe is limited, nearly 60 percent of the PTH boards in Japan are manufactured by this method.

### 5.8.4 Additive Plating

Plated-through holes can be formed by additive (electroless) copper deposition, of which there are three basic methods: fully additive, semiadditive, and partially additive. Of these, semiadditive involves pattern electroplating for PTHs with very thin surface copper, but the other two form PTHs solely by electroless copper deposition. The additive process has various advantages over the subtractive process in forming fineline conductors and PTHs of high aspect ratio. A detailed account of the additive process is given in Chap. 31.

## 5.9 SUMMARY

---

Modern electronic packaging has become very complex. Interconnections are pushed more into lower levels of packaging. The choice of which packaging technology to use is governed by many factors: cost, electrical requirements, thermal requirements, density requirements, and so on. Material also plays a very important role. All things considered, PWBs still play important roles in electronic packaging.

# INTRODUCTION TO BASE MATERIALS

---

**Edward J. Kelley**

*Isola Group, Chandler, Arizona*

---

## 6.1 INTRODUCTION

---

The field of base materials can appear deceptively simple. In simple terms, base materials are comprised of just three components: the resin system, the reinforcement, and the conductive foil. However, the variants in each of these components and the many possible combinations of these components make the discussion of base materials much more complex. One of the primary reasons for this complexity is the fact that printed circuits are used in so many differing applications. This results in many different sets of requirements in terms of cost and performance, and therefore many grades of base materials.

Also, because base materials are the most fundamental components of the printed circuit itself, they interact with virtually every other printed circuit manufacturing process. Therefore, not only are the physical and electrical properties of the material critical, but their compatibility with manufacturing processes is also of great importance.

In addition, the advent of the European Union's Restriction of Hazardous Substances (RoHS) directive and the lead-free assembly processes that result are redefining the requirements for base materials. RoHS has a severe impact on all aspects of base materials technology. The impact of lead-free assembly on base materials and a method of selecting materials for lead-free assembly are discussed in Chaps. 10 and 11. Requirements to support circuit densification, reliability, and electrical performance are also critical and will be discussed in Chap. 9. This chapter discusses grades and specifications of base materials, as well as the manufacturing processes used to make them.

---

## 6.2 GRADES AND SPECIFICATIONS

---

The various types of base materials can be classified by the reinforcement type, the resin system used, the glass transition temperature ( $T_g$ ) of the resin system, as well as many other properties of the material. With the advent of lead-free assembly processes, properties other than  $T_g$  are becoming as important, if not more important when selecting a base material. The decomposition temperature ( $T_d$ ) is one of these properties and will be defined shortly.

The most commonly referenced specification for base materials is IPC-4101, "Specification for Base Materials for Rigid and Multilayer Printed Boards." Historically, the National Electrical Manufacturers Association, NEMA, has also been used in specifying base materials.

### 6.2.1 NEMA Industrial Laminating Thermosetting Products

One of the first classifications of base materials for printed circuits (and other electrical components) was completed by the National Electrical Manufacturers Association (NEMA). NEMA's industrial laminating thermosetting products standard documents many of the materials used in printed circuits as well as specifications for some of their properties. Historical NEMA grades are outlined in Table 6.1 and cross-referenced with IPC-4101 in Table 6.2. Some of the commonly used materials have been FR-2, CEM-1, CEM-3, and, of course, FR-4.

**TABLE 6.1** NEMA Base Material Grades

Grade	Resin	Reinforcement	Flame Retardant
XXXPC	Phenolic	Cotton Paper	No
FR-2	Phenolic	Cotton Paper	Yes
FR-3	Epoxy	Cotton Paper	Yes
FR-4	Epoxy	Woven Glass	Yes
FR-5	Epoxy	Woven Glass	Yes
FR-6	Polyester	Mat Glass	Yes
G-10	Epoxy	Woven Glass	No
CEM-1	Epoxy	Cotton Paper/Woven Glass	Yes
CEM-2	Epoxy	Cotton Paper/Woven Glass	No
CEM-3	Epoxy	Woven Glass/Mat Glass	Yes
CEM-4	Epoxy	Woven Glass/Mat Glass	No
CRM-5	Polyester	Woven Glass/Mat Glass	Yes
CRM-6	Polyester	Woven Glass/Mat Glass	No
CRM-7	Polyester	Mat Glass/Glass Veil	Yes
CRM-8	Polyester	Mat Glass/Glass Veil	No

FR-2 is comprised of multiple plies of paper impregnated with a flame-resistant phenolic resin. It possesses good punching characteristics and is relatively low in cost. It has typically been used in simple applications such as radios, calculators, and toys, where dimensional stability and high performance are not required. FR-3 is also paper-based, but uses an epoxy resin system.

CEM-1 uses a paper-based core with woven glass cloth on the surfaces, both impregnated with an epoxy resin. This enables the material to be punched while realizing improved electrical and physical properties. CEM-1 has been used in both consumer and industrial electronics.

CEM-3, a composite of dissimilar core materials, uses an epoxy resin impregnated, non-woven fiberglass core with epoxy resin impregnated, woven fiberglass cloth surface sheets. It is higher in cost than CEM-1, but is more suitable for plated through holes. CEM-3 has been used in early home computers, automobiles, and home entertainment products.

FR-4, by far the most commonly used material for printed circuits, is constructed of woven fiberglass cloths impregnated with an epoxy resin or epoxy resin blend. The outstanding electrical, mechanical, and thermal properties of FR-4 have made it an excellent material for a wide range of applications including computers and peripherals, servers and storage networks, telecommunications, aerospace, industrial controls, and automotive applications. FR-4 will be discussed in more detail later.

These grades are also used by ANSI, the American National Standards Institute.

**TABLE 6.2** IPC-4101 Base Material Summary

Spec. Sheet #	Reinforcement Type	Resin System	ID Reference*	T <sub>g</sub> Range	Other Properties
00	Cellulose Paper	Phenolic	XPC	N/A	UL94 HB
01	Cellulose Paper	Phenolic	XXXPC	N/A	UL94 HB
02	Cellulose Paper	Phenolic, Flame Resistant	FR-1	N/A	UL94 V-1
03	Cellulose Paper	Phenolic, Flame Resistant	FR-2	N/A	UL94 V-1
04	Cellulose Paper	Epoxy, Flame Resistant	FR-3	N/A	UL94 V-1
05	Cellulose Paper	Phenolic, Phosphorus Flame Resistant	FR-2	N/A	UL94 V-1, limits on Br and Cl content
10	Woven E-Glass Surface/ Cellulose Paper Core	Epoxy/Phenolic, Flame Resistant	CEM-1	100°C min.	UL94 V-0
11	Woven E-Glass Surface/ Non-Woven E-Glass Core	Polyester/Vinyl Ester, Flame Resistant	CRM-5	N/A	UL94 V-1, inorganic fillers
12	Woven E-Glass Surface/ Non-Woven E-Glass Core	Epoxy, Flame Resistant	CEM-3	N/A	UL94 V-0, with or without inorganic fillers
14	Woven E-Glass Surface/ Non-Woven E-Glass Core	Epoxy, Flame Resistant	CEM-3	N/A	UL94 V-0, limits on Br and Cl content
20	Woven E-Glass Fabric	Epoxy, Non-Flame Resistant	G-10, MIL-S-13949/ 03-GE/GEN	N/A	UL94 HB
21	Woven E-Glass	Difunctional and Multifunctional Epoxy, Flame Resistant	FR-4, MIL-S-13949/04-GF/ GFN/GFK/GFP/GFM	110°C min.	UL94 V-0
22	Woven E-Glass	Epoxy, Hot Strength Retention, Non-Flame Resistant	G-11 MIL-S-13949/02-GB/ GBN/GBP	135°C–175°C	UL 94 HB

## 6.2.2 PC-4101 Specification for Base Materials for Rigid and Multilayer Printed Boards

The most commonly used specification for base materials is IPC-4101. This specification presents a classification scheme and specification sheets for the various materials in use. Table 6.2 summarizes the various materials by specification sheet number. Each specification sheet in IPC-4101<sup>1</sup> includes property requirements for that particular material type. As these specification sheets are updated periodically, it is recommended that the latest revision of this document be reviewed. This is particularly true in light of new requirements for materials that must be compatible with lead-free assembly. Table 6.2 is presented for reference only and is not all-inclusive. UL94 comments in Table 6.2 reference the minimum flammability requirements for that material. Materials may exceed these minimum ratings. Also note that where a non-halogen-based flame retardant is used, it is shown along with the resin system description. Definitions of the UL flammability ratings are given in Chap. 8.

Some of the properties documented in the specification sheets of IPC-4101 include  $T_g$ , copper peel strengths at different conditions, volume resistivity, surface resistivity, moisture absorption, dielectric breakdown voltage, permittivity, loss tangent, flexural strengths and arc resistance. These properties will be discussed further in Chap. 8.

IPC-4101 also provides a classification scheme for identification of laminate and prepreg materials; this is described in Secs. 6.5 and 6.6.

## 6.3 PROPERTIES USED TO CLASSIFY BASE MATERIALS

---

Historically, the  $T_g$  has been the most common property used to classify FR-4 base materials, and this is one of the primary properties documented in IPC-4101. Materials with high  $T_g$  values were generally viewed as being more reliable. While this question was never as simple as specifying only the  $T_g$ , the move toward lead-free assembly has caused a fundamental redefinition of what properties are needed to ensure a given level of reliability. The reason is that the alloys used in lead-free assembly require higher peak temperatures than those used in tin-lead assembly. These higher peak temperatures can approach the point where many base materials begin to decompose. For this reason, the decomposition temperature is becoming another property used to classify base materials.

Other important properties include Z-axis expansion characteristics, moisture absorption, and adhesion characteristics within the material, commonly measured using time-to-delamination tests such as the T260 test. The  $T_g$  and its impact on Z-axis expansion are summarized below along with the decomposition temperature. The other properties will be discussed in Chaps. 8 and 10.

### 6.3.1 Glass Transition Temperature, $T_g$

The  $T_g$  of a resin system is the temperature at which the material transforms from a relatively rigid or “glassy” state, to a more deformable or softened state. This is a thermodynamic change in the material which is reversible as long as the resin system has not been degraded. This is to say that when a material that has been heated above its  $T_g$  is cooled back below the  $T_g$ , it returns to a more rigid state with essentially the same properties as before. However, if the material is heated to too high a temperature beyond  $T_g$ , irreversible changes in properties may result. The temperature at which this will happen varies by material type and is related to resin decomposition, discussed later.

**FIGURE 6.1** Glass transition temperature by TMA.

A material is not in a liquid state when it is above the  $T_g$ , as some discussions of  $T_g$  imply. It is a temperature at which physical changes take place due to the weakening of molecular bonds within the material. It is important to understand  $T_g$  since the properties of base materials are different above  $T_g$  than below  $T_g$ . While the  $T_g$  is typically described as being a very precise temperature, this is somewhat misleading, because the physical properties of the material can begin to change as the  $T_g$  is approached and some of the molecular bonds are affected. As the temperature increases, more of the bonds become weakened until for all practical purposes, all relevant bonds are affected. This explains the curved line in Fig. 6.1, which is discussed in the following text.

The  $T_g$  of a resin system has several important implications. These include:

- The impact on thermal expansion.
- A measure of the degree of cure of the resin system.

**6.3.1.1 Thermal Expansion.** All materials will undergo changes in physical dimensions in response to changes in temperature. The rate at which the material expands is much lower below the  $T_g$  than above. Thermomechanical analysis (TMA) is a procedure used to measure dimensional changes versus temperature. Extrapolating the linear portions of the curve to the point at which they intersect provides a measure of the  $T_g$  (see Fig. 6.1). The slopes of the linear portions of the curve above and below the  $T_g$  represent the respective rates of thermal expansion, or as they are typically called, the coefficients of thermal expansion (CTEs). CTE values are important since they influence the reliability of the finished circuit. Other things being equal, less thermal expansion will result in greater circuit reliability as less stress is applied to plated holes.

**6.3.1.2 Degree of Cure.** The resin systems used in base materials begin with subcomponents that contain reactive sites on their molecular structures. The application of heat to the resin system and curing agents causes the reactive sites to *cross-link* or bond together. This process of curing the resin system brings about physical changes in the material in proportion to the degree to which the cross-linking occurs, including increases in the  $T_g$ . When most of the reactive sites have cross-linked, the material is said to be fully cured and its ultimate physical properties will be established.

Besides TMA, two other thermal analysis techniques are also commonly used for measuring  $T_g$  and degree of cure: differential scanning calorimetry (DSC) and dynamic mechanical analysis (DMA).

- DSC measures heat flow versus temperature rather than the dimensional changes measured by TMA. The heat absorbed or given off will also change as the temperature increases through the  $T_g$  of the resin system.  $T_g$  measured by DSC is often somewhat higher than measurements by TMA.
- DMA measures the modulus of the material versus changes in temperature, and also will give somewhat higher values for  $T_g$ .

Materials that are not fully cured can cause problems in circuit manufacturing processes and with finished circuit reliability. For example, an undercured multilayer circuit at the drilling process can result in excessive resin smear across the internal circuit connections in

the hole formed. This happens because an undercured resin system, and the resulting lower than normal  $T_g$ , will result in excessive softening of the resin when it is subjected to the heat generated during the drilling process. If this smeared resin is not completely removed, it can prevent electrical connection when the hole is plated with copper. In addition, finished circuits in which the resin system is not fully cured can exhibit greater amounts of Z-axis thermal expansion. This adversely affects circuit board reliability due to the increased stress on the plated through holes as the circuit expands.

Because increased cross-linking will require greater amounts of energy (heat) to weaken the bonds in the molecular structure of the resin system, measurements of  $T_g$  can be used to determine the degree of cure of the resin system. For example, a measure of the degree of cure can be obtained by performing two thermal analyses on the same sample. After the first analysis, the sample is subjected to a thermal cycle designed to promote any additional cross-linking available within the resin system, and then a second thermal analysis is performed. The degree of cure is measured by comparing the difference in measured  $T_g$  between the two analyses (see Fig. 6.2). If the material is fully cured, the difference between  $T_{g2}$  and  $T_{g1}$  will be very small, typically within a few degrees Celsius. Negative differences in these measured values or negative “delta  $T_g$ ” values where  $T_{g1}$  is greater than  $T_{g2}$  are also indicative of full cure. However, great care must be exercised when using these methods to assess degree of cure. An understanding of the resin system is important because not all resins will behave the same way when performing sequential tests such as this. The degree of cure for some advanced resin systems is not easily assessed by these techniques. In addition, sample preparation methods, particularly sample drying prior to testing, can also influence results.

**FIGURE 6.2** Measuring the degree of cure by measuring  $T_g$  values.

**6.3.1.3 Advantages and Disadvantages of High  $T_g$  Values.** Implicit in many discussions of  $T_g$  is the assumption that higher values of  $T_g$  are always better. This is not always the case. While it is certainly true that higher values of  $T_g$  will delay the onset of high rates of thermal expansion for a given resin system, total expansion can differ from material to material. A material with a lower  $T_g$  could exhibit less total expansion than a material with a higher  $T_g$ , due to differing resin CTE values or by incorporating fillers into the resin system that lower the CTE of the composite material. This is illustrated in Fig. 6.3. Material C exhibits a higher  $T_g$  than material A, but material C exhibits more total thermal expansion because its CTE value above  $T_g$  is much higher. On the other hand, with the same CTE values above and below the  $T_g$ , the higher- $T_g$  material B exhibits less total thermal expansion than material A. Finally, although the  $T_g$  values are the same, material B exhibits less total expansion than material C due to a lower CTE value above  $T_g$ . This will be discussed further in Chap. 10 in the context of the impact of lead-free assembly temperatures on base materials.

There are other considerations as well. Most notably, many standard 140°C  $T_g$  FR-4 materials exhibit higher decomposition temperatures,  $T_d$ 's, than the standard 170°C  $T_g$  FR-4s.  $T_d$  is an important property for lead-free

**FIGURE 6.3**  $T_g$  versus thermal expansion.

assembly, with higher values generally preferred. Advanced FR-4 resin systems can combine both high- $T_g$  and high- $T_d$ . This will be discussed in detail in Chap. 10.

In addition, higher  $T_g$  resin systems can be harder and more brittle than lower  $T_g$  systems. This can adversely affect productivity in the printed circuit manufacturing process. In particular, the drilling process can be affected as slower drilling, reduced drill bit life or reduced stack heights can be required for high- $T_g$  materials.

Lower copper peel strength values and shorter times to delamination can also be correlated with higher  $T_g$  values, though other factors influence these properties as well. The time to delamination is a measure of the time it takes for the resin and copper, or resin and reinforcement, to separate or delaminate, and can be correlated to  $T_d$ . This will also be discussed in Chaps. 8 and 10, in the context of lead-free assembly. This time-to-delamination test utilizes TMA equipment to bring a sample to a specified temperature and then measures the time it takes for failure to occur. Failure is typically delamination between the resin and copper foil, or resin and glass within the laminate. Temperatures of 260°C (T260) and 288°C (T288) are commonly used for this testing.

### 6.3.2 Decomposition Temperature, $T_d$

As a material is heated to higher temperatures, a point is reached where the resin system will begin to decompose. The chemical bonds within the resin system will begin to break down and volatile components will be driven off, reducing the mass of the sample. The decomposition temperature,  $T_d$ , is a property which describes the point at which this process occurs. The traditional definition of  $T_d$  is the point where 5 percent of the original mass is lost to decomposition. However, 5 percent is a very large number when multilayer PCB reliability is considered, and temperatures where lower levels of decomposition occur are very important to understand, particularly with respect to lead-free assembly. To illustrate this, consider Fig. 6.4.

In Fig. 6.4, you can see curves for two FR-4 materials. The “traditional FR-4,” a 140°C  $T_g$  material in this case, has a decomposition temperature of 320°C by the 5 percent weight loss definition. The “enhanced FR-4” has a decomposition temperature of 350°C by the 5 percent weight loss definition. Many standard high- $T_g$  FR-4 materials actually have decomposition

FIGURE 6.4 Illustration of decomposition curves.

temperatures in the range of 290–310°C, while the 140°C  $T_g$  FR-4 materials generally have slightly higher  $T_d$  values. The shaded regions indicate the peak temperature ranges for standard tin-lead assembly and lead-free assembly. A very common question is, if a PCB will be assembled at 260°C, and the material has a decomposition temperature of 310–320°C, then why wouldn't it be compatible with lead-free assembly?

The answer lies in the level of decomposition in the temperature ranges where assembly will take place. In the tin-lead temperature range, neither material exhibits a significant level of decomposition. However, in the lead-free assembly temperature range, the traditional FR-4 begins to exhibit 1.5–3 percent weight loss. This level of decomposition can compromise long-term reliability or result in defects such as delamination during assembly, particularly if multiple assembly cycles or rework cycles are performed.

## 6.4 TYPES OF FR-4

---

As can be seen in Table 6.2, several materials listed are considered FR-4. This begs the question: What is FR-4? In Table 6.2, it can be seen that each material considered FR-4 is flame-resistant, uses a woven fiberglass reinforcement and is primarily an epoxy-based resin system.

### 6.4.1 The Many Faces of FR-4

So what can be different about these materials? The most obvious difference between the commercially available FR-4 materials is in  $T_g$  values. Specification sheet 21 refers to an FR-4 with a minimum  $T_g$  of 110°C. More common are FR-4 materials with  $T_g$  values between 130°C to 140°C and 170°C to 180°C. Therefore, it is obvious that FR-4 materials can consist of different types of epoxy resins. Indeed, there are many types of epoxy resins that will provide differing  $T_g$  values, as well as differences in other properties.

Specification sheets 92-95 list FR-4 materials with non-halogen-based flame retardants, as well as different  $T_g$  ranges. Sheets 92 and 94 indicate the use of a phosphorus-based flame retardant, whereas sheets 93 and 95 show the use of aluminum hydroxide. So FR-4 may include different types of flame retardants.

In addition, several FR-4 materials, such as those shown in sheets 99, 101, and 126, show that these materials contain inorganic fillers. These fillers are often used to reduce the amount of Z-axis expansion. Some of these materials also have requirements for  $T_d$ , Z-axis expansion and time-to-delamination, which historically were not properties included on the specification sheets. The addition of specification sheets with these properties was partly driven by their relevance to compatibility with lead-free assembly processes.

Finally, specification sheet 82 covers an FR-4 material catalyzed for an additive copper-plating process. A catalyst used for this material is a kaolin clay filler coated with palladium. In short, there are many combinations of resin system, flame retardant and filler that can result in many types of FR-4.

### 6.4.2 The Longevity of FR-4

FR-4 materials have been the most successful, most commonly used materials in printed circuit manufacturing for many years. Why? Well, as we just discussed above, FR-4 actually encompasses a range of material types, even though they share certain properties and are primarily epoxy-based. The result is that there is often an FR-4 material readily available for the most common end-use applications. For relatively simple applications, the 130°C to 140°C  $T_g$  FR-4s have become the material of choice. In higher layer count multilayer circuits, in very

thick circuits, as well as those requiring improved thermal properties, the 170°C to 180°C  $T_g$  FR-4s have become the material of choice. With the advent of lead-free assembly,  $T_d$  and other properties must also be considered along with  $T_g$ . Further, as noted above, higher  $T_g$  does not always translate to better performance in lead-free assembly applications. In other words, as the range of end-use applications has grown, so has the range of available FR-4 materials.

In addition, the components used in FR-4 materials, particularly woven fiberglass cloth and epoxy resins, provide a very good combination of performance, processability, and cost. The range of woven fiberglass cloth styles available makes it easy to control dielectric and overall circuit thicknesses. As noted earlier, the range of epoxy resin types also makes it relatively simple to tailor material properties to end-use applications. The combination of good electrical, thermal, and mechanical properties of epoxies also explains why they have become the primary type of resin used in printed circuits. Epoxy-based materials are also relatively easy to process through conventional printed circuit manufacturing processes, at least in comparison to some of the other types of materials available. The processability of these materials has helped control the cost of FR-4-based printed circuits.

Last, the development of FR-4 materials took advantage of established manufacturing processes and materials. Weaving processes have been in place for many years. The fundamental process of weaving fiberglass yarns into glass cloth is not so different from weaving textile yarns into cloth fabrics. Using the same basic manufacturing technology avoided additional upfront research and development costs, but more importantly it avoids to some extent highly specialized capital assets and aids in achieving economies of scope for the suppliers of fiberglass cloth. The result is good control of the costs of these materials. Likewise, epoxy resins have been in use in a wide range of applications outside of printed circuits, resulting in a very large installed manufacturing base for these types of materials. This also results in good cost competitiveness for epoxy resins. In summary, the range of FR-4 types and their unique combination of performance, processability and cost characteristics have made them the workhorse of the printed circuit industry.

## 6.5 LAMINATE IDENTIFICATION SCHEME

As IPC specifications are regularly reviewed and updated, it is recommended that the latest IPC specification be used for actual applications. However, an example of a laminate designation in IPC-4101 is:

<b>L</b>	<b>25</b>	<b>1500</b>	<b>CI/CI</b>	<b>A</b>	<b>A</b>
Material Designator	Specification Sheet Number	Nominal Laminate Thickness	Metal Cladding Type and Nominal Weight/Thickness	Thickness Tolerance Class	Surface Quality Class

- **Material designator** “L” refers to laminate.
- **Specification sheet number** This designation references the specification sheet number as in Table 6.2.
- **Nominal laminate thickness** Four digits identify this variable. It may be specified either over the cladding or over the dielectric. For metric specification, the first digit represents whole millimeters, the second represents tenths of millimeters, and so on. For orders requiring English units, the four digits indicate the thickness in ten-thousandths of an inch (tenths of mils). In the example shown, 1500 is designated for the English usage of 0590.

**TABLE 6.3** Metal Cladding Types Summarized in IPC-4101 (IPC-CF-148, IPC-4562, and IPC-CF-152 are Actual Metal Cladding Specifications)<sup>2</sup>

Designation	Metal Cladding Type
A	Copper, wrought, rolled (IPC-4562, grade 5)
B	Copper, rolled (treated)
C	Copper, electrodeposited (IPC-4562, grade 1)
D	Copper, electrodeposited, double treat (IPC-4562, grade 1)
G	Copper, electrodeposited, high ductility (IPC-4562, grade 2)
H	Copper, electrodeposited, high temperature elongation (IPC-4562, grade 3)
J	Copper, electrodeposited, annealed (IPC-4562, grade 4)
K	Copper, wrought, light cold rolled (IPC-4562, grade 6)
L	Copper, wrought, annealed (IPC-4562, grade 7)
M	Copper, wrought, rolled, low temperature annealable (IPC-4562, grade 8)
N	Nickel
O	Unclad
P	Copper, electrodeposited, high temperature elongation, double treat (IPC-4562, grade 3)
R	Copper, reverse treated electrodeposited (IPC-4562, grade 1)
S	Copper, reverse treated electrodeposited, high temperature elongation (IPC-4562, grade 3)
T	Copper, copper foil parameters as dictated by contract or purchase order
U	Aluminum
V	Copper, reverse treated electrodeposited, high temperature elongation (IPC-4562, grade 3) for buried capacitance applications
X	As agreed between user and supplier
Y	Copper Invar Copper
Z	Copper, electrodeposited, high temperature elongation, double-treat (IPC-4562, grade 3) for buried capacitance applications

- Metal cladding type and nominal weight/thickness** Five designators are used to specify cladding type and thickness. The first and fourth indicate the type, the second and fifth indicate thickness, and the third is a slash to differentiate sides of the base material. Table 6.3 lists the types of metal cladding. Table 6.4 lists copper foil weights and thicknesses.
- Thickness tolerance class** This variable references the thickness tolerance as agreed between user and supplier (see Table 6.5). Classes A, B, and C refer to measurement by micrometer of the base material without cladding. Class D requires measurement by microsection (see Fig. 6.5). Classes K, L, and M refer to measurement by micrometer of the base material with the metal cladding. Class X refers to a requirement agreed upon between user and supplier.
- Surface quality class** This class is identified by either A, B, C, D, or X (as agreed upon between user and supplier). Specimens are examined with normal or corrected 20/20 vision. The worst 50 mm × 50 mm (1.97 in. × 1.97 in.) is examined at 10 × magnification. Indentations are located visually using normal or corrected 20/20 vision. The longest dimension of each foil indentation in a specimen is measured with a suitable reticule on a minimum 4 × magnifier, with referee inspections at 10 ×. A point value is allocated according to the longest dimension, as shown in Table 6.6. Surface quality class is determined by the total point count of foil indentations within 300 mm × 300 mm (11.81 in. × 11.81 in.), as shown in Table 6.7.

**TABLE 6.4** Foil Weights and Thicknesses from IPC-4101 (IPC-CF-148, IPC-4562, and IPC-CF-152 are Actual Metal Cladding Specifications)

Foil Designator	Common Industry Terminology	Area Weight (g/m <sup>2</sup> )	Nominal Thickness (μm)	Area Weight (oz/ft <sup>2</sup> )	Area Weight (g/254 in. <sup>2</sup> )	Nominal Thickness (μm)
E	5 μm	45.1	5.1	0.148	7.4	0.20
Q	9 μm	75.9	8.5	0.249	12.5	0.34

## 6.6 PREPREG IDENTIFICATION SCHEME

---

An example of a prepreg identification in IPC-4101 is:

P	25	E7628	TW	RE	VC
Material	Specification	Reinforcement	Resin	Flow	Optional
Designator	Sheet	Style	Content	Parameter	Prepreg
		Number	Method	Method	Method

- **Material designator** P refers to prepreg.
- **Specification sheet number** This designation references the specification sheet number as in Table 6.2.
- **Reinforcement style** The reinforcement type and style of prepreg is indicated by five digits based on the chemical type and style. In the example, E refers to E-glass and 7628 is the glass fabric style.
- **Resin content method** This variable refers to the method used to specify resin content of a prepreg. The two methods are RC, which refers to percent resin content of the prepreg, and TW, which refers to the treated weight of the prepreg. A 00 designator would indicate that no method is specified.
- **Flow parameter method** This variable indicates how much the resin in the prepreg will flow under specified conditions—a critical property. The options are:

MF: resin flow percent

SC: scaled flow thickness

NF: no flow

RE: rheological flow

DH: delta H

PC: percent cure

00: no method specified

- **Optional prepreg method** Other test methods may also be designated here. These include:

VC: volatile content

DY: dicy inspection

GT: gel time

00: none specified

The choice of test methods and their required nominal values and tolerances are normally agreed upon between user and supplier.

In addition to properties on the specification sheets, IPC-4101 includes class specifications for other properties as well. These include length and width, bow and twist, and thermal conductivity, among others.

## 6.7 LAMINATE AND PREPREG MANUFACTURING PROCESSES

---

While there are a few different processes that can be used to integrate the components that make up printed circuit base materials, the overwhelming majority of materials are manufactured using a common process. In recent years however, new techniques have been developed and continue to be developed. These new processes have been designed to either lower the

**FIGURE 6.6** The conventional manufacturing process.

cost of manufacturing or to improve material performance, or both. Common to all processes is the need to manufacture a copper clad laminate and the bonding sheets or *prepregs* used to manufacture multilayer circuits.

### 6.7.1 Conventional Manufacturing Processes

The overall conventional manufacturing process is illustrated in Fig 6.6. This process can be subdivided into two processes: prepreg manufacturing and laminate manufacturing. Prepreg is also called *B-stage* or bonding sheets, while laminate is sometimes called *C-stage*. The terms B-stage and C-stage refer to the degree to which the resin system is polymerized or cured. B-stage refers to a state of partial cure. B-stage is designed to melt and continue polymerizing when it is exposed to sufficient temperatures. C-stage refers to a state of “full” cure (typically we never realize *full* cure, in the sense that not all reactive sites on the resin molecules have cross-linked; however, we use the term *full cure* to mean that the overwhelming majority of such sites have reacted and additional exposure to temperature will do little to advance the state of cure).

### 6.7.2 Prepreg Manufacturing

The first step in most of these processes involves coating a resin system onto the chosen reinforcement, most commonly a woven fiberglass cloth. Rolls of fiberglass cloth or alternative reinforcement type are run through equipment called *treaters*. Figure 6.7 shows some of the resin system components that are mixed and aged prior to application to the fiberglass cloth. Figure 6.8 illustrates the overall treating process. The fiberglass cloth is drawn through a pan containing the resin system and then precise metering rolls help control thickness and also push resin into the yarns of the glass cloth (see Fig. 6.9).

**FIGURE 6.7** Resin mixing, aging, and treating.

Next the cloth is pulled through a series of heating zones. These heating zones commonly utilize forced air convection, infrared heating, or a combination of the two. In the first set of zones, solvent used to carry the resin system components is evaporated off. Subsequent zones are dedicated to partially curing the resin system, or B-staging the resin. Finally, the prepreg is then rewound into rolls or cut into sheets.

A number of process controls are required in this operation. The concentrations of the resin system components must be controlled and the viscosity of the resin system maintained within acceptable limits. Tension on the cloth as it is pulled through the treater is also important, for among other reasons, it is vital not to distort the weave pattern of the cloth. Control of the

**FIGURE 6.8** “Treating” fiberglass cloth with resin.

resin-to-glass ratio or resin content, the degree of cure of the resin and cleanliness are also critical.

Because the resin system at this point is only partially cured, prepregs must typically be stored in temperature- and humidity-controlled environments. Temperature, for obvious reasons, could affect the degree of cure of the resin and therefore its performance in laminate or multilayer circuit pressing. Since moisture can affect the performance of many curing agents and accelerators, not to mention the performance of the resin system during lamination or press cycles, humidity is also important to control during prepreg storage. Absorbed moisture that becomes trapped during lamination cycles can also lead to blisters or delaminations within the laminate or multilayer circuit.

**FIGURE 6.9** Prepreg after treating with resin.

### 6.7.3 Laminate Manufacturing

The process of copper clad laminate manufacturing begins with the prepreg material. Prepregs of certain fiberglass cloth styles and specific resin contents are combined with the desired copper foils to make the finished laminate. First, the prepregs and copper foils are sheeted to the desired size. Figure 6.10 shows an automated copper-sheeting process.

These materials are then laid up in the proper sequence to produce the desired copper clad laminate. Figures 6.11 and 6.12 are examples of an automated build-up process where the prepreg and copper foil materials are combined prior to being pressed together. Several of these individual sandwiches of prepreg and copper foil are stacked on top of each other, typically separated by stainless steel plates, although other separator materials, including aluminum, can also be used. These stacks are then loaded into multi-opening lamination

**FIGURE 6.10** Sheeting of rolls of copper foil.

FIGURE 6.11 Automated build-up of copper and prepreg.

FIGURE 6.12 Automated build-up of copper and prepreg.

FIGURE 6.13 Laminate pressing.

**FIGURE 6.14** Lamination press with multiple openings.  
(Photo Courtesy of Polyclad Laminates, Inc.)

presses (see Figs. 6.13 and 6.14), where pressure, temperature, and vacuum are applied. The specific press cycle used will vary depending upon the particular resin system, the degree of cure of the prepregs and other factors. The presses themselves have many platens that can be heated by steam or hot oil that flows through the platens, or they can also be heated electrically.

Process controls in the lamination/pressing process are also critical. Cleanliness in the manufacturing environment and cleanliness of the steel separator plates are critical in achieving good surface quality and in avoiding embedded foreign material within the laminate. Control of the temperature rise during lamination will provide the desired amount of resin flow, while control of the cooldown rate can impact warp and twist. The length of time that the laminate is above the temperature required to initiate the curing reaction will determine the degree of cure, as will the degree to which the actual temperature exceeds this temperature.

While these descriptions of prepreg and laminate manufacturing give a simple description of the processes used, it is important to understand that there are many variables that influence the quality and performance of the finished products. In addition, many of these variables interact with each other, meaning that a change in one may influence others and may require adjustments to these other process variables. In summary, prepreg and laminate manufacturing is much more complex than it appears at first glance.

#### 6.7.4 Direct Current or Continuous Foil Manufacturing

Continuous foil or direct current manufacturing is an alternative method used to manufacture copper clad laminates (see Fig. 6.15). Prepregs are still used in this process, however, the lay-up and pressing operations are somewhat different. In this process, the copper foils are not sheeted, but kept in rolls. To start, copper foil with the side to be bonded to the prepreg facing up, is laid

**FIGURE 6.15** Laminate pressing with continuous copper foil and direct current heating. (Illustration Courtesy of Cedral)

down, while still part of a continuous roll. The prepregs are laid up in the proper sequence, and then the roll of copper foil is passed over the prepregs so that it is applied to the top of what will become the finished laminate. Typically, two rolls of foil are used to allow dissimilar copper weights or types to be bonded to either side of the laminate. A separator plate, typically anodized aluminum, is then placed on top of this sandwich, and the process is repeated so that several laminates are stacked up.

At this point, the stack of laminates is loaded into a press and subjected to heat, pressure, and vacuum. However, as opposed to the conventional process, this technique involves applying direct current to the copper foil that runs throughout the stack. The current heats the foil and therefore the prepregs are adjacent to the foils. By controlling the amount of current, you control the temperature of the materials in the stack.

### 6.7.5 Continuous Manufacturing Processes

Over the years, continuous lamination processes have also been designed. Rather than cut the prepregs and foils into sheets, lay them up and press them as individual laminates, these processes use rolls of prepreg or bare fiberglass cloth and rolls of copper foil that are continuously unwound and fed together into a continuous horizontal press. One process starts with rolls of prepreg. Another starts with the bare, untreated fiberglass cloth, applies a resin to the cloth and is sandwiched with the copper foil as it is fed continuously into a horizontal press. At the back end of the press, sections of the continuous laminate can be cut into sheets, or with thin laminates, rolls of copper clad laminate can be manufactured.

# CHAPTER 7

---

## BASE MATERIAL COMPONENTS

---

**Edward J. Kelley**

*Isola Group, Chandler, Arizona*

---

### 7.1 INTRODUCTION

---

Although there are many types of base materials, they all contain three components:

- The resin system, including additives
- The reinforcement(s)
- The conductor

Each of these components is important in its own right, and in combination they determine the properties of the base material as well as the relative cost of the material.

Environmental legislation such as the European Union's Restriction of Hazardous Substances (RoHS) directive has a profound impact on all levels of the electronics supply chain, including these components. RoHS restricts the use of lead, which is an element in the solder used for component assembly onto printed circuits. The impact on the base materials and components is primarily the result of higher assembly temperatures that are associated with lead-free assembly. Table 7.1 summarizes the key issues for base material components. RoHS issues will be discussed further in Chap. 10.

The RoHS directive also restricts specific halogen-containing flame retardants. However, most base materials for printed circuits do not contain the restricted flame retardants. Nevertheless, there is growing interest in halogen-free materials, and this will be discussed further in this chapter.

---

### 7.2 EPOXY RESIN SYSTEMS

---

The most successful and widely used resin systems for printed circuit applications are epoxy resin systems. There are many types of epoxy resins, and this class of resin system continues to be the workhorse among printed circuit board materials. This is a result of the combination of good mechanical, electrical, and physical properties and the relatively low cost of epoxies in comparison to the higher-performance resins. In addition, epoxy systems are relatively easy to process, which aids in keeping manufacturing costs down.

**TABLE 7.1** Lead-Free Assembly Impact on Base Material Components

Component	Lead-Free Assembly Impact	Potential Solutions	Related Considerations
Resin System	<ol style="list-style-type: none"> <li>1. Peak assembly temperatures can reach the point where resin decomposition begins.</li> <li>2. Higher temperatures result in increased thermal expansion and stress on plated holes as a result.</li> <li>3. Vapor pressure of absorbed moisture much higher at lead-free assembly temperatures; can lead to blistering/delamination.</li> <li>4. "Phenolic" lead-free compatible materials often not as good for electrical performance, especially Df.</li> </ol>	<ol style="list-style-type: none"> <li>1. ### 7.2.1 Definition of Epoxy

One of the most common versions of epoxy resin for printed circuit applications is manufactured from reacting epichlorohydrin and bisphenol-A. This reaction is shown in Fig. 7.1. The bromination of the bisphenol-A provides flame retardancy to the finished resin system.

**FIGURE 7.1** Reaction to form difunctional epoxy resin.

Figure 7.2 shows the structure of tetrabromobisphenol-A, or TBBPA. Figure 7.3 shows a reaction used to manufacture brominated epoxy resins. Brominated epoxy resins such as this are the most common component used to incorporate flame retardancy to the finished product, although non-halogen-based flame retardants can also be used, and are discussed in Sec. 7.4.2.3. The triangular rings on either end of the difunctional epoxy are the epoxide functional groups. In subsequent resin polymerization, these groups react and result in the curing of the resin system. The  $-OH$  groups present on the epoxy molecule also react with the epoxide groups, providing cross-linking among the epoxy molecules (see Fig. 7.4).

**FIGURE 7.2** Tetrabromobisphenol-A (TBBPA).

#### Difunctional epoxy resin

#### Tetrabromobisphenol A (TBBPA)

#### Brominate epoxy resin

**FIGURE 7.3** Brominated difunctional epoxy resin.

## 7.2.2 Difunctional Epoxies

The epoxy resins shown in Figs. 7.1 and 7.3 are difunctional epoxies. The molecular weight of the epoxy can be varied based on the number of repeating groups shown in the center of the molecule. On either end of the molecule, you see the epoxide functional groups. The name *difunctional epoxy* is derived from the fact that there are two epoxide groups, one on either

**FIGURE 7.4** Cross-linking of  $-OH$  and epoxide functional groups.

end of the molecule. The molecular weight, the curing agents used to react the resin and other factors will affect the finished properties of the resin system, including  $T_g$  and  $T_d$ . The  $T_g$  is the temperature at which the resin turns from a rigid or glassy state to a softer, more deformable state. The  $T_g$  is important because it affects the thermal and physical properties of the base material and finished circuit board, especially thermal expansion properties. The  $T_d$  is the decomposition temperature and will influence thermal reliability of the printed circuit. These properties are discussed in more detail in Chaps. 6 and 8, and again in Chap. 10 as they relate to compatibility with lead-free assembly processes.

Difunctional epoxies can have a range of  $T_g$ 's, but are typically below 120°C. These epoxies are sometimes used in relatively unsophisticated products such as simple double-sided printed circuits, but are more commonly blended with other epoxies in higher performance systems.

### 7.2.3 Tetrafunctional and Multifunctional Epoxies

The use of epoxy compounds with more than two epoxide functional groups per molecule results in greater cross-linking when the resin is cured. Among other things, this can result in higher  $T_g$  levels. Resin systems with these types of epoxies can exhibit improved thermal and physical properties. However, the curing chemistry will also have an impact on these properties, and often the higher- $T_g$  materials can be harder and more brittle, requiring process adjustments in the printed circuit manufacturing process. Common commercially available laminate materials based on epoxy resin systems can be segmented into a few  $T_g$  ranges, 125 to 145°C, 150 to 165°C, and greater than 170°C. There are epoxy systems above 190°C, but they are less common. These resin systems are normally blends of difunctional, tetrafunctional, and multifunctional epoxy resins. Figures 7.5 and 7.6 are examples of tetrafunctional and multifunctional epoxies.

A cost-performance trade-off exists among the commonly used epoxy resin systems. In general, resin systems offering higher levels of  $T_g$  and  $T_d$  will cost more. In addition, the high- $T_g$  systems can incur increased circuit manufacturing costs, due primarily to increased multi-layer lamination cycle times and decreases in drilling productivity. However, the improvement in performance is often required to meet design and reliability requirements. Chapter 11 outlines a procedure for selecting cost-effective materials for various printed circuit designs.

FIGURE 7.5 A tetrafunctional epoxy resin.

**FIGURE 7.6** A multifunctional epoxy phenol novolac resin.

### 7.3 OTHER RESIN SYSTEMS

Many other resin systems are also available. In choosing a resin system, the circuit board designer and fabricator will have to consider what level of performance is needed, as there is typically a strong cost-performance relationship. This cost-performance relationship is driven not only by the base price of the material itself, but also by the impact the material has on processing costs, both during laminate and prepreg manufacturing, and during printed circuit manufacturing processes.

#### 7.3.1 Epoxy Blends

Blends of epoxy resins with other types of resins have also been developed. These are used when performance demands exceed the capabilities of even the high- $T_g/T_d$  epoxies, but where the costs of the highest performance materials cannot be justified. In many cases, the driving force behind these materials is the need for improved electrical properties versus the standard epoxy offerings. Specifically, improvements in the dielectric constant (permittivity) and dissipation factor (loss tangent) are the properties of interest. Materials with lower values for these properties are needed for circuits that operate at high frequencies.

These blends include epoxy-polyphenylene oxide (PPO) (see Fig. 7.7), epoxy-cyanate ester, and epoxy isocyanurate (see Fig. 7.8). While these materials have been developed to minimize impacts to common printed circuit manufacturing processes, they can affect productivity in multilayer lamination and drilling and can require special desmear and hole wall conditioning processes, depending on the design of the printed circuit and fabrication process used. On the other hand, they typically have less of an impact to these processes when compared to the even higher performance materials.

2,6 Xylenol

**FIGURE 7.7** Polyphenylene oxide (PPO).

FIGURE 7.8 Epoxy isocyanurate.

These epoxy blends are often used in high-frequency applications including antennas, radio frequency (RF), and wireless communications equipment, and high-speed computing applications.

### 7.3.2 Bismaleimide Triazine (BT)/Epoxy

Typically, epoxy is added to BT resins to modify the properties of pure BT. Therefore these materials are also considered epoxy blends. BT/epoxies normally have  $T_g$  values in the range of 180°C to 220°C and exhibit a good combination of electrical, thermal and chemical resistance properties. BT/epoxy is commonly used in BGA substrates and chip scale packages since it can meet the requirements of specifications for use in semiconductor chip packaging. It is also suitable for high-density multilayers requiring good thermal, electrical, and chemical performance.

The primary disadvantage of BT-based materials is cost. The greater the amount of BT, the higher the cost. BT can also be more brittle than pure epoxy systems, and moisture absorption can also be higher.

### 7.3.3 Cyanate Ester

Cyanate ester systems possess very high- $T_g$  values, typically in the neighborhood of 250°C, and exhibit very good electrical performance. Thermal stability is also good. However, cyanate esters are relatively expensive and require special processing that can add additional cost to the finished circuit. For these reasons, cyanate ester materials are still used only in niche applications. Blends with epoxies have also been used to modify processability and cost.

### 7.3.4 Polyimide

When extreme heat resistance is required, polyimide resins offer outstanding performance. With a  $T_g$  of 260°C for the purest systems to 220°C for modified or toughened systems, and very high decomposition temperatures, circuits manufactured with polyimide materials exhibit very high levels of thermal reliability. The high  $T_g$  of these resin systems also helps to minimize thermal expansion, as most of the thermal expansion occurs pre- $T_g$ , where expansion rates are relatively low. These materials have commonly been used in burn-in boards, aerospace and avionics, down-well oil drilling, and military applications where thermal performance is vital. Again, however, these resin systems are relatively expensive and more difficult to process, generally limiting them to niche applications.

### 7.3.5 Polytetrafluoroethylene (PTFE, Teflon®)

A variety of PTFE-based products are also available for applications where extremely good electrical properties are required. These materials often require very specialized processing and are relatively expensive. Hybrids of PTFE-based materials and other material types are often used to gain the performance benefits of the PTFE-based materials where needed, while controlling the total circuit cost by using other less costly materials in other layers of the multilayer circuit.

### 7.3.6 Polyphenylene Ether (PPE)

PPE-based products offer superior electrical properties compared to the epoxy blends discussed above, and also offer excellent thermal performance. This resin system is well suited for RF and wireless communications and high-speed computing applications. While early versions of these resin systems were more difficult to process, improvements in resin formulation and rheology control have been made so that PPE systems can be processed using conventional PCB manufacturing processes with minor adjustments.

### 7.3.7 Other Resins and Formulations

For many of these resins, several different types of molecular structures can be used to modify the ultimate properties of the base material. In addition, other types of resins are also in use or are being developed to meet the growing requirements for the various applications in which printed circuits are used. Often, these resins are proprietary in nature, and therefore discussions of these products focus on their properties rather than the specific chemistry used to achieve the properties. In addition, fillers are increasingly being used to modify thermal expansion or electrical performance, or both. Fillers will be discussed later in this chapter.

## 7.4 ADDITIVES

The resin systems discussed above will typically contain a variety of additives that either promote curing of the resin system or modify the properties in some way. Some important types of additives include the following.

### 7.4.1 Curing Agents and Accelerators

Each resin system contains organic components that must be reacted together to promote polymerization and cross-linking. Curing agents and accelerators are used to promote these reactions. Amine-based curing agents are commonly used to cure epoxy resins. Some of these, such as aliphatic diamines, are used to cure epoxies at room temperature. Others, such as aromatic diamines, require elevated temperatures. Figure 7.9 shows an example of curing epoxy with an aromatic amine. Note the  $-OH$  group formed on the new molecule. As shown in Fig. 7.4, the  $-OH$  can also cross-link with other epoxide groups.

Historically, the most common curing agent used in epoxy resin systems for printed circuit base materials has been dicyandiamide, or “dicy.” Figure 7.10 illustrates the polymerization of

**FIGURE 7.9** Curing epoxy with an aromatic amine.

**FIGURE 7.10** Curing epoxy with dicyandiamide (dicy).

epoxy and dicy. However non-dicy systems have been developed to promote faster curing, reduce moisture sensitivity, and improve thermal stability. The choice of curing agent and accelerator is also driven by the resin type. Non-dicy-cured epoxy materials will be discussed further in Chap. 6, as they are often used in lead-free assembly applications. Figure 7.11 illustrates

#### Dicyandiamide Cure

some of the curing reactions that occur as the resin system polymerizes, and Fig. 7.12 illustrates a phenol curing mechanism.

## 7.4.2 Flame Retardants

While once the subject of little attention, flame retardants used in the resin system have become a more significant consideration. This is due primarily to legislative initiatives and the increasing focus on the toxicity and environmental impact of some of these compounds. While scientific evidence shows that some of these compounds truly pose a risk, the scientific community also generally agrees that other flame retardants are generally safe. Unfortunately, politics often clouds the decision-making process, and sometimes marketing efforts promoting environmental friendly or “green” products are based more on perception than scientific reality. Some have even argued that specific alternative flame retardant chemistries could even be worse, on balance, than those currently used. Nevertheless, the subject of flame retardants has become, and is expected to remain, an area of continued research.

**7.4.2.1 Legislative Issues.** The European Union’s RoHS and WEEE directives (the WEEE directive addresses waste electronic equipment and recycling requirements) affect not only the lead used in printed circuits, but the flame retardants used in the resin system as well. The RoHS directive restricts the use of specific types of brominated flame retardants. The restricted class of compounds consists of polybrominated biphenyls (PBBs) and polybrominated biphenyl oxides (PBBOs), also called polybrominated diphenyl ethers (PBDEs). The generic structure of these compounds is shown in Fig. 7.13. Specific compounds within these classes of flame retardants can vary in their toxicity, and given the dynamic nature of legislative initiatives, it is important to check the current status of these compounds when making decisions on what materials to use.

In the case of standard epoxy materials used in printed circuits, flame retardancy has commonly been achieved by brominating the epoxy resin. This normally involves manufacturing

**Polybrominated Biphenyl Oxide (PBBO or PBDE)**

**Polybrominated Biphenyl (PBB)**

**FIGURE 7.13** Restricted brominated flame retardants.

the epoxy resins with tetrabromobisphenol A (TBBPA), which contains bromine within the chemical backbone (see Fig. 7.2). The RoHS directive does not restrict TBBPA. Because TBBPA is reacted into the epoxy resin itself, it is not available for release into the environment. Under excessive exposure to heat, the bromine is released and retards burning. TBBPA has been used successfully for many years as a flame retardant and is still used in the overwhelming majority of materials. However, while the RoHS directive applies only to specific brominated flame retardants, the WEEE directive may require separation and special handling of materials containing any brominated flame retardant. The separation and special handling relate to concerns about the by-products of incineration, especially if incineration is done at too low a temperature. Furthermore, individual countries continue to look at introducing their own legislative initiatives in regard to these flame retardants, and thus is always important to check the status of these efforts.

**7.4.2.2 Flame-Retardant Chemistry.** Polymer combustion occurs in a continuous cycle, as highlighted in Fig. 7.14. Heat generated in the flame is transferred back to the polymer surface, producing volatile polymer fragments that constitute fuel for further burning. These fragments diffuse into the flame zone, where they react with oxygen by free-radical chain reactions. This in turn produces more heat and continues the cycle. Flame retardancy is achieved by interrupting this cycle.

There are two basic ways to interrupt this cycle. One method is called solid phase inhibition and involves changes in the polymer substrate. Systems that promote extensive polymer cross-linking at the surface form a carbonaceous char upon heating. The char then insulates the underlying polymer from the heat of the flame, preventing production of new fuel and further burning. Other systems evolve water during heating, cooling the surface and increasing the amount of energy needed to maintain the flame.

The second method is called vapor phase inhibition and involves changes in the flame chemistry. Reactive species are built into the polymer that are transformed into volatile free-radical inhibitors during burning. These materials diffuse into the flame and inhibit the branching radical reactions. As a result, increased energy is required to maintain the flame and the cycle is interrupted. For many materials, both solid and vapor phase inhibition occur.

Polymers, including the various types of epoxy resins, differ in their inherent flammability. The types of resins and curing agents selected can impact the fundamental flammability of the resin system and determine how much additional flame-retardant components are needed to achieve the desired flammability rating. For example, polymers with a high concentration of

**FIGURE 7.14** Polymer combustion.

aromatic groups will generally have higher thermal stability as well as the ability to form char on burning. Additives such as TBBPA or epoxy resins built from TBBPA contain bromine on the molecular backbone. Most organic halogen compounds such as these retard burning by vapor phase inhibition. They typically decompose to yield HBr or HCl (HBr in the case of TBBPA-based materials), which quench chain-branching free radical reactions in the flame. Some halogen acids also catalyze char formation.

**7.4.2.3 Halogen-Free Systems.** Halogen-free flame retardants and resin systems are also available. Alternatives include phosphorus-based compounds, nitrogen-based flame retardants, inorganic flame retardants, and hydrated fillers. These can be subdivided into reactive components and additives. A reactive component is one that becomes directly incorporated into the resin system itself, such as TBBPA. As with TBBPA, reacted components have the advantage of not being available for release to the environment through leaching or solvent extraction. An example of a reactive, non-halogen flame retardant would be epoxidized phosphorus compounds. The epoxide groups of these compounds make them reactive and result in chemical bonding into the polymer backbone. In contrast, red phosphorus is an inorganic solid that can be dispersed into an epoxy formulation. Hydrates, such as aluminum hydroxide or magnesium hydroxide, decompose and liberate water, which then suppresses the burning process.

In choosing a flame retardant, consideration must be given to the impact on the performance of the resin system and the finished base material. These materials, at the levels required for flame retardancy, can affect the physical properties of the laminate, change rheological properties, and alter cure kinetics of the resin system. Generally, the reactive compounds are preferred since they are bound to the polymer backbone, which prevents release into the environment, and, in comparison to additives or fillers, they seem better suited to obtaining the desired material properties. Table 7.2 summarizes some of the available halogen-free flame retardants.

Organic phosphorus-based flame retardants have become the most common alternative flame retardants used in printed circuit base materials. However, others are also being used and combinations of two or more types of halogen-free flame retardants can also be used synergistically to achieve adequate flammability levels while minimizing adverse impacts on material properties. Some of the adverse impacts that must be evaluated are moisture absorption, copper peel strength degradation,  $T_g$  reduction, changes in resin flow, degradation in mechanical or electrical performance, and the impact on Conductive Anodic Filament (CAF) resistance.

**TABLE 7.2** Halogen-Free Flame Retardants

Type	Primary Mechanism	Examples	Considerations
Phosphorus	Forms char	Red phosphorus, ammonium polyphosphate, organic phosphorus compounds	Red phosphorus is difficult to process and toxic. Organic phosphorus compounds are a common alternative, but generally more costly and can lower $T_g$ .
Inorganic/Hydrated Fillers	Evolve water, endothermic, may promote char	Alumina trihydrate, magnesium hydroxide, zinc borate, antimony oxides	Inexpensive, but generally require high loadings and can degrade mechanical and other properties. Toxicity of antimony-based retardants is a concern. Can be used with other flame retardants synergistically.
Nitrogen	Intumescent system, generates gas that foams char	Melamine, melamine cyanurate	Impact on material properties and other environmental effects are concerns.

### 7.4.3 UV Blockers/Fluorescing Aids

Some resins naturally absorb ultraviolet light. Others absorb very little. There are two reasons why this property is important. First, automatic optical inspection (AOI) equipment is often laser-based and relies on the resin system in the base material to fluoresce upon exposure. In this way, the AOI equipment can distinguish between the base laminate and the conductor pattern. The second reason involves photoimaging on very thin circuits, during the solder mask imaging process, for example. This process commonly involves exposure to ultraviolet (UV) light through an image of the desired pattern onto both sides of the circuit, which is coated with a mask or photoresist. The UV light initiates chemical changes to the photoresist, typically polymerization, which makes it less soluble in a developer solution. In very thin circuits, if the base material does not absorb UV light sufficiently, the UV light from one side of the circuit board can pass through to the other side and cause unwanted exposure of the photoresist on the opposite side. Therefore, components that absorb UV light are sometimes added to resin systems that do not sufficiently absorb UV light.

## 7.5 REINFORCEMENTS

While there are also a variety of reinforcements used in base materials, woven fiberglass cloths are by far the most common. Other materials include paper, glass matte, non-woven aramid fibers, non-woven fiberglass, and a variety of fillers. The advantages of woven glass cloths include a good combination of mechanical and electrical properties, a wide range of types for achieving various laminate thicknesses, and good economics.

### 7.5.1 Woven Fiberglass

The process of manufacturing woven fiberglass cloth begins with melting the various inorganic components required for a particular grade of glass. The molten components travel through a furnace and ultimately flow through specialized bushings to form the individual fiberglass filaments and yarns. These yarns are then used in a weaving process to manufacture the fiberglass cloth. The relative concentrations of the components used affect the chemical, mechanical, and electrical properties of the fiberglass. The compositions of a few fiberglass types are provided in Table 7.3. Figure 7.15 illustrates the process used to manufacture the fiberglass yarns. The yarns are then woven into fiberglass cloths.

**TABLE 7.3** Fiberglass Compositions in Percentages

Component	E-Glass	NE-Glass	S-Glass	D-Glass	Quartz
Silicon Dioxide	52–56	52–56	64–66	72–75	99.97

Titanium Oxide	0–0.8	0.5–5			
Fluorides	0–1.0				

**FIGURE 7.15** Illustration of fiberglass yarn manufacture.

E-glass is by far the most commonly used fiberglass for printed circuits. It provides an excellent combination of electrical, mechanical, and chemical properties at a reasonable cost. NE-glass is used in limited quantities and offers improved permittivity (Dk) and loss (Df) properties (see Table 7.4). However, NE-glass is more expensive than E-glass. S-glass provides greater strength but is more difficult to process through the mechanical drilling operation. Other glass types are seldom used.

**TABLE 7.4** Comparison of E-Glass and NE-Glass

Property	E-Glass	NE-Glass

FIGURE 7.16 Plain weave.

types in the weaving process leads to many different types of cloth styles. While there are also many different weave types, virtually all cloths for printed circuits use a plain weave (see Fig. 7.16). The plain weave consists of yarns interlaced in an alternating fashion, one over and one under every other yarn. This weave pattern provides good fabric stability. Some of the common plain weave cloth styles used for printed circuits are shown in Table 7.6. The fiberglass cloths are also coated with a finish or coupling agent tailored for improving the bond between the glass filaments and the specific resin coated onto the glass. This coupling agent and the resin-to-glass bond that results are important considerations for CAF resistance, which will be discussed in Chap. 9.

## 7.5.2 Yarn Nomenclature

Because there can be so many types of yarn manufactured from the available grades of glass and filament diameters, special nomenclature systems have been developed. The two systems used are the U.S. System and the TEX/Metric System.

**7.5.2.1 The U.S. System.** An example of a yarn name in the U.S. system is ECD 450-1/0. This yarn is used in making a 1080 style glass cloth. Each letter and number in the name describes something about the yarn:

- **First letter** This describes the glass composition. Electrical grade, or E-glass, is the most common grade used for manufacturing materials for printed circuits.
- **Second letter** C indicates that the yarn is composed of continuous filaments. S would indicate staple filaments, and T indicates texturized continuous filaments.
- **Third letter** This letter indicates the individual filament diameter (see Table 7.5).

TABLE 7.6 Common Fiberglass Cloth Styles for Printed Circuit Base Materials

Style	Approx. Fiberglass Thickness (In.)	Warp Yarn	Fill Yarn	Count (Ends/In.)	Weight (Oz./Yd. <sup>2</sup> )
104	0.0013	ECD 900-1/0	ECD 1800-1/0	60 × 52	0.55
106	0.0014	ECD 900-1/0	ECD 900-1/0	56 × 56	0.73
1067	0.0014	ECD 900-1/0	ECD 900-1/0	69 × 69	0.71
1080	0.0023	ECD 450-1/0	ECD 450-1/0	60 × 47	1.42
1280	0.0026	ECD 450-1/0	ECD 450-1/0	60 × 60	1.55
1500	0.0052	ECE 110-1/0	ECE 110-1/0	49 × 42	4.95
1652	0.0045	ECG 150-1/0	ECG 150-1/0	52 × 52	4.06
2113	0.0028	ECE 225-1/0	ECD 450-1/0	60 × 56	2.31
2116	0.0038	ECE 225-1/0	ECE 225-1/0	60 × 58	3.22
2157	0.0051	ECE 225-1/0	ECG 75-1/0	60 × 35	4.36
2165	0.0040	ECE 225-1/0	ECG 150-1/0	60 × 52	3.55
2313	0.0029	ECE 225-1/0	ECD 450-1/0	60 × 64	2.38
3070	0.0031	ECDE 300-1/0	ECDE 300-1/0	70 × 70	2.74
3313	0.0033	ECDE 300-1/0	ECDE 300-1/0	60 × 62	2.40
7628	0.0068	ECG 75-1/0	ECG 75-1/0	44 × 32	6.00
7629	0.0070	ECG 75-1/0	ECG 75-1/0	44 × 34	6.25
7635	0.0080	ECG 75-1/0	ECG 50-1/0	44 × 29	6.90

- **First number** This represents 1/100th the normal bare glass yardage in one pound of the basic yarn strand. In the preceding example, multiply 450 by 100, which results in 45,000 yards in one pound.
- **Second number** Here 1/0 represents the number of basic strands in the yarn. The first digit represents the original number of twisted strands. The second digit separated by the diagonal represents the number of strands plied or twisted together. Thus 1/0 means that the yarn is a singles yarn (no or “zero” plying required).

The name may also include a designation indicating the number of turns per inch in the twist of the final yarn, and the direction of the twist. An example would be 3.0S, or three turns per inch with an “S” direction twist. An “S” twist has spirals that run up and to the left. A “Z” twist has spirals that run up and to the right.

**7.5.2.2 The TEX/Metric System** An example of a yarn name in the TEX/Metric System is EC9 33 1X2.

- **First letter** This designates the glass composition.
- **Second letter** C indicates that the yarn is composed of continuous filaments. T would indicate textured continuous filaments. D indicates staple filament.
- **First number** Here 9 indicates the individual filament diameter expressed in microns.
- **Second number** In this example, 33 represents the nonlinear weight of the bare glass strand expressed in TEX. TEX is the mass in grams per 1,000 meters of yarn.
- **Third number** 1X2 indicates yarn construction or the basic number of strands in the yarn. The first digit represents the original number of twisted strands and the second digit, after the X, indicates the number of these strands twisted or plied together.

### 7.5.3 Fiberglass Cloths

With the possible combinations of glass compositions, filament diameters, yarn types, and the number of different weave patterns available, the number of possible fiberglass cloths can almost be unlimited. The effects that these glass fabrics have on the base material are driven by these variables. In addition, the fabric count, or the number of warp yarns and fill yarns, also helps determine the properties of the fabric and the base material. Warp yarns are those that lie in the length (machine direction) of the fabric, whereas the fill yarns lie across the warp direction. The warp direction is also commonly called the grain direction.

As pointed out earlier, glass cloths used in printed circuits are typically, though not always, made from E-glass, and virtually all use what is called a plain weave. A plain weave results in a fabric constructed so that one warp yarn passes over and under one filling yarn (and vice versa). This weave pattern offers good resistance to yarn slippage and fabric distortion. Common fiberglass cloths used in materials for printed circuits are shown in Table 7.6. Three of the most common are shown in Fig. 7.17. At a given resin content, each style will yield a different nominal thickness. Having the flexibility of many glass styles and thicknesses is important for meeting controlled impedance and overall thickness requirements.

During the manufacture of the filaments and woven fabrics, a variety of surface finishes may be applied to the glass to improve manufacturability, help prevent abrasion and static, and aid in holding the filaments together. The most important of these surface finishes to the laminate and printed circuit manufacturer is the coupling agent applied to the finished fabric. The coupling agent, typically an organosilane compound, aids in the wetting of and adhesion to the resin applied to the glass. It is important for the reliability of the finished

(a) 1080 Cloth

(b) 2116 Cloth

(c) 7628 Cloth

**FIGURE 7.17** The three most common fiberglass cloths used in materials for printed circuits.

circuit board that this coupling agent improves the resin to glass adhesion both during the circuit manufacturing process (for example, in mechanical drilling) as well as within the actual end-use environment of the circuit. The coupling agent also plays a role in long-term CAF resistance, which is discussed in Chap. 9. A variety of these compounds are commercially available, with the specific choice primarily driven by the type of resin to be applied to the fiberglass cloth. Figure 7.18 provides examples of silane coupling agents.

**FIGURE 7.18** Examples of silane coupling agents.

## 7.5.4 Other Reinforcements

While woven fiberglass cloth makes up the overwhelming majority of the reinforcements used for printed circuit base materials, other types can be used exclusively or in combination with woven glass fabric. These other reinforcements include the following.

**7.5.4.1 Glass Matte.** Compared to woven cloths, glass matte reinforcement exhibits a more random orientation. Chopped strand matte consists of fiberglass strands that have been chopped into 1- to 2-inch lengths and distributed evenly. Continuous strand matte, as the name implies, consists of continuous strands of fiberglass in a random, spiral orientation. Glass matte is used in the core of CEM-3, which is used in relatively unsophisticated products.

**7.5.4.2 Aramid Fiber.** As opposed to the inorganic chemistry of fiberglass reinforcements, aramid fibers consist of aromatic polyamide organic compounds, and therefore exhibit different properties. The unique properties of aramid fibers can offer advantages in specific high-performance printed circuits and laminate-based multichip modules (MCM-L). For example, aramid fiber-reinforced materials are sometimes used in microvia applications since they are easily ablated by plasma or laser. Other interesting properties of aramid fibers are their low weight, high strength, and negative coefficient of thermal expansion (CTE) in the axial direction. When combined with the resin system, the resulting composite can offer reduced overall CTEs in the X-Y plane compared to conventional materials.

**7.5.4.3 Linear Continuous Filament Fiberglass.** A unique process for producing fiberglass-reinforced laminates winds continuous yarns in a linear orientation. The resulting laminate possesses three layers of fiberglass filaments, with the outside layers parallel to each other and the middle layer perpendicular to the outside. With an equal number of linear filaments running in each axis, this type of reinforcement results in a laminate with improved dimensional stability.

**7.5.4.4 Paper.** Cellulose-based papers can also be used as a reinforcement for base materials. Paper-based reinforcements are also used with other reinforcements such as woven glass, and these materials can also allow punching of through holes rather than drilling. This makes them economical in some high-volume, low-technology applications including consumer electronics such as radios, toys, calculators, and video game systems. Paper is used in FR-2, FR-3, and the core of CEM-1.

**7.5.4.5 Fillers.** Fillers are small particles that can be added to a resin system to modify the properties of the composite material. These materials range from talc, silica, kaolin clay powders, and tiny hollow glass spheres to a variety of other inorganic materials. These materials are typically used to tailor the properties of the base material for specific uses. For example, kaolin clay powders coated with a layer of palladium and dispersed within the base materials have been used as catalysts for electroless copper plating. Hollow glass microspheres have been used to reduce the dielectric constant of materials. Other fillers are being used to reduce thermal expansion properties and improve reliability, enhance the machinability of materials in the drilling process, alter electrical properties such as Dk and Df, and lower total costs. The use of fillers to reduce z-axis expansion has become quite common, especially as lead-free assembly is adopted. The reduced z-axis expansion helps offset the increased expansion and stress on plated through holes that results from the higher temperatures associated with lead-free assembly. This is discussed further in Chap. 9.

**7.5.4.6 Expanded Teflon.** Although not typically thought of as a reinforcement, Teflon® that has been “expanded” into a spongelike structure on a microscopic scale is currently being used in applications that require prepregs with very low dielectric constants or loss properties.

**FIGURE 7.19** Expanded Teflon (left) and a PCB cross section showing prepreg using expanded Teflon (right). (Courtesy of W.L. Gore and Associates.)

A resin system is applied to the expanded Teflon structure and is made into a b-staged sheet capable of bonding printed circuit layers together. This material can be used to make prepreps for high-frequency applications and is shown in Fig. 7.19.

## 7.6 CONDUCTIVE MATERIALS

The primary conductive material used in printed circuits is copper foil. However, the trend toward circuit densification has brought about recent developments in copper foil technology as well. In addition, copper foils subsequently plated with other metal alloys are employed to manufacture printed circuits with resistive components buried within a multilayer structure. Copper foil grades are shown in Table 7.7.

**TABLE 7.7** Foil Grades from IPC-4562

Grade	Foil Description
1	Standard electrodeposited (STD-Type E)
2	High-ductility electrodeposited (HD-Type E)
3	High-temperature elongation electrodeposited (HTE-Type E)
4	Annealed electrodeposited (ANN-Type E)
5	As rolled-wrought (AR-Type W)
6	Light cold rolled-wrought (LCR-Type W)
7	Annealed-wrought (ANN-Type W)
8	As rolled-wrought low-temperature annealable (LTA-Type W)
9	Nickel, standard electrodeposited
10	Electrodeposited low temperature annealable (LTA-Type E)
11	Electrodeposited annealable (A-Type E)

### 7.6.1 Electrodeposited Copper Foil

The most common foil used in manufacturing printed circuits is electrodeposited copper foil (ED foil). ED foil is produced through an electrochemical process in which copper feed stock or scrap copper wire is first dissolved in a sulfuric acid solution. The purified copper sulfate/sulfuric acid solution is then used to electroplate copper onto a cylindrical drum typically made from stainless steel or titanium. Figure 7.20 illustrates the overall process used to make electrodeposited copper foil. This process results in a copper foil with a relatively smooth, shiny side, and a coarser matte side, as illustrated in Fig. 7.21. The shiny side mirrors the surface

**FIGURE 7.20** Process for manufacturing electrodeposited copper foil.

of the plating drum, while the microscopically rough matte side is formed by the copper grain structure. By controlling the plating solution chemistry, the surface condition of the plating drum, and the electroplating parameters, one can modify the properties of the copper foil for various usage environments. For example, mechanical properties such as tensile strength and elongation, as well as the surface profile of the matte side, can all be adjusted through control

**FIGURE 7.21** Electroplating copper foil.

**FIGURE 7.22** Treating of copper foil.

of these process variables. The foil produced in this process is then run through a treatment process. This treatment process typically plates copper nodules that further roughen the surface for adhesion, and also applies other metal barrier layers and antitarnish coatings, as shown in Fig. 7.22. Standard copper foil area weights and thicknesses were shown in Table 6.4.

The foils most commonly used in printed circuit manufacturing are Grade 1 and Grade 3 foils. Unlike Grade 1 foil, Grade 3 foil must meet specific elongation requirements at elevated temperatures (180°C). Grade 3 foil—also commonly referred to as high-temperature elongation, or simply “HTE” foil—is widely used in base laminates employed to manufacture multilayer printed circuit boards. The increased ductility at elevated temperatures provides resistance to copper foil cracks when the multilayer circuit is thermally stressed and expands in the z-axis. Changes to the plating bath are made to alter the grain structure of HTE foil. This results in different mechanical properties. Tables 7.8 and 7.9 show the tensile strength and ductility requirements for standard Grade 1 copper foil and high-temperature elongation Grade 3 copper foil. These requirements come from IPC-4562, “Metal Foil for Printed Wiring Applications,” which lists requirements for the other grades as well.

The surface profile of the copper foil is also important in printed circuit manufacturing. On one hand, a relatively rough surface profile aids in the bond strength of the foil to the resin system. On the other hand, a rough profile may require longer etching times, which impact productivity and the geometry of the etched features. With longer etching times, propensity to

**TABLE 7.10** Foil Profile Criteria

Foil Profile Type	Max. Foil Profile (Microns)	Max. Foil Profile ( $\mu$ Inches)
S – Standard	N/A	N/A
L – Low profile	10.2	400
V – Very low profile	5.1	200
X – No treatment or roughness	N/A	N/A

form trapezoidal circuit traces increases since there is more time for lateral etching of the conductor. This has obvious implications for manufacturing fine-line circuits in high-yield and controlling impedance properties. Low-profile and very-low-profile characteristics are included in the IPC-4562 specification and are summarized in Table 7.10. Figures 7.23 and 7.24 give an example of profile differences between a standard and low-profile copper foil. In addition, as circuit operating frequencies increase, roughness of the copper foil can also impact signal attenuation. At higher frequencies, more of the electrical signal is conducted near the surface of the conductor. A rougher profile results in a longer path for the signal to travel, which also results in greater attenuation, or loss. As a result, high-performance materials require foils with low profiles that have adequate adhesion to the high-performance resin systems.

Subsequent to the manufacturing of the base copper foil, a variety of surface treatments are typically applied, and these too will vary depending on the usage environments. These treatments fall into four categories.

**FIGURE 7.23** Cross section and the matte side of standard Grade 1 foil. (Courtesy of Gould Electronics)

**FIGURE 7.24** Cross section and the matte side of low-profile Grade 1 foil. (Courtesy of Gould Electronics)

**7.6.1.1 Bonding Treatments or Nodularization.** This treatment increases the surface area of the foil by plating copper or copper-oxide nodules to the surface of the foil. The increased surface area results in increased foil to resin bond strengths. The thickness of this treatment is relatively small, but can be tailored for adhesion to high-performance resin systems such as polyimides, cyanate esters, and BT. The matte side images in Figs. 7.23 and 7.24 include these nodules.

**7.6.1.2 Thermal Barriers.** A coating of zinc, nickel, or brass is usually applied over the nodules. This coating can prevent thermal or chemical degradation of the foil to resin bond during manufacture of the laminate, the printed circuit, and the circuit assembly. These coatings typically measure several hundred angstroms in thickness and vary in color due to the specific metal-alloy used, although most treatments are brown, gray, or a yellow mustard color.

**7.6.1.3 Passivation and Antioxidant Coatings.** In contrast to the other coatings, these treatments are virtually always applied to both sides of the foil. Although many of these treatments are chromium-based, organic coatings can also be utilized. The primary purpose of these treatments is to prevent oxidation of the copper foil during storage and lamination. These coatings are usually less than 100 angstroms thick and are typically removed by the cleaning, etching, or scrubbing processes normally used at the start of printed circuit manufacturing processes.

**7.6.1.4 Coupling Agents.** The use of coupling agents, primarily silanes such as those used to promote fiberglass to resin adhesion, can also be used on copper foils. These coupling agents can improve the chemical bond between the foil and the resin system and can also be used to help prevent oxidation or contamination.

## 7.6.2 Drum Side Treated Foils (DSTF) or Reverse Treated Foils (RTF)

Drum side treated (DSTFoil®) or reverse treated foil (RTF) is also an electrodeposited copper foil, but the treatments are coated onto the smooth drum side of the foil rather than the matte side, as with conventional electrodeposited foil (see Figs. 7.25 and 7.26). This results in a very-low-profile surface bonded to the laminate, with the rough matte side facing out. The low

**FIGURE 7.25** External sides for RTF (upper photo) and standard (lower photo) foils. (Photos Courtesy of Gould Electronics)

surface profile against the laminate aids in the production of fine circuit features on the inner layer, while the matte surface can aid in photoresist adhesion. The low profile against the laminate can also improve electrical performance at high frequencies. In addition, in very thin laminates, the low-surface profile can aid in achieving consistent dielectric thickness with a reduced concern of inadequate dielectric separation between the corresponding points on the tooth profile. These benefits come at the expense of a slight reduction in peel strength.

**FIGURE 7.26** Sides bonded to laminate for RTF (upper photo) and standard foils (lower photo). (Photos Courtesy of Gould Electronics)

### 7.6.3 Wrought Annealed Copper Foils

Wrought annealed foil is typically used in flexible circuit manufacturing because of its superior ductility. In contrast to an electrodeposition process, the process of creating wrought annealed foil begins with working a slab or ingot of copper through a series of rollers in conjunction with heat cycles to obtain the desired thickness and mechanical properties. The resulting grain structure of wrought annealed copper foil, which is very random compared to the columnar or fine-grain structure of electrodeposited foil, is a significant contributor to the differences in mechanical properties. In addition, wrought annealed foil consists of two very-low-profile sides, so the treatment steps account for any surface roughness. The tensile and elongation requirements for Grade 7 wrought annealed copper are provided in Table 7.11. The requirements for other wrought foils are included in IPC-4562.

**TABLE 7.11** Tensile and Elongation Properties of Wrought Annealed Foil

Property	1/2 Ounce	1 Ounce	2 Ounce
Tensile strength @ 23°C:			
kpsi	15	20	25
MPa	103	138	172
Fatigue ductility % @ 23°C	65	65	65
Elongation % @ 23°C	5	10	20
Tensile strength @ 180°C:			
kpsi	TBD	14	22
MPa		97	152
Elongation % @ 180°C	TBD	6	11

### 7.6.4 Copper Foil Purity and Resistivity

IPC-4562, "Metal Foil for Printed Wiring Applications," also specifies the purity and resistivity of electrodeposited and wrought copper foils. Electrodeposited copper foils without treatment have a minimum purity of 99.8%, with any silver counted as copper. The value for wrought foils is 99.9%. Table 7.12 provides the resistivity requirements for electrodeposited foil. The maximum resistivity requirements for wrought copper range from 0.155 to 0.160 ohm-gram/m<sup>2</sup>, depending on the weight.

**TABLE 7.12** Maximum Resistivity of Deposited Foil

Weight Designator	Common Industry Terminology	Maximum Resistivity
E	5 μm	0.181 ohm-gram/m <sup>2</sup>
Q	9 μm	0.171 ohm-gram/m <sup>2</sup>
T	12 μm	0.170 ohm-gram/m <sup>2</sup>
H	1/2 ounce	0.166 ohm-gram/m <sup>2</sup>
M	3/4 ounce	0.164 ohm-gram/m <sup>2</sup>
1 oz. and over (305 g/m <sup>2</sup> )	1 ounce	0.162 ohm-gram/m <sup>2</sup>

### 7.6.5 Other Foil Types

The electrodeposited copper foils described above account for most of the conductive foils used in rigid printed circuits. However, modified versions of these foils are sometimes used in niche applications. These modified versions include double-treated copper foil and resistive foils.

**7.6.5.1 Double-Treated Copper Foil.** As discussed in the preceding section, the foil surface that is bonded to the base laminate is treated with coatings designed to improve foil-to-resin bond strength and reliability. In double-treated foils, these coatings are also applied to the foil surface that forms the outside laminate surface. It is also possible to have a “reverse-treated” double-treat foil, meaning that the smooth surface is bonded to the laminate with the matte surface facing out, with both sides having been treated.

The advantage of double-treat foil is that it eliminates the oxide or other surface preparation process typically used to prepare the inner-layer circuitry for multilayer lamination. However, no abrasion of this double-treat coating can be tolerated, and removal of any surface contamination becomes difficult. This also makes double-treated foil more sensitive to handling practices in the circuit manufacturing process.

**7.6.5.2 Resistive Foils.** Other treatments can also be applied to the base foil for use in manufacturing inner-layer circuits with *buried resistors*. This technology can enable the creation of resistors on internal layers of a multilayer circuit, with removal of many of the resistors commonly assembled on the outside of the multilayer circuit. This can improve board reliability and free up space on the outside of the board for active components. These foils typically use a resistive metal alloy coated onto the base foil. The laminate made with this foil can then be sequentially imaged and etched to produce the desired circuit pattern along with resistive components.

# PROPERTIES OF BASE MATERIALS

---

**Edward J. Kelley**

*Isola Group, Chandler, Arizona*

---

## 8.1 INTRODUCTION

---

A variety of base material properties are of interest to the printed circuit manufacturer, assembler, and original equipment manufacturer (OEM). These include thermal, physical, mechanical, and electrical properties. This chapter introduces some of the most important properties and also provides some comparisons between material types. Most of the test methods used to evaluate these properties can be found in the IPC Test Methods Manual, IPC-TM-650.

---

## 8.2 THERMAL, PHYSICAL, AND MECHANICAL PROPERTIES

---

Historically, the properties that received the greatest amount of attention were the glass transition temperature,  $T_g$ , and the coefficients of thermal expansion, or CTEs, particularly in the z-axis. With the advent of lead-free assembly processes, other properties have increased in importance as well. The most notable is the decomposition temperature,  $T_d$ . These properties were described in more detail in Chap. 6, and will be discussed again in Chap. 10, which focuses on the impact of lead-free assembly on base materials. However, some additional information as well as examples of the test data are included here, as well as comparisons of some common material types.

### 8.2.1 Thermomechanical Analysis $T_g$ and CTEs

Materials undergo changes in physical dimensions in response to changes in temperature. The rates of expansion of fiberglass cloth reinforced materials differ in the respective axes of the material due to the directionality of the reinforcement. The length and width of the laminate, or printed circuit, are termed the X/Y plane, whereas the axis perpendicular to this plane is the z-axis.

Thermal expansion can be measured by thermomechanical analysis (TMA). TMA uses a device that measures a dimension of a sample versus temperature. Depending upon the orientation of the sample in the device, either the x/y CTE or the z-axis CTE can be measured.

Figure 8.1 provides an example of a TMA scan on a high- $T_g$ , filled FR-4 material designed to be compatible with most lead-free assembly applications. The  $T_g$  is determined by extrapolating the linear portions of the expansion curve to the point where they intersect. In this case, a  $T_g$  of

**FIGURE 8.1** TMA scan illustrating T<sub>g</sub> and CTE determination.

154.45°C is measured. The z-axis CTE values are typically calculated both pre-T<sub>g</sub>, also called “alpha 1” ( $\alpha_1$ ), and post-T<sub>g</sub>, also called “alpha 2” ( $\alpha_2$ ). In this example, the pre-T<sub>g</sub> CTE is measured at just over 45 ppm/°C, and the post-T<sub>g</sub> CTE is measured at just over 219 ppm/°C. The total expansion from 50°C to 250°C is also shown as a percent expansion value at 2.58 percent.

Thermal expansion in the z-axis can significantly affect the reliability of printed circuits. Since plated through holes run through the z-axis of the printed circuit, thermal expansion and contraction in the base materials causes strain and plastic deformation in the plated through holes and can also deform the copper pads on the surface of the printed circuit. With sufficient stress on the external pads, they can be pulled toward the plated through hole during thermal stress and subsequently appear lifted from the surface upon cooling. These “lifted” or “rotated” pads are an indication of excessive thermal expansion. Thermal cycling over time can fatigue the plated through hole and ultimately cause failure from cracking of the copper plating within the hole or separation of the conductor from the hole wall.

Thermal expansion in the x/y axes is of more importance when discussing the attachment of components to the printed circuit. This is of particular importance when chip scale packages (CSPs) and direct chip attach components are used because the difference in thermal expansion between the printed circuit board and the component can compromise the reliability of the bond between them as they undergo thermal cycles. The x/y CTE can also impact interlaminar adhesion and delamination resistance in copper clad laminates or PCBs. If individual layers of materials with very different x/y CTE properties are adjacent to each other, thermal cycling or thermal excursions can cause enough stress at the interface of these layers to cause a separation or delamination. The thermal excursions experienced in PCB assembly processes can severely stress these interfaces, and the higher temperatures of lead-free assembly result in additional stress. For this reason, more attention should be given to the x/y CTE values of individual layers in a PCB that will experience lead-free assembly. With a given material type, this typically means that the choice of fiberglass cloth styles and resin contents adjacent to each other be examined. Furthermore, hybrid constructions,

**TABLE 8.1**  $T_d$  and CTE Values at 40% Resin Content of Some Common Base Materials

Material	$T_g$ ( $^{\circ}\text{C}$ )	Decomposition Temp. $T_d$ (5% Wt. Loss), $^{\circ}\text{C}$	Z-Axis Expansion (% from 50 $^{\circ}\text{C}$ to 260 $^{\circ}\text{C}$ )	X/Y CTE (ppm/ $^{\circ}\text{C}$ from– 40 $^{\circ}\text{C}$ to 125 $^{\circ}\text{C}$ )

Advanced Low $D_k/D_f$	215	363	2.8	13–14
Cyanate Ester	245	375	2.5	11–13
Polyimide	260	415	1.75	12–16
Halogen-Free, Filled High- $T_g$ FR-4	175	380	2.8	13–16

meaning PCBs that utilize different base material types, should be analyzed very carefully, as different base material types can have different CTE values even with a given fiberglass cloth style and resin content.

**8.2.1.1 CTE Values.** CTE values of some common materials at approximately 40 percent resin content are shown in Table 8.1.

**8.2.1.2 Controlling Thermal Expansion.** The rate of thermal expansion is a function of the components used in the base material and their relative concentrations. The resin system will have a relatively high coefficient of thermal expansion compared to fiberglass cloth or other types of inorganic reinforcements.

In controlling z-axis expansion, the key factors to consider are the choice of resin system, the resin system  $T_g$ , and the resin content of the base materials. Fillers in the resin system, in addition to the fiberglass cloth, can also be used to lower the CTE of the material. Table 8.1 compares the thermal expansion of several commercially available base materials. These values can vary significantly based on the exact resin content of the material or PCB tested. In multilayer PCBs, the amount of copper in the sample will also have a significant impact as the z-axis expansion of copper is very low compared to the resin system.

Note the general difference in CTE values as  $T_g$  increases. A higher  $T_g$  delays the onset of the more rapid post- $T_g$  rate of expansion. Also note that the filled materials have lower levels of z-axis expansion in comparison to equivalent unfilled materials.

## 8.2.2 $T_g$ Determination by Other Methods

Besides TMA, two other methods are commonly used to measure  $T_g$ . These are differential scanning calorimetry (DSC) and dynamic mechanical analysis (DMA). DSC measures heat flow versus temperature rather than dimensional changes as measured by TMA. The heat absorbed or given off will change as the temperature increases through the  $T_g$  of the resin system.  $T_g$  measured by DSC is typically higher than measurements by TMA. DMA measures the modulus of the material versus temperature and also typically results in higher measured values of  $T_g$ .

As more complex resin systems are developed, and as more blends of resins are used, it becomes more difficult to measure  $T_g$  by TMA. For example, if two resins are used that have

FIGURE 8.2 Measurements of  $T_g$  by DSC.

somewhat different TMA  $T_g$ s, the combination of the two resins makes it difficult to get a clear transition in expansion rates. For these materials, DSC and especially DMA are the preferred techniques for measuring  $T_g$ . Figures 8.2 and 8.3 provide examples of DSC and DMA scans, respectively, and the resulting measurement of  $T_g$ .

FIGURE 8.3 Measurement of  $T_g$  by DMA.

### 8.2.3 Decomposition Temperature

As a material is heated to higher temperatures, a point is reached where the resin system will begin to decompose. The chemical bonds within the resin system begin to break down and volatile components are driven off, reducing the mass of the sample. The decomposition temperature,  $T_d$ , is a property that describes the point at which this process occurs. The traditional definition of  $T_d$  is the point where 5 percent of the original mass is lost to decomposition. Table 8.1 shows 5 percent decomposition temperatures for several common materials. However, 5 percent is a very large number when multilayer PCB reliability is considered, and temperatures where lower levels of decomposition occur are very important to understand, particularly with respect to lead-free assembly. To illustrate this, consider Fig. 8.4.

**FIGURE 8.4** Illustration of decomposition temperature measurement.

In Fig. 8.4, you can see curves for two FR-4 materials. The “traditional FR-4”—a 140°C  $T_g$  material, in this case—has a decomposition temperature of 320°C by the 5 percent weight loss definition. The “enhanced FR-4” has a decomposition temperature of 350°C by the 5 percent weight loss definition. Many standard high- $T_g$  FR-4 materials actually have decomposition temperatures in the range of 290–310°C, whereas the 140°C  $T_g$  FR-4 materials generally have slightly higher  $T_d$  values. The shaded regions indicate the peak temperature ranges for standard tin-lead assembly and lead-free assembly. A very common question is, if a PCB will be assembled at 260°C, and the material has a decomposition temperature of 310–320°C, then why wouldn’t it be compatible with lead-free assembly?

The answer lies in the level of decomposition in the temperature ranges where assembly will take place. In the tin-lead temperature range, neither material exhibits a significant level of decomposition. However, in the lead-free assembly temperature range, the traditional FR-4 begins to exhibit 1.5-3 percent weight loss. This level of decomposition can compromise long-term reliability or result in defects such as delamination during assembly, particularly if multiple assembly cycles or rework cycles are performed. Figures 8.5 through 8.7 show ThermoGravimetric Analysis (TGA) curves assessing decomposition temperatures for three types of base material.

These curves show different measurements for decomposition temperature. The value traditionally reported is the level at which 5 percent weight loss occurs, or where the mass is 95 percent of the starting sample mass. But as already discussed, this is a very high level of

**FIGURE 8.5** Decomposition curve for standard high-T<sub>g</sub> FR-4.

decomposition when considering PCB reliability. These curves also show 1 percent and 2 percent decomposition temperatures, as well as the “onset” decomposition temperature. The onset temperature extrapolates the linear portions of the curve. The point at which they intersect is reported as the onset temperature.

Note that in Figs. 8.5 and 8.6 decomposition occurs very rapidly, while in Fig. 8.7 decomposition is more gradual, highlighted by the much bigger range between 1 percent, 2 percent, and 5 percent decomposition temperatures. With the material in Fig. 8.7, the 5 percent decomposition temperature would be reported as 405°C, even though some decomposition is beginning around 336°C. This highlights the need to understand not just the 5 percent decomposition temperature, but lower levels as well.

### 8.2.4 Time to Delamination

Time to delamination refers to a specific test procedure used to measure how long a material will resist blistering or delamination at a specific temperature. The procedure utilizes a thermomechanical analyzer (TMA) in which a sample is heated to the specified temperature. The most common temperature used is 260°C. This test is commonly called a T260 test. Other temperatures are also used, such as 288°C or 300°C. Table 8.2 compares the performance of various material types. When reviewing this table, it is important to note that there can be large variation between similar materials across the manufacturers of these materials. T260 values can be affected by the specific resins and curing agents used in a given material as well as the differences in CTE values between the components in the sample. For example, note the lower T260 values reported for the 175°C epoxy versus the 140°C epoxy. Although the T260 value is shorter, thermal cycling tests typically show improved reliability with the 175°C T<sub>g</sub> material because of the lower levels of thermal expansion that result with the higher-T<sub>g</sub> material. The enhanced FR-4 materials, which use a different curing chemistry, generally exhibit

FIGURE 8.6 Decomposition curve for an enhanced high- $T_g$  FR-4.

FIGURE 8.7 Decomposition curve for a low  $D_k/D_f$  material.

**Table 8.2** Time to Delamination and Arc Resistance Data for Common Materials

Material	T <sub>g</sub> (°C)	T260	T288	Arc Resistance
Standard FR-4 Epoxy	140	8–18	—	65–120
Enhanced FR-4 Epoxy	140	20–30	5–10	75–120
Enhanced, Filled FR-4	150	25–45	6–12	80–120
High-T <sub>g</sub> FR-4 Epoxy	175	4–10	—	70–120
Enhanced High-T <sub>g</sub> FR-4	175	30+	7–15	70–120
Enhanced, Filled High-T <sub>g</sub> FR-4	175	30+	8–16	80–120
BT/Epoxy Blend	190	30+	2–8	100–120
PPO/Epoxy	175	30+	8–20	110–120
Low D <sub>k</sub> /D <sub>f</sub> Epoxy Blend-A	200	30+	6–12	110–125
Low D <sub>k</sub> /D <sub>f</sub> Epoxy Blend-B	180	30+	10–20	110–120
Advanced Low D <sub>k</sub> /D <sub>f</sub>	220	30+	15–35	110
Polyimide	260	30+	30+	120–130
Halogen-Free, Filled High-T <sub>g</sub> FR-4	175	20–30	8–12	120–130

better performance in both time-to-delamination tests as well as thermal cycling tests. Figure 8.8 is an example of a TMA scan on a multilayer PCB that evaluates T260 performance. The top curve plots the temperature while the other curve measures sample thickness. Delamination results in a rapid increase in sample thickness and indicates the endpoint for the test. Figure 8.9 is a T288 scan for the same material. Note that times to delamination on PCBs are generally much shorter than times on either copper clad laminate or unclad laminate.

Although time-to-delamination tests have received much attention as lead-free assembly processes have become common, it is important not to focus exclusively on one property or type of measurement when specifying laminate materials for lead-free applications. First, the correlation between time-to-delamination performance and lead-free assembly compatibility is not always apparent. Long T260 or T288 times by themselves do not ensure good reliability in lead-free applications. Conversely, some materials with good but not necessarily great T260 or T288 times have exhibited excellent performance in lead-free applications. So although it is important to consider time-to-delamination performance when specifying materials for lead-free assembly applications, these values should not be looked at exclusively. A balance of several properties, as will be discussed in Chap. 10, is necessary for these applications.

### 8.2.5 Arc Resistance

In this test technique, a low current arc is placed above the surface of a material. Arc resistance describes the time the material resists tracking, or forming a conductive path, under this condition. Arc resistance values are also shown in Table 8.2. Figure 8.10 illustrates the test technique.

### 8.2.6 Density

The density of various materials is given in Table 8.3.

### 8.2.7 Copper Peel Strength

Peel strength testing is the most popular method used to measure the bond between the conductor and the substrate. Peel strengths can be measured in the “as received” condition, after thermal stress, at elevated temperature, and after exposure to processing chemicals. The standard procedure requires that the sample consist of traces or strips of copper foil, or other metal to be tested, and that they be imaged onto the sample using standard printed circuit

**FIGURE 8.8** T260 example for an enhanced high- $T_g$  FR-4.

**FIGURE 8.9** T288 example for an enhanced high- $T_g$  FR-4.

FIGURE 1.10 Arc resistance test technique.

manufacturing processes. The strips should be at least 0.79 mm (0.032 in.) in width for testing after exposure to processing chemistries and 3.18 mm (0.125 in.) in width for the other tests. Metal cladding thickness can influence the measured peel strength and therefore it is accepted practice to use 1 oz. cladding, and if a thinner cladding is used, it may be plated up to 1 oz. thickness.

One end of the strip is peeled back and attached to a load tester such as a tensile strength tester equipped with a load cell. The peel strength is calculated per the formula:

$$\text{lb./in.} = L_m/W_s$$

where  $L_m$  = Minimum load, and

$W_s$  = Measured width of the peel strip

TABLE 8.3 Densities of Common Base Material Types

Material	Density (g/cm <sup>3</sup> )
FR-4 Epoxy	1.79
Filled FR-4 Epoxy	1.97
High-T <sub>g</sub> FR-4 Epoxy	1.79
BT/Epoxy Blend	1.77
Low Dk Epoxy Blend	1.77
Cyanate Ester	1.71
Polyimide	1.68
APPE	1.51

For testing after thermal stress, the sample is first floated on solder at 288°C for 10 seconds. For testing after exposure to processing chemistries, the sample is exposed to a series of conditions. First the sample is exposed to an organic stripper at 23°C for 75 seconds. Historically, methylene chloride has been used, but due to environmental concerns, equivalents are now allowed. After drying, the sample is then immersed in a solution of 10 grams/liter sodium hydroxide at 90°C for 5 minutes. The sample is rinsed and then exposed to 10 grams/liter sulfuric acid and 30 grams/liter boric acid at 60°C for 30 minutes. The sample is again rinsed and dried and then immersed in a hot oil bath maintained at 220°C for 40 seconds. Finally, the sample is immersed in a degreaser at 23°C for 75 seconds to remove the oil and then dried. Testing at an elevated temperature may be performed by placing the sample in a hot fluid or in hot air while performing the peel strength measurements. For FR-4 materials, 125°C is commonly used.

Table 8.4 shows 1 oz. copper peel strength values in pounds per inch at various conditions for several common materials.

Note that polyimide, long used for its thermal reliability characteristics, exhibits the lowest peel strength values. This illustrates that the absolute value of peel strength is not always the best indicator of quality or reliability. Measuring and monitoring of peel strengths for a given material type for comparison to its normal values can be used as a process control tool, an inspection criteria, or for failure analysis purposes, but in choosing a material, a higher peel strength does not necessarily imply higher reliability. Last, if drum-side treated foil, also called reverse-treated foil, is used, the peel strength values will be lower because of the lower surface profile.

**TABLE 8.4** Peel Strength Values for Common Base Material Types with Standard Copper (lb./in.)

Material	T <sub>g</sub> (°C)	Peel Strength after Solder Float	Peel Strength at Elevated Temperature	Peel Strength after Exposure to Chemistry
Standard FR-4 Epoxy	140	9.0	7.0	9.0
Enhanced FR-4 Epoxy	140	8–9	6–7	8–9
Enhanced, Filled FR-4	150	8–9	6–7	8–9
High-T <sub>g</sub> FR-4 Epoxy	175	8.5–9	6.5–7.0	8.5–9.0
Enhanced High-T <sub>g</sub> FR-4	175	8–9	6–7	8–9
Enhanced, Filled High-T <sub>g</sub> FR-4	175	8–9	6–7	8–9

Low Dk/Df Epoxy Blend-A	200	6–7	6–8	7–9
Low Dk/Df Epoxy Blend-B	180	7–8	6–7	7–8
Advanced Low Dk/Df	215	7.0	6.0	7.0
Cyanate Ester	245	8.0	7.5	8.0
Polyimide	260	7.0	6.0	7.0
Halogen Free, Filled High-T <sub>g</sub> FR-4	175	7–9	6–8	7–9

**8.2.8 Flexural Strength**

Flexural strength is a measure of the load that a material will withstand without fracturing when supported at the ends and loaded in the center, as shown in Fig. 8.11. IPC-4101 specifies the minimum flexural strength of various materials, some of which are summarized in Table 8.5.

**FIGURE 8.11** Flexural strength test.

**8.2.9 Water and Moisture Absorption**

The ability of a material to resist water absorption, either from the air or when immersed in water, is important for printed circuit reliability. Besides the obvious concerns of moisture causing defects when a material is subjected to thermal excursions, absorbed moisture also affects the ability of a material to resist conductive anodic filament (CAF) formation when a bias is applied to the circuit.

The test method for measuring water absorption for metal-clad base laminates involves immersing a sample in distilled water at 23°C for 24 hours after etching off the metal cladding and drying the sample for 1 hour at 105°C to 110°C and cooling in a desiccator. The sample is

**TABLE 8.5** Flexural Strength Requirements of Base Materials

Material Type	Min. Flexural Strength Lengthwise (kg/m <sup>2</sup> )	Min. Flexural Strength Crosswise (kg/m <sup>2</sup> )
XXXPC	8.44 × 10 <sup>6</sup>	7.39 × 10 <sup>6</sup>
CEM-1	2.11 × 10 <sup>7</sup>	1.76 × 10 <sup>7</sup>

**TABLE 8.6** Moisture Absorption and Methylene Chloride Resistance of Common Materials

Material	T <sub>g</sub> (°C)	Moisture Absorption (%)	Methylene Chloride Resistance (%)
FR-4 Epoxy	140	0.1	0.7
Filled FR-4 Epoxy	155	0.22	0.42
High-T <sub>g</sub> FR-4 Epoxy	180	0.1	0.7
BT/Epoxy Blend	185	<0.5	0.7
Low D <sub>k</sub> Epoxy Blend	210	0.1	0.7
Cyanate Ester	250	<0.5	0.32
Polyimide	250	0.35	0.41

weighed after drying, immersed in water under the specified conditions, and weighed again. The water absorption is calculated as follows:

$$\text{Increase in weight, percent} = (\text{wet weight} - \text{conditioned weight}) / \text{conditioned weight} \times 100$$

An additional moisture absorption test measures weight gain after 60 minutes at 15 psi. Table 8.6 shows the moisture absorption of some common material types. These values can vary with resin content.

### 8.2.10 Chemical Resistance

One common method used to evaluate the chemical resistance of base laminates is to measure absorption of methylene chloride. Similar to water absorption testing, etched samples are exposed to this solvent and the weight gain is measured. The standard procedure starts by etching off the metal cladding of the samples, drying them in an oven for 1 hour at 105°C to 110°C, and measuring the initial weights. The samples are then soaked in methylene chloride at 23°C for 30 minutes, allowing them to dry for 10 minutes, and weighing again. The calculation is as follows:

$$\text{Change in weight, percent} = (\text{final weight} - \text{initial weight}) / \text{initial weight} \times 100$$

Table 8.6 lists methylene chloride resistance for some common materials.

### 8.2.11 Flammability

Underwriters Laboratories (UL) classifies flammability properties as 94V-0, 94V-1, or 94V-2. Definitions of these classifications are as follows:

- **94V-0** Specimens must extinguish within 10 seconds after each flame application (see Fig. 8.12) and a total combustion of less than 50 seconds after 10 flame applications. No samples are to drip flaming particles or have glowing combustion lasting beyond 30 seconds after the second flame test.
- **94V-1** Specimens must extinguish within 30 seconds after each flame application and a total combustion of less than 250 seconds after 10 flame applications. No samples are to drip flaming particles or have glowing combustion lasting beyond 60 seconds after the second flame test.
- **94V-2** Specimens must extinguish within 30 seconds after each flame application and a total combustion of less than 250 seconds after 10 flame applications. Samples may drip flaming particles, burning briefly, and no specimen will have glowing combustion beyond 60 seconds after the second flame test.

**FIGURE 1.12** Flammability testing.

### 8.3 Electrical Properties

A variety of base material electrical properties are important to understand when designing and manufacturing printed circuits. Some of the most important properties are discussed in this section. As noted earlier in the chapter, the demand for circuits operating at high frequencies requires materials with good permittivity and loss characteristics. These properties will be discussed further in Chap. 4.

#### 8.3.1 Dielectric Constant or Permittivity

The dielectric constant can be defined as the ratio of the capacitance of a capacitor with a given dielectric material to the capacitance of the same capacitor with air as a dielectric, as illustrated in Fig. 8.13. In other words, the dielectric constant is a measure of the ability of a material to store an electric charge. There are actually several test methods used to measure dielectric constant or permittivity and a complete discussion of these methods is beyond the scope of this chapter. However, it should be noted that measuring permittivity at high frequencies can be very difficult and that reported values can vary with the specific test method used. Therefore, when comparing the reported values for different materials, the best comparisons will be those that used the same test method.

**FIGURE 8.13** Dielectric constant.

Furthermore, the dielectric constant is not really a constant. As just implied, the dielectric constant will vary with frequency. It will also vary with temperature and humidity. So besides test method, the frequency, temperature, and humidity conditions must also be considered. Last, even with the same material type, variations in resin content (resin-to-reinforcement ratio) also affect the dielectric constant. These variations will be further discussed in Chap. 10. Table 8.7 shows dielectric constants for some common fiberglass (E-glass) reinforced materials at 50 percent resin content.

#### 8.3.2 Dissipation Factor or Loss Tangent ( $\tan \delta$ )

The dissipation factor in an insulating material is the ratio of the total power loss in the material to the product of the voltage and current in a capacitor in which the material is a dielectric. Many of the test methods (such as that shown in Fig. 8.14) used for measuring dielectric constant also measure the dissipation factor. Dissipation factor also varies with frequency,

**FIGURE 8.14** Dissipation factor.

**TABLE 8.7** Dielectric Constants and Dissipation Factors of Common Materials

Material	Dielectric Constant		Dissipation Factor	
	(1 MHz)	(1 GHz)	(1 MHz)	(1 GHz)
Standard FR-4 Epoxy	4.7	4.3	0.025	0.016
Filled FR-4 Epoxy	4.7	4.4	0.023	0.016
High-T <sub>g</sub> FR-4 Epoxy	4.7	4.3	0.023	0.018
BT/Epoxy Blend	4.1	3.8	0.013	0.010
Epoxy/PPO	3.9	3.8	0.010	0.011
Low D <sub>k</sub> Epoxy Blend	3.9	3.8	0.009	0.010
Cyanate Ester	3.8	3.5	0.008	0.006
Polyimide	4.3	3.7	0.013	0.007
APPE	3.7	3.4	0.005	0.007

resin content, temperature, and humidity. Dissipation factor is discussed in more detail in Chap. 10. Table 8.7 also lists the dissipation factors of some common fiberglass (E-glass) reinforced materials.

**8.3.3 Insulation Resistance**

The insulation resistance between two conductors or plated holes is the ratio of the voltage to the total current between the conductors. Two measures of electrical resistance are volume and surface resistivities. Since these properties can vary with temperature and humidity, testing is normally performed at two standardized environmental conditions, one involving humidity conditioning, the other involving elevated temperature. Humidity conditioning subjects the sample to 90 percent relative humidity and 35°C for 96 hours (96/35/90). The elevated temperature conditioning normally subjects the sample to 125°C for 24 hours (24/125).

**8.3.4 Volume Resistivity**

Volume resistivity is the ratio of the DC potential applied to electrodes embedded in a material to the current between them, typically expressed in megohm-centimeters. The measured current flows between electrodes 1 and 3, while stray current flows between electrodes 2 and 3, as shown in Fig. 8.15. Table 8.8 shows the volume resistivity values of some common fiberglass-reinforced material types.

**FIGURE 8.15** Circuit for volume resistance.

**8.3.5 Surface Resistivity**

The surface insulation resistance between two points on the surface on any insulating material is the ratio of the DC potential applied between the two points to the total current between them. For surface resistivity, the measured current flows between electrodes 1 and 2, while stray current flows between electrodes 1 and 3, as shown in Fig. 8.16. Table 8.8 shows the surface resistivity values of some common fiberglass-reinforced materials.

**FIGURE 8.16** Circuit for surface resistance.

**TABLE 8.8** Additional Electrical Properties of Common Base Materials

Material	Volume Resistivity		Surface Resistivity		Electric Str. (V/mil)
	(96/35/90)	(24/125)	(96/35/90)	(24/125)	
FR-4 Epoxy	10 <sup>8</sup>	10 <sup>7</sup>	10 <sup>7</sup>	10 <sup>7</sup>	1250
Filled FR-4 Epoxy	10 <sup>11</sup>	10 <sup>10</sup>	10 <sup>8</sup>	10 <sup>9</sup>	1250
High-T <sub>g</sub> FR-4 Epoxy	10 <sup>8</sup>	10 <sup>7</sup>	10 <sup>7</sup>	10 <sup>7</sup>	1300
BT/Epoxy Blend	10 <sup>7</sup>	10 <sup>7</sup>	10 <sup>6</sup>	10 <sup>7</sup>	1200
Low D <sub>k</sub> Epoxy Blend	10 <sup>8</sup>	10 <sup>7</sup>	10 <sup>7</sup>	10 <sup>7</sup>	1200
Cyanate Ester	10 <sup>7</sup>	10 <sup>7</sup>	10 <sup>7</sup>	10 <sup>7</sup>	1650
Polyimide	10 <sup>7</sup>	10 <sup>7</sup>	10 <sup>7</sup>	10 <sup>7</sup>	1350

**8.3.6 Electric Strength**

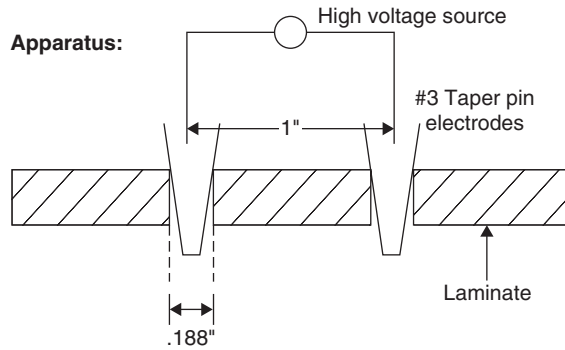

Electric strength is a measure of the ability of an insulating material to resist electrical breakdown perpendicular to the plane of the material when subjected to short-term, high voltages at standard AC power frequencies of 50 to 60 Hz and is reported in volts per mil (see Fig. 8.17). Results can be affected by moisture content in the sample, so measurements may vary with different preconditioning environments. Unless otherwise noted, measurements are taken at 23°C, after preconditioning for 48 hours in distilled water at 50°C and immersion in ambient temperature distilled water for 30 minutes minimum, 4 hours maximum. Measurements are performed under an oil medium to prevent flashover on a small specimen. The values may decrease with increasing specimen thickness for an otherwise identical material. Table 8.8 compares the electric strength of some common fiberglass-reinforced materials.

**FIGURE 8.17** Dielectric strength.

**8.3.7 Dielectric Breakdown**

Dielectric breakdown measures the ability of rigid insulating materials to resist breakdown parallel to the laminations (or in the plane of the material) when subjected to extremely high voltages at standard AC power frequencies of 50 to 60 Hz (see Fig. 8.18). As with electric

**FIGURE 8.18** Dielectric breakdown strength parallel to laminations.

strength, values obtained on most materials are highly dependent on the moisture content and preconditioning method. Unless otherwise noted, measurements are performed at 23°C after preconditioning for 48 hours in distilled water at 50°C followed by immersion in ambient temperature distilled water for 30 minutes minimum, 4 hours maximum. Dielectric breakdown is also performed in an oil medium. Dielectric breakdown for the materials shown in Table 8.8 is normally above 50 kilovolts.

## BASE MATERIALS PERFORMANCE ISSUES

---

**Edward J. Kelley**

---

### 9.1 INTRODUCTION

---

As the fundamental building block for printed circuits, base materials must meet the needs of the printed circuit board (PCB) manufacturer, the circuit assembler, and the original equipment manufacturer (OEM). A balance of properties must be achieved that satisfies each member of the supply chain. In some cases, the desires of one member of the supply chain conflict with another. For example, the need for improved electrical performance by the OEM, or improved thermal performance by the assembler, may necessitate the use of resin systems that require longer multilayer press cycles or less productive drilling processes, or both.

Lead-free assembly processes are driving the need for greater thermal reliability. This will be discussed further in Chaps. 10 and 11. Other trends are also driving the need for greater performance. These include:

- Circuit densification
- Higher circuit operating frequencies

The density of IC packaging technologies such as ball grid array (BGA) and chip scale packages continues to increase. In turn, this requires greater interconnection density in the printed circuits onto which they are assembled. The need for increased density in the PCB impacts each of the components of the base material as well as the way in which they are manufactured. To achieve high levels of interconnection, component pitch densities result in smaller and more closely spaced plated through holes and circuit features. As the space between these holes and features decreases, the potential for conductive anodic filament (CAF) failures increases substantially.

Higher operating frequencies can also impact each of the three main components of base materials. Circuits operating at high frequencies are driving the use of materials with low dielectric constants, low dissipation factors, and tighter thickness tolerances. These performance issues and the impact to the printed circuit manufacturing process are discussed in this chapter.

## 9.2 METHODS OF INCREASING CIRCUIT DENSITY

---

There are basically three ways to increase printed circuit density:

- Decrease conductor line widths and the spacings between them
- Increase the number of circuit layers in the PCB
- Reduce via and pad sizes.

Decreasing conductor line widths requires very-low-profile copper foils for high yields in circuit etching processes. However, other things being equal, lower profiles result in decreased foil adhesion to the dielectric. Balancing the copper surface profile for both adhesion to the dielectric and the ability to etch fine circuit features, not to mention the impact of surface roughness on electrical performance at high frequencies, is an important consideration. Copper foil manufacturers continue to research methods to improve the chemical adhesion between the foil and the various dielectric materials in use, relying less on a rough surface profile for mechanical adhesion, and allowing for very low profiles for circuit etching and lower conductor losses at high frequencies.

Increasing circuit layer counts have resulted in both greater overall multilayer thicknesses and thinner individual dielectrics, making thickness control and thermal reliability more important than ever. Adding layers to a PCB also demands improved registration capabilities. One of the critical variables in controlling registration is the dimensional stability of the laminate material, which can become more challenging with the thinner laminates generally used as layer counts increase. Reducing via and pad sizes also requires improved laminate dimensional stability for registration of high layer count circuits.

## 9.3 COPPER FOIL

---

One obvious method to increase printed circuit functionality is to put more circuitry per unit area of the circuit. Printed circuit densification has driven several improvements in copper foil technology. One of the first developments was high temperature elongation (HTE) foils. Other advances include low- and very-low-profile foils, thin foils, and foils for high-performance resin systems.

### 9.3.1 HTE Foil

HTE or Class 3 copper foil exhibits improved elongation properties at elevated temperatures as compared to standard electrodeposited or Class 1 copper foil. Typical elongation values for HTE copper foil range from 4–10 percent at 180°C.

The growth in multilayer printed circuits has resulted in HTE becoming the most commonly used foil, since its excellent ductility at elevated temperatures helps prevent inner-layer copper foil cracking. As a printed circuit experiences a thermal cycle, the base materials will expand. The z-axis expansion applies stress to the connection of the inner-layer foil and the plated hole. With HTE foil, the reliability of this connection is improved. This property is particularly important in thicker circuits and high resin content constructions where increased z-axis expansion occurs.

### 9.3.2 Low-Profile and Reverse-Treated Copper Foils

Three classifications describe the profile of the copper foil surface as shown in Table 9.1.

Copper foil profile is important for etching of fine-line circuits. Figures 7.23 through 7.26 illustrate the difference between standard- and low-profile foils. As can be seen in those photos,

**TABLE 9.1** Copper Foil Profiles

Foil Profile Type	Max. Foil Profile (Microns)	Max. Foil Profile ( $\mu$ Inches)
S – Standard	N/A	N/A
L – Low Profile	10.2	400
V – Very Low Profile	5.1	200
X – No Treatment or Roughness	N/A	N/A

the tooth profile of the standard-profile foil is much more pronounced. The etching of the lower-profile foil results in more control of the geometry of the circuit trace. In addition, in very thin laminates, the large tooth structure of the standard profile foil can result in inconsistent dielectric thickness, making impedance control more difficult, and can even result in electrical failures if the tooth structures from the opposing sides of the laminate protrude sufficiently.

Reverse-treated foils (RTF) take this concept a step further. When copper foil is manufactured, there is a very smooth, shiny side and a rougher matte side. Conventional technology involved treating the matte side and laminating this side to the base material. Reverse-treated foil, as its name implies, involves putting the treatments on the smooth, shiny side of the foil and laminating this side to the base material. This has two important effects. First, the side bonded to the base material has an extremely low profile that aids in etching very fine circuit traces. Second, the rougher matte side, which is now on the surface of the laminate, can improve photoresist adhesion. This enables the removal of surface roughening processes during PCB manufacturing and can also improve inner-layer imaging and etching yields. Figure 9.1 compares laminates made with conventional and RTF foils.

**FIGURE 9.1** Comparison of laminates with standard (left) versus RTF (right) copper foils.

### 9.3.3 Thin Copper Foils

The capability to etch fine-line circuits is also improved through the use of thinner copper foils. Although electrical considerations can limit the use of very thin foils on innerlayer circuits,

these thin foils can be used on external layers since the outerlayer process involves plating on top of the foil to the desired overall thickness. For dense, fine-line circuitry, 5.0 micron and 9.0 micron copper foils are sometimes used. Processes to use 3.0 micron copper foil have also been developed.

### 9.3.4 Foils for High-Performance Resin Systems

Many of the high-performance resin systems such as BT, polyimide, cyanate ester, and even some high- $T_g$  epoxies exhibit lower peel strengths and resistance to undermining of the copper foil when exposed to aggressive chemistries. For these applications, foils with increased nodularization and coupling agents tailored to the resin system are often used. The increased nodularization results in more surface area for mechanical adhesion whereas the specific coupling agent aids in chemically bonding the foil to the resin system.

### 9.3.5 Copper Roughness and Attenuation

As circuit operating frequencies increase, more of the signal travels in the outermost part of the conductor. The “skin depth”—that is, the region where much of the signal travels—is shown in Fig. 9.2 as a function of frequency. As shown in this graph, the skin depth approaches the average roughness of 0.5 oz. copper foil above 1 GHz. Signal attenuation due to conductor losses related to the roughness of the foil becomes an important factor at these frequencies, and should be considered by the design engineer.

**FIGURE 9.2** Skin depth versus frequency.

A study of several different copper foil types correlated roughness and attenuation values.<sup>6</sup> Figures 9.3 and 9.4 show pictures of the foils to highlight their relative roughness differences. Figure 9.5 shows the roughness distributions of these foils. Finally, in Fig. 9.6, the loss values associated with each of these foil types are graphed versus frequency. Up to about 1 GHz, there is very little difference in the observed loss across the several foil types. However, at higher frequencies, the difference becomes much greater, correlating to the roughness of the individual foil types; the greater the roughness, the greater the measured attenuation.

**FIGURE 9.3** Cross-sectional view of several copper foils.

**FIGURE 9.4** SEM views of several copper foils.

**FIGURE 9.5** Roughness distributions for several foil types.

The roughness that results from the oxide/oxide alternative surface preparation process during printed circuit manufacturing is also important. Figures 9.7 and 9.8 compare the roughness obtained from two of these processes. The base copper foil and FR-4 resin system used were held constant. The test vehicles from which these cross sections were taken were also measured for attenuation. This measurement technique was used to calculate an effective dissipation factor,  $D_f$ , for these material sets. The measured  $D_f$  for the sample in Fig. 9.7, with the relatively smooth profile, was 0.021 at 1 GHz. The measured  $D_f$  for the sample in Fig. 9.8, with the rougher profile, was 0.026. Obviously, the rougher profile created by the oxide alternative process in Fig. 9.8 resulted in a significantly higher loss value.

**FIGURE 9.6** Loss versus frequency for several foil types.

**FIGURE 9.7** Copper profile obtained from process A.

**FIGURE 9.8** Copper profile obtained from process B.

## **9.4 LAMINATE CONSTRUCTIONS**

---

To satisfy requirements for impedance, layer count, and overall PCB thickness, a broad range of laminate dielectric thicknesses are needed. Table 9.2 shows many common laminate dielectric thicknesses, along with typical constructions and resin contents. Individual laminate suppliers may have preferred constructions, so not every construction shown in this section will be available from every laminate supplier. In addition, some of the high-performance resin systems will have slightly different constructions or resin contents in order to target certain performance characteristics, such as dielectric constant.

### **9.4.1 Single-Ply versus Multiple-Ply Constructions**

With dielectrics below 0.0040 in., there is often no choice but to use a single ply of fiberglass cloth to achieve the desired thickness. With dielectrics in the 0.0040 in. to 0.0080 in. range,

**TABLE 9.2** Common Laminate Constructions

Laminate Thickness (in.)	Fiberglass Cloth(s)	Approx. Resin (%)
0.0020	1-106	71-72
0.0025	1-1080	53-54
0.0030	1-2113	46-47
0.0035	1-2113	52-53
0.0040	1-2113	53-54
0.0040	1-3070	49-50
0.0040	1-2116	43-44
0.0040	1-106/1-1080	59-60
0.0040	2-106	68-69
0.0040	2-1080	50-51
0.0045	1-2116	50-51
0.0045	2-1080	55-56
0.0050	1-2116	52-53
0.0050	1-2165	47-48
0.0050	1-1652	42-43
0.0050	2-1080	56-57
0.0050	1-2313/1-106	52-53
0.0060	2-2113	46-47
0.0062	1-2157	49-50
0.0062	1-1080/1-2313	53-54
0.0080	1-7628	44-45
0.0080	1-2116/1-2313	49-50
0.0080	2-2116	45-46
0.0090	2-2116	50-51
0.0100	2-1652	42-43
0.0100	2-2165	47-48
0.0120	2-2157	47-48
0.0120	2-1080/1-7628	47-48
0.0140	2-7628	40-41
0.0210	3-7628	40-41

there are both single-ply and multiple-ply options. Above 0.0080 in., multiple plies of cloth are typically required to achieve the desired thickness. Within each range, there are often multiple cloth and resin content combinations that can achieve the desired dielectric thickness. The choice of laminate construction can significantly impact both cost and performance. The choice of single-ply versus multiple-ply construction, when the option is available, is no exception.

As should be expected, a single-ply construction will typically represent a cost savings compared to a multiple-ply construction. The magnitude of this savings will depend on the specific glass styles involved and a host of other parameters. Performance can also be affected and should be considered when specifying the constructions to be used. First, single-ply constructions are often lower in resin content, as can be observed in Table 9.2. Resin content issues are discussed in the following section. The other main benefit of single-ply constructions is dielectric thickness control, beyond resin content considerations. Other things being equal, as with resin contents, tighter thickness tolerances can be achieved using a single-ply construction than

a multiple-ply construction since the variation in thickness control with one ply of prepreg will statistically be less than with multiple plies.

#### 9.4.2 Resin Contents

As Table 9.2 illustrates, the same dielectric thickness can be achieved with multiple fiberglass cloth and resin content combinations. Constructions with relatively lower resin contents are often preferred since they result in less z-axis expansion and can therefore improve reliability in many applications. In addition, lower resin contents can also improve dimensional stability, resistance to warpage, and dielectric thickness control. On the other hand, constructions with higher resin contents result in lower dielectric constant values, which are sometimes preferred for electrical performance, which is discussed further in Section 9.8. In addition, a certain minimum resin content is required to ensure adequate resin-to-glass wet-out and to prevent voids from occurring within the laminate. The ability to wet out the glass filaments fully with resin is also important for CAF resistance. In summary, for each glass style, there is an optimal resin content range that balances the various performance requirements.

#### 9.4.3 Laminate Flatness and Flexural Strength

When manufacturing the innerlayer circuit patterns, the flatness and flexural strength of the base material is important for successfully transporting these circuit layers through conveyORIZED equipment. This is particularly important for very thin laminates. If the laminate is curled, it can become caught or damaged inside this equipment. If the thin laminate with the circuit image sags on the conveyors, similar damage can occur.

For these reasons, it is sometimes preferred to use constructions with relatively high glass contents and use the thickest cloths possible, as this will result in greater flexural strengths, bearing in mind the performance requirements just discussed in Section 9.4.2. In addition, *balanced* constructions, or those that use a symmetrical construction, are normally preferred to avoid curling. Asymmetrical constructions are more prone to curling and causing problems in conveyORIZED equipment. Consider a 0.0080-in. laminate as an example. Table 9.2 shows three constructions for this thickness, 1-7628, 1-2313/1-2116, and 2-2116. The asymmetrical 1-2313/1-2116 construction will be more prone to curling than the other constructions. One word of caution is warranted, however: Curling is but one property that must be considered. Dimensional stability, thickness control, and other properties must also be considered when choosing a construction.

### 9.5 PREPREG OPTIONS AND YIELD-PER-PLY VALUES

---

Just as there are a variety of base laminate constructions, there are a variety of prepreg options. Each fiberglass cloth style can be treated to multiple resin contents and flow values. While the same properties must be considered for prepreg materials as for base laminates, prepregs must also contain sufficient resin to flow and fill in the innerlayer circuitry of a multilayer circuit board. Since the innerlayer circuits can vary in terms of copper thickness and circuit density, a variety of resin content and flow value options are typically required when specifying prepreg styles. Higher resin contents may be needed when filling heavy copper weights and signal layers, while lower resin contents can be used against lighter copper weights and power or ground circuit patterns. Table 9.3 shows some common prepreg styles with various resin contents and thickness yields per ply.

**TABLE 9.3** Common Prepreg Styles

Glass Style	Approximate Resin Content (%)	Thickness (in.)*
106	62	0.0015
106	66	0.00175
106	71	0.0020
106	75	0.00225
1080	54	0.00225
1080	57	0.0025
1080	64	0.0030
1080	66	0.00325
2113	50	0.0035
2113	55	0.0040
2116	50	0.0045
2116	52	0.00475
2116	55	0.00525
2165	47	0.0050
2165	50	0.00525
2165	54.0	0.0060
2157	45	0.00575
2157	47	0.0060
2157	48	0.00625
2157	50	0.0065
7628	40	0.0070
7628	42	0.00725
7628	44	0.0075
7628	45	0.00775

\*Assumes a given flow value and represents thickness without filling circuitry.

## 9.6 DIMENSIONAL STABILITY

As circuit layer counts grow and via-to-pad size ratios get tighter, the alignment or registration of the layers of circuitry become extremely important. Although several material and process variables contribute to the capability to achieve layer-to-layer and via-to-innerlayer feature registration, laminate dimensional stability is one of the most important. This is especially true in high-layer-count circuits that use thin laminates, since thinner laminates are generally not as dimensionally stable as thicker laminates. An example can help illustrate this point.

### 9.6.1 A Model of Printed Circuit Registration Capability

Table 9.4 lists several of the key variables that influence an overall via-to-innerlayer pad registration capability in the printed circuit manufacturing process. The values in the table represent individual process standard deviations using a specific multilayer circuit design. If we make the assumption that these processes are normally distributed and that they are centered on the desired nominal value, we can use additivity of variance to estimate an overall registration capability. In other words, taking the square root of the sum of the squares of each individual process standard deviation gives an overall process standard deviation that can be used to assess capability.

In other words, if we are trying to maintain at least tangency of a drilled hole to an inner-layer pad with a 13.5 mil hole, the pad needs to be almost 27.5 mil in diameter for material type A ( $13.5 + 13.8 = 27.3$ ). The same procedure can be used to calculate clearance or antipad diameters with the desired plated through hole to clearance distance, which is also an important design consideration. It is important to note that items such as dimensional stability and

**TABLE 9.4** Multilayer Registration Variables

Process Variable	Process $\sigma$ Material Type A	Process $\sigma$ Material Type B
Artwork Plotting	0.33	0.33
Artwork Alignment	0.70	0.70
Post Etch Punch	0.40	0.40
Laminate Stability	1.70	0.90
Drill Set-Up	0.80	0.80
Hole Location	1.00	1.00
<i>Overall <math>\sigma</math></i>	<i>2.30</i>	<i>1.79</i>
<i>Overall <math>\pm 3\sigma</math></i>	<i>6.90</i>	<i>5.37</i>
Drill + ? Capability	13.80	10.75

hole location will be significantly impacted by the specific material type, board design, and manufacturing processes used, and that actual registration systems are more complex than described here. The point of this analysis is to show the impact of laminate dimensional stability on printed circuit design. As you can see in this example, improving laminate stability from a standard deviation of 1.70 to 0.90 improves the overall registration capability from drill size + 13.8 mil to drill size + 10.75 mil, or a reduction of over 3 mil in the required diameter of the internal feature. Requirements for increased circuit density require smaller circuit features, such as internal pad sizes. This, in turn, drives the need for better registration capabilities and therefore improved laminate dimensional stability, as this model suggests.

## 9.6.2 Dimensional Stability Test Methods

A common test method used to evaluate dimensional stability starts with a sample of a copper-clad laminate with scribed targets or holes in the four corners of the sample. Baseline measurements of the distances between these holes are taken prior to conditioning of the sample. One conditioning procedure involves etching the copper cladding off and remeasuring and determining the dimensional movement compared to the baseline. A second method subjects the sample to a thermal cycle, commonly a bake at 150°C for 2 hours. Again, measurements are taken after conditioning and compared to the baseline dimensions. A third method involves first etching the cladding off, measuring, subjecting the sample to the bake cycle, and measuring again. Each of these methods can be used as a process control tool in the laminate manufacturing process.

However, these test methods are of limited value to the printed circuit manufacturer, who etches circuit images on these laminates, combines them with prepreg materials and other laminates, and presses them together under temperature and pressure to form a multilayer circuit. It is the predictability and consistency of laminate movement through the printed circuit manufacturing process, across a variety of circuit patterns and especially through the multilayer lamination cycle, that is of concern for the circuit manufacturer and ultimately for the designer who wants to increase circuit density. Multilayer lamination cycles commonly reach 185°C or higher, and normally exceed the  $T_g$  of the base material. Above the  $T_g$ , the resin softens and allows tension in the laminate to be released and is also subject to stresses from the surrounding materials and lamination pressure. Most of the movement of the laminate in the circuit manufacturing process occurs during this lamination cycle.

## 9.6.3 Improving Dimensional Stability

Although many variables in laminate and circuit manufacturing processes can influence dimensional stability, some common techniques involve laminate press cycle optimization,

control of laminate resin contents, and the use of higher  $T_g$  materials. New materials and process techniques have also been developed to improve dimensional stability.

**9.6.3.1 Laminate Manufacturing Process Considerations.** Historically, some printed circuit manufacturers had the laminate manufacturer bake the laminate prior to shipment, or would bake it themselves prior to use. The intent was to relieve any stress that may be stored within the laminate prior to use in the circuit manufacturing operation. Although this process may help, the added material handling and cycle time does not usually justify the process. Instead, many laminate manufacturers reduce the lamination pressure at a specified point in their lamination cycle to minimize the stress that becomes stored in the finished product.

New laminate manufacturing techniques may also offer improved dimensional stability. The direct current and continuous manufacturing processes described in Chap. 6 result in consistent thermal profiles from laminate to laminate and can use low lamination pressures. Optimizing these parameters can lead to improved consistency in dimensional stability.

Other process controls in the laminate manufacturing process are also important for dimensional stability. Control of the raw materials, especially the glass cloth, can contribute to dimensional stability. The tension applied to the cloth during the treating process, the heat rise, temperature, and pressure profiles during lamination, as well as laminate stack-up techniques during lamination can all affect dimensional stability. Consistency in these parameters will generally improve the consistency observed during the printed circuit manufacturing process.

**9.6.3.2 Impact of Reverse-Treated Foils (RTF).** RTF copper foils typically allow the elimination of surface-roughening processes in the innerlayer circuit imaging process. These surface-roughening processes are normally mechanical scrubbing processes that can stretch or distort thin laminates. Much of the distortion induced by these processes is elastic in that the laminates tend to move back toward their original dimensions. This movement takes time, however. So laminates imaged one length of time after scrubbing can potentially move a different amount if imaged after a different length of time after scrubbing. If the laminates are imaged before they have a chance to fully relax after mechanical scrubbing, some movement may occur after imaging, which then distorts the image placed on the laminate. In addition, variation in the mechanical scrubbing process over time can introduce lot-to-lot variation, which adversely impacts registration capabilities. RTF foil, which facilitates the removal of these scrubbing processes because of the improved photoresist adhesion to the matte side of the foil, can therefore result in improvements in registration capability.

**9.6.3.3 Fiberglass Cloths and Resin-to-Glass Ratios.** Each fiberglass cloth style used in laminates and prepregs has a resin content range that results in sufficient wet-out of the glass cloth, is relatively easy to control, and therefore results in more uniform thickness and more consistent dimensional stability. The specification of laminates and prepregs with resin contents in the desired ranges can result in improvements in dimensional stability and therefore registration capabilities. As a result, having a range of fiberglass cloth styles available is important to be able to achieve a wide range of dielectric thicknesses.

**9.6.3.4 Non-Woven Reinforcements.** Because of the woven, serpentine geometry of the yarns in fiberglass cloths, they can behave like springs when used as the reinforcement of base materials. During the resin treating process and the laminate pressing operation, the fiberglass cloth is subjected to stresses that can be stored in the laminate as the resin is cured. These stresses can then be released during the circuit manufacturing process, causing dimensional changes.

Non-woven materials can avoid these stresses. In one non-woven material type, short, randomly oriented fibers are treated with the resin system. In a second type, linear strands of fiberglass are laid down in a balanced, cross-ply orientation which resists subsequent stresses.

**9.6.3.5 Multilayer Press Cycle Optimization.** Most of the dimensional changes in the laminate occur during the multilayer press cycle when the temperature exceeds the  $T_g$  of the

resin in the laminate. Above the  $T_g$ , the resin system in the laminate softens and allows any stored stress in the reinforcement to be released and allows the laminate to be affected by the adjacent materials and the pressure of the lamination cycle.

Understanding the rheology of the resin in the prepreg is important when designing the multilayer lamination cycle. The point at which the resin begins to melt, the point at which it begins to cure, and the relationship between the heat rise and the viscosity profile of the resin are all important. With respect to viscosity, not only is the minimum viscosity achieved important, but the length of time that the resin is below a certain viscosity, allowing the resin to flow and fill the internal circuit features, is also important. With an understanding of these parameters, it is possible to design “kiss” cycles, or “soak” cycles, where pressure and temperature profiles, respectively, are designed to improve performance, including dimensional stability.

In addition, although seldom done in practice, using a resin system in the prepreg materials that can be cured below the  $T_g$  of the resin system in the laminate can avoid the softening of the laminate resin system and therefore prevent much of the movement that takes place. The resistance to the use of this technique is usually driven by a desire to keep the resin system same throughout the multilayer PCB.

## 9.7 HIGH-DENSITY INTERCONNECT/MICROVIA MATERIALS

One method used to increase circuit density is to use blind and buried vias. Rather than placing a via hole completely through the printed circuit board, blind and buried vias go only partly through the multilayer circuit, joining only the layers that require connection. By not extending these vias through the entire multilayer, real estate on the other layers becomes available for additional circuit routing. Buried vias are those that are not visible from the outside of the finished circuit board, and are formed in a subcomposite or copper-clad laminate. Blind vias are those that are visible from the outside of the multilayer circuit but do not go completely through it. By limiting the size of these vias, you can significantly increase interconnection density. Microvia or high-density interconnection (HDI) printed circuit designs utilize these technologies to increase circuit density.

While the materials already discussed are used in blind and buried via applications using conventional processes, additional materials can be used to increase density using more specialized process techniques. The specialized processes used to form microvias include laser ablation, plasma etching, and photoimaging, with laser formation by far the most common.

The resin system will generally ablate much faster in laser drilling processes. Also, plasmas are not effective in etching through fiberglass. As a result, materials that use an alternative reinforcement or do not contain an inorganic reinforcement have been developed for these applications.

For blind via applications, resin-coated copper foil can be used to form the external circuit layer and dielectrics between layers 1 to 2 and  $n$  to  $n-1$ , using laser or plasma processes to form the vias. Buried vias could be formed in sequential processes. Two basic types of resin-coated copper foil are available. The first type uses one layer of partially cured resin (see Fig. 9.9).

**FIGURE 9.9** Resin-coated copper foil with a single layer of B-staged resin.

**FIGURE 9.10** Resin-coated copper foil with a C-stage and B-stage layer.

**FIGURE 9.11** C-stage plus B-stage resin-coated copper foil laminated to PCB.

This resin-coated foil is then laminated to the rest of the multilayer circuit. A second type of resin-coated copper foil uses two layers of resin (see Figs. 9.10 and 9.11). The first layer is fully cured whereas the second is partially cured. This technique guarantees a minimum dielectric separation between the external foil and the circuitry on the next layer in, since the cured resin layer limits how close the internal circuit layer can get to the external foil.

Another material used in HDI designs utilizes an organic reinforcement that can be laser-ablated or plasma-etched. The most common organic reinforcement used is aramid fiber-based. The aramid fibers are randomly oriented and formed into a sheet that is impregnated with the resin system. In this way, both copper-clad laminates and prepregs can be manufactured and used in multilayer applications. Table 9.5 shows some available thicknesses of Thermount aramid fiber reinforcement with 50 percent resin content. An additional reinforcement that can be used to make a prepreg material is expanded polytetrafluoroethylene (PTFE). This material has a sponge like structure that can also be impregnated with a resin system and used in HDI applications (see Fig. 7.19). Expanded PTFE also has a very low dielectric constant and loss factor.

**TABLE 9.5** Commonly Available Thicknesses of Thermount

Thermount Type	Prepreg Thickness	Laminate Thickness
E210	0.0018 in./46 $\mu\text{m}$	0.0020 in./51 $\mu\text{m}$
E220	0.0030 in./76 $\mu\text{m}$	0.0032 in./81 $\mu\text{m}$
E230	0.0037 in./94 $\mu\text{m}$	0.0039 in./99 $\mu\text{m}$

The third process technique used in these applications involves photoimaging a permanent dielectric material in order to form the microvias. These photoimageable dielectrics resemble plating resists but must be able to be catalyzed for subsequent plating operations that will form the external circuit image, and must adhere sufficiently to the rest of the multilayer circuit to provide long-term reliability.

## 9.8 CAF GROWTH

Conductive anodic filament (CAF) formation is a term used to describe an electrochemical reaction in which conductive paths are formed within a dielectric material due to transport of metal or metal salts through the dielectric. These paths may form between two circuit traces, between two vias, or between a trace and a via, as illustrated in Fig. 9.12. CAF formation between a hole and a plane inside the PCB is also possible, and is similar in concept to hole-to-trace CAF formation. By definition, as circuit density increases, the space between these features decreases. With shorter paths between features, CAF growth becomes a more critical reliability consideration.

For CAF growth to occur, a bias and a path for this filament growth must be present. In fiberglass-reinforced materials, a gap between the resin and the fiberglass filaments is the most common pathway. If the glass is not completely wet-out with resin, or if the bond between the resin system and the fiberglass filaments is insufficient or is compromised, the resulting gap can become such a path. Hollow fiberglass filaments can also provide a path. In addition, there must be a medium in which this electromigration can occur, such as absorbed moisture that allows dissolved ionic species to migrate and promote the electrochemical reaction that leads to CAF. Figure 9.13 is an actual example of CAF formation.

Research on CAF has been done for many years. Some of the key findings of this research include the following:

- CAF is a two-step process consisting of path formation and the electrochemical reaction.
- The filament is usually in the form of a copper salt.

**FIGURE 9.12** Pathways for CAF formation: (a) hole to hole; (b) hole to track; (c) track to hole; (d) track to track.

**FIGURE 9.13** An example of CAF between two plated through holes.

- Moisture absorption can influence the rate of CAF formation, and there is a minimum threshold for moisture absorption below which CAF is unlikely to occur.
- Temperature can influence the rate of the electrochemical reaction.
- The level of bias can also influence the rate of CAF formation.
- Resin-to-glass wet-out is critical in that it eliminates a potential pathway.
- Beyond glass wet-out, the bond between the resin and the glass is important to ensure that adhesion is not lost due to moisture or thermal stress. Selection of the coupling agent used to improve adhesion between the resin and the glass is critical in this regard, and different resin systems may require different coupling agent types. Figure 9.14 shows examples of silane coupling agents, where “R” represents various chemical species that can be modified for different applications.
- The cleanliness of the glass, both before coating with silane as well as prior to coating with the resin system, is important to ensure proper wetting and bonding of resin to glass.
- The curing agent used in the resin system can influence CAF formation. This may be due to the tendency of some curing agents to absorb moisture, or to the electrochemical nature of the specific curing agent, or both.
- Contaminants on the glass cloth or within the resin system can also accelerate CAF formation. For example, residual hydrolyzable chlorides present in some epoxy resins are known to catalyze electrochemical reactions that can lead to CAF.

**FIGURE 9.14** Examples of silane coupling agents.

- Resin system thermal stability and thermal expansion may influence performance as well, especially as lead-free assembly processes cause PCBs to be subjected to more severe thermal excursions. This is due to the possibility of thermal decomposition of the resin causing reduced resin-to-glass adhesion or even voids within the laminate that can provide pathways for CAF formation. With respect to thermal expansion, the higher temperatures of lead-free assembly result in a greater total stress at the resin-to-glass interface due to the CTE mismatch between them. If this stress is high enough, or the bond strength low enough, separation of the resin from the glass can occur and provide a pathway for CAF as well.

The processing used in printed circuit fabrication can also influence CAF resistance. Some of the factors to consider in PCB fabrication include the following:

- The innerlayer surface must be clean. Adequate rinsing of the innerlayers after chemical processes is important to minimize residual ionic contamination.
- Storage conditions and shelf life of prepreg materials are important to control to ensure adequate flow properties during multilayer lamination.
- Multilayer lamination processing is important to ensure good resin flow and full wetting of resin to glass in the prepreg layers. Vacuum, temperature, and pressure profiles are all important.
- Drilled hole quality is also important. With respect to CAF performance, minimizing resin-to-glass fracturing that can result in excessive wicking of plating chemistries is critical.
- Control of desmear and electroless copper-plating chemistries is also important. Minimizing any further attack of the resin-to-glass interface and plating into the dielectric are the key considerations. Good rinsing to minimize residual ionic contamination from these processes is also important.

### 9.8.1 CAF Testing

Many different types of test vehicles are used to assess CAF performance, but most include the design features described in Fig. 9.12. Differences between common test vehicles include the distances between features, the thickness and layer counts of the PCBs, and the glass styles and resin contents used to build the PCB. All of these factors influence CAF, if not directly, as a result of the processes used to build the specific test vehicle. In addition, testing parameters such as bias, temperature, and humidity also influence results. Various OEMs will also have different requirements for the time of testing, with typical time requirements ranging from 500 to 1,000 hours.

Figure 9.15 shows an example of CAF found in one test vehicle. In this case, the pathway formed between individual filaments of the glass cloth, either because they had not been sufficiently coated with resin or because resin decomposition, moisture, or other volatile compounds created a void.

**9.8.1.1 CAF Test Example #1.** One of the common test vehicles used to assess CAF performance consists of a 10 layer PCB, often made of single-ply 2116 style dielectrics in each of the core and prepreg layers. Common test conditions are either 65°C/85 percent relative humidity (RH) or 85°C/85 percent RH, with 10 volts or 100 volts bias. This test vehicle includes design features such as those shown in Fig. 9.12, but the hole-to-hole features are typically the most critically examined. In addition, placement of the holes relative to the glass cloth weave can influence results. When the holes are placed in line with the glass weave, the filaments can bridge the holes, providing a potential CAF pathway. If the holes are placed diagonal to the weave orientation such that no individual filament bridges two holes under test, this potential pathway is eliminated. In practice, holes placed in line with the glass weave are the most relevant for assessing CAF resistance. Hole spacing is also a critical parameter,

**FIGURE 9.15** CAF formation between glass filaments in a PCB test vehicle.

and this particular test vehicle examines holes placed approximately 10, 15, 20, and 25 mil apart. Although the definition of failure can vary slightly from OEM to OEM, the criteria usually consist of some minimum insulation resistance value, and often a maximum decrease in resistance of one order of magnitude, or “a decade drop in resistance.” Figure 9.16 provides results for one laminate material processed by one PCB fabricator.

This chart plots average insulation resistance for 25 test coupons (on a log scale in this example) versus time in hours at a 10 volt bias with 65°C/85 percent RH environmental conditions. It also shows the data separately for the 10, 15, 20, and 25 mil hole-to-hole spacings. Other things being equal, average insulation resistance will be higher for holes spaced further apart, as this means there will be more dielectric between features. For this particular test, the average insulation resistance for each spacing did not decrease by an order of magnitude, indicating good results. However, it is also important to examine the individual coupons tested, and a common way to

**FIGURE 9.16** Insulation resistance CAF test results for example #1.

FIGURE 9.17 Percent failing coupons in CAF test example #1.

assess performance in this regard is to calculate the percentage of individual test coupons that pass or fail. Figure 9.17 provides this data for this same test, and shows results for the test material highlighted in Fig. 9.16 versus a control group that utilized a different laminate material.

As is common, the control group shows fewer individual failures as the spacing between holes increase. The test material shows a much lower percentage of individual failures for each spacing.

**9.8.1.2 CAF Test Example #2.** In a second example, four commonly available FR-4 materials were compared by building the same CAF test vehicle as described in example #1. These materials are all promoted as being “CAF-resistant.” The coupons were manufactured by the same PCB fabricator during the same time period. In this evaluation, the test conditions were 100 volts bias, 85°C and 85 percent RH. The same hole-to-hole spacings were evaluated, but for simplicity, Figs. 9.18 and 9.19 show only the data for the 15 and 25 mil spacings, respectively. It is common to use a 1 meg-ohm resistor in series with the test point in these tests, so where the average insulation resistance drops to  $10^6$  ohm (6 on the y-axis of the chart), this indicates that the resistance has dropped excessively and it is the resistor that is now being

FIGURE 9.18 CAF results for 15 mil hole spacings in example #2.

FIGURE 9.19 CAF results for 25 mil hole spacings in example #2.

measured. In this evaluation, materials A, C, and D all drop to this level at 500 hours of testing with 15 mil hole-to-hole spacings. At 25 mil spacings A and C both drop to this level. B and C do not, but C drops in resistance by more than one order of magnitude. Only material B drops by less than one order of magnitude at both spacings. By these criteria, materials A, C, and D would have failed this test. Only material B passed.

**9.8.1.3 CAF Test Example #3.** In this third example of CAF testing, a different test vehicle design was used, and different temperature, humidity, and bias levels were also used. However, all the test coupons were manufactured at the same time by the same PCB fabricator, and in addition, the same resin system was used in groups 1 through 4. The differences between groups 1 through 4 involve different types of fiberglass cloth and differences in process controls used when treating the glass cloth with the resin system. This is the key point of this third example.

Figure 9.20 shows that while each group used exactly the same laminate material type, differences in glass cloth and treating process controls resulted in different CAF performance levels.

FIGURE 9.20 Results for CAF test example #3.

For each group, the chart shows average insulation resistance for a set of coupons over time. Clearly, the average insulation resistance varied by group, with group 1 showing the most significant decline in resistance. In addition, evaluating the individual coupons in each group provides additional insight into performance differences. In group 1, 40 percent of the coupons failed by 600 hours, with the first failure occurring at 400 hours. In group 2, 20 percent of the coupons failed at 600 hours. Groups 3 through 5 did not have any failures in this test. So even though the resin system was the same for each group, differences in glass cloth and laminate manufacturing processes clearly can have a significant impact on CAF performance.

### 9.8.2 Choosing a Base Material for CAF Resistance

Some of the key conclusions of these examples and other research on CAF performed in the industry include the following:

- All base materials have some level of CAF resistance, but even materials promoted as “CAF-resistant” can vary widely in actual performance.
- The test vehicle design has a significant impact on results. The closer the circuit features, the more likely that CAF failures will occur. In addition, the other attributes of the test vehicle design can impact the fabrication variables that influence CAF—for example, the thickness of the PCB and drilled hole sizes can lead to high aspect ratios that can be more challenging to manufacture. As a result of these factors, there is not universal agreement on what constitutes a “CAF-resistant” material. This can vary by OEM and application.
- Even one type of base material (resin system type) can vary in performance based on other factors, such as the glass cloth quality and the controls used during laminate and prepreg manufacturing.
- The specific glass styles can also impact performance. Although 7628 glass was the focus of much attention in CAF testing, 106 and 1080 styles can be challenging as well, in that getting full resin-to-glass wetting can be challenging with these styles.

When selecting a material for applications requiring CAF resistance, consider the following:

- It is critical to define appropriately the performance level required and to design a test vehicle and test protocol that reflects the requirements of the application. Failure to do so can result in either underspecifying the material attributes and risking PCB failures or overspecifying the material and paying too much for it.
- For resistance to CAF growth, the resin system and the bonding of the resin system to the fiberglass cloth are key considerations. Coupling agents, typically silanes, are used to promote adhesion between the fiberglass filaments and the resin system. The molecular structure of the coupling agent includes a portion that bonds well to the fiberglass surface and other portions that bond well to the resin system. Specific coupling agents have been developed for specific resin types. Achieving a good bond between the fiberglass filaments and the resin system with an appropriate coupling agent helps prevent this interface from becoming a path for CAF growth.
- The use of expanded glass cloths can facilitate full wet-out of the resin to the glass, but such cloths typically cost more. The important point is that each glass style must be able to achieve good wet-out of all of the glass filaments.
- Low rates of moisture absorption and low levels of ionic contamination within the resin system also aid in resisting CAF growth. Epichlorohydrin is a precursor material used to make epoxy resins. The use of this compound can result in residual hydrolyzable chlorides in the epoxy resin. In the presence of moisture, these hydrolyzable chlorides form ionic species that can promote electromigration. When CAF resistance is a critical consideration, the use of high-purity resins may be required.

- Comparisons of dicy-cured materials with non-dicy cured materials, especially the “phenolic” FR-4 materials developed for lead-free assembly, show that the elimination of dicy can have a positive impact on CAF resistance. This may be due to reduced moisture absorption when dicy is removed, or to the elimination of an electrochemical reaction that may be promoted in the presence of dicy, or to both.
- Lead-free assembly can stress the resin-to-glass bond, and even cause some level of resin decomposition, which can create microvoids within a PCB. These phenomena can make it easier for pathways for CAF formation to be created. The use of more thermally stable resin systems may be required when CAF resistance is needed in products that will experience lead-free assembly.

## 9.9 ELECTRICAL PERFORMANCE

---

Base material electrical properties are an important consideration in sophisticated printed circuits operating at high frequencies. High data rates, measured in gigabits per second (Gbps), and high clock speeds make the dielectric constant ( $D_k$ ) and dissipation factor ( $D_f$ ) of base materials very important in high-speed digital circuits. Wireless and RF applications operating at very high frequencies also demand very low  $D_k$  and  $D_f$  values. Moreover, the consistency of these properties over a large frequency range is also important. These properties were defined in Chap. 8 as follows:

- **Dielectric constant/permittivity** This is the ratio of the capacitance of a capacitor with a given dielectric material to the capacitance of the same capacitor with air as a dielectric. It refers to the ability of a material to store an electric charge.
- **Dissipation factor/loss tangent** The property is the ratio of the total power loss in a material to the product of the voltage and current in a capacitor in which the material is a dielectric.

### 9.9.1 Importance of $D_k$ and $D_f$

These properties are important because they affect signal transmission in the printed circuit. At low frequencies, a signal path in a printed circuit can typically be represented electrically as a capacitance in parallel with a resistance. However, as frequencies increase, at some point signal paths must be considered transmission lines where the electrical and dielectric properties of the base materials have a greater effect on signal transmission. A full discussion of capacitive versus transmission line environments is beyond the scope of this chapter, but the premise is to determine, for the transmission of a signal pulse of a given rise time, the acceptable length of a conductor before a significant voltage difference is realized along its length. Conductors longer than this critical value are then regarded as transmission lines. Because the velocity of signal propagation is inversely proportional to the square root of the permittivity of the dielectric, a lower permittivity value results in faster signal speeds and a longer rise distance. With a larger rise distance, larger conductor lengths are acceptable before a significant voltage drop is experienced. However, if the ratio of conductor length to rise distance is large enough, signal reflections from a mismatched load impedance may be received back at the source after the pulse has reached its maximum plateau value, and pulse additions that occur under these circumstances may lead to false triggering of a device.

On the other hand, signal attenuation can result in missed signals. One of the causes of signal attenuation is dielectric loss. As the circuit operates, the dielectric medium absorbs energy from the signal. Attenuation of the signal by the dielectric is directly proportional to the square root of permittivity and directly proportional to the loss tangent. In addition, dielectric

losses increase as frequencies increase. When a high bandwidth is desired, this effect has a greater impact on the higher-frequency components, and the bandwidth of the propagating pulse decreases and degrades the rise time.

Because the permittivity and loss tangent vary with frequency, and other factors to be discussed later in this chapter, the degree to which these properties vary is also an important circuit design consideration. If these properties vary significantly with frequency, designing a circuit with devices that operate at various frequencies becomes that much more complex. In addition, operating within a given bandwidth becomes that much more difficult as different frequency components experience different dielectric properties, which in turn lead to differences in signal propagation and loss.

Therefore, base materials with low permittivity values and low loss factors are desired for high-speed, high-frequency printed circuits. In addition, consistency of these properties across frequencies is also required. Besides frequency dependence, since operating environments can also vary, the consistency of these properties across environmental conditions is also important and is discussed in the following sections.

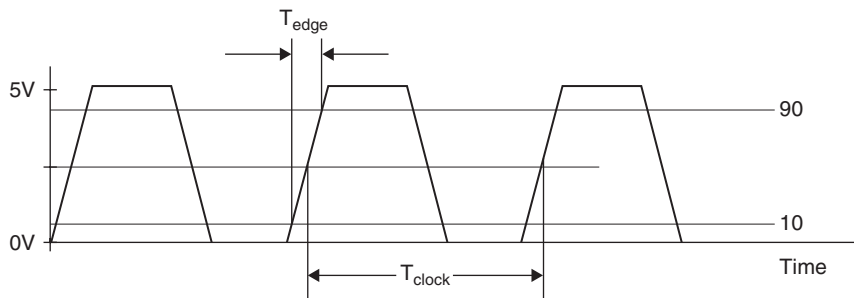

## 9.9.2 High-Speed Digital Basics

Figure 9.21 is a representation of high-speed digital communication that involves sending bits of information coded in waveforms.

The zeros and ones of binary information are coded on the rise time or on both the rise time and fall time. The high voltage represents 1 and the low voltage represents 0. The faster the rise time, the faster the signal. To achieve faster rise times, sinusoidal wave forms are superimposed on one another. The range of frequencies used is called the bandwidth, with the bandwidth given as  $0.35/\text{rise time}$ . In short, a faster rise time allows for a greater range of frequencies, or greater bandwidth.

Figure 9.22 provides an example of eye pattern analysis. In this analysis, the height of the central eye opening measures noise margin in the received signal. The width of the signal band at the corner of the eye measures the jitter. The thickness of the signal line at the top and bottom of the eye is proportional to noise and distortion in the receiver output. Transitions between the top and bottom of the eye show the rise and fall times of the signal.

Figure 9.23 illustrates potential signal integrity differences when different base materials are used. The top chart shows an example of a 10 Gbps signal at the source. Note the pattern in this chart. It changes from 0 in the x-axis (0) to its peak value (1). Now look at the chart in the lower-left corner of Fig. 9.23, representing the use of a standard FR-4 material. Note the change in the pattern, particularly the decreased amplitude. When the signal degrades as illustrated

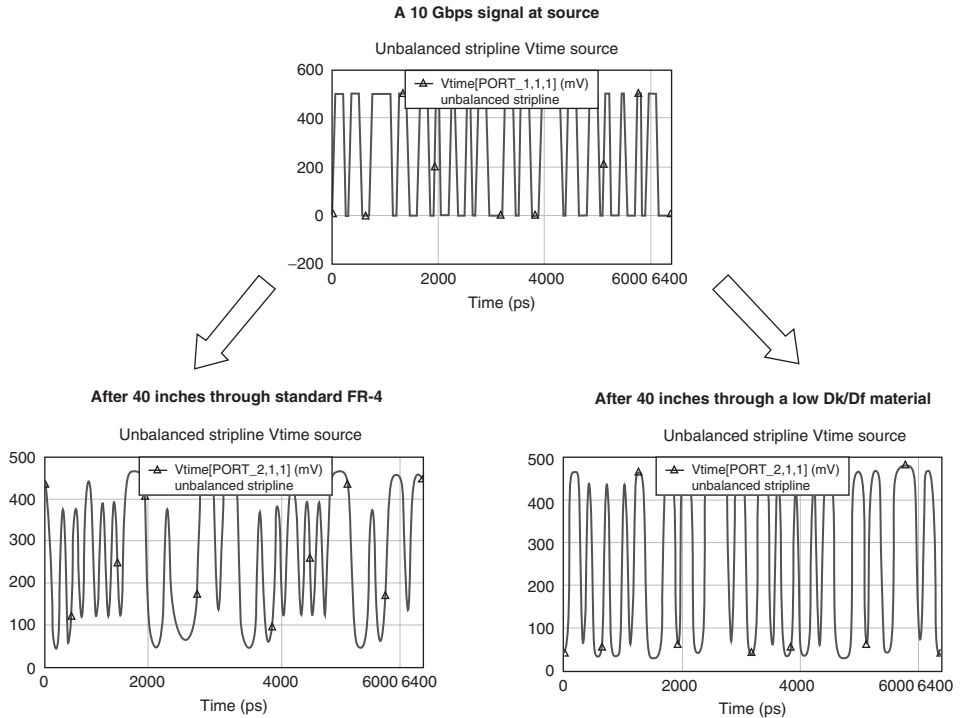

**FIGURE 9.21** Digital communication.

**FIGURE 9.22** Eye pattern analysis.

here, the function of the circuit can be significantly impacted. Now examine the chart in the lower-right corner. This is for a low  $D_k/D_f$  material. Note the improved amplitude compared to the standard FR-4 material and a pattern much closer to the signal at the source. Figure 9.24 takes this analysis further. The chart in the upper-left corner is the signal at the source. This is as good as it gets. The remaining charts illustrate how the signal is affected with materials of

**FIGURE 9.23** Substrate influence on signal integrity.

Simulated Eye Diagrams @ 5 Gbps-1 M-50 Ohms impedance 5 Mil Track width PRBS 35 PS Rise time

increasing  $D_f$ . Note the diagram for the standard FR-4 under these conditions. This would represent an unacceptable condition, as the eye is almost completely closed. As the  $D_f$  is decreased from the FR-4 level, the pattern improves.

Another way to illustrate the impact of  $D_f$  is to graph loss in decibels (dB) per meter versus the  $D_f$ . Figure 9.25 provides a simulation of this relationship for a 5 mil line. Because wider line widths are less “lossy” because of reduced skin effect, some of this can be compensated for by using a wider line. However, this negatively impacts circuit density. Figure 9.26 shows

$$a_{Dielectric}(\text{in dB}) \text{ approx} = 2.3 * f(\text{In GHz}) * Df * v Dk$$

FIGURE 9.25 The effect of  $D_f$  on dielectric loss in dB/m simulated on a 5 mil line.

FIGURE 9.26 Effect of line width on loss for two material types.

the impact of line width on loss for two different low  $D_k/D_f$  materials. In this case, material B would allow the designer to use a thinner line to increase circuit density while maintaining a given level of loss. For example, to keep the loss in this example below 15 dB/m, material A would require a line width of approximately 8 mils. However, with the same loss requirement, material B enables the line to be reduced to approximately 5 mil. This is a significant benefit in increasing circuit density.

### 9.9.3 Choosing a Base Material for Electrical Performance

The dielectric constant and dissipation factor of the dielectric material are determined by both the resin system and the reinforcement type. Therefore, each of these should be considered when choosing a material.

A variety of low-dielectric, low-loss resin systems are available for high-speed circuit applications. These include polytetrafluoroethylene (PTFE or Teflon®), cyanate ester, epoxy blends, and allylated polyphenylene ether (APPE). Likewise, a few different reinforcements and fillers are available that can be used to modify the electrical properties of the base material. Although E-glass is still the most commonly used fiberglass reinforcement, it should be noted that others are available. In addition, inorganic fillers are sometimes used to modify electrical properties as well. Table 9.6 provides electrical property data on some of the available fiberglass materials. Table 9.7 provides data on some of the base material composites available.

TABLE 9.6 Dielectric Constants and Dissipation Factors of Common Glass Types

Reinforcement	$D_k@1\text{ MHz}$	$D_k@1\text{ GHz}$	$D_f@1\text{ MHz}$	$D_f@1\text{ GHz}$

Table 9.7 lists values for approximately 50 percent resin content. These values change as the resin content varies, with the magnitude of the change depending on the specific resin system. Also, comparable resin system types from various suppliers could differ. For example, since there are many types of epoxies, with a wide range of electrical properties, specific epoxy formulations from different material suppliers can exhibit somewhat different dielectric and loss properties. In addition, the test method used to measure  $D_k$  and  $D_f$ , especially at higher frequencies, will have a significant impact on the reported value. When comparing materials, it is critical to compare values derived from the same test method, or at least to understand the differences in the test methods. The differences in test methods are beyond the scope of this chapter, but their importance should not be underestimated. The purpose of this table is to highlight the relative differences between various resin systems and reinforcement types.

These values also vary with resin content and frequency. Figure 9.27 illustrates the resin content dependence of the dielectric constant for a few materials. Figure 9.28 shows the impact of resin content on the dissipation factor of the low  $D_k$  epoxy blend, and Fig. 9.29 shows the impact of frequency on  $D_k$  for a few of these materials. Beyond frequency and resin content effects, the dielectric constant and dissipation factor can vary with temperature and moisture absorption.

**FIGURE 9.27** Dielectric constant versus resin content.

**FIGURE 9.28** Dissipation factor versus resin content for a low  $D_k$  epoxy blend.

When choosing a material for a specific application, it is important to understand the operating conditions and environment in which the circuit will be used. Some resin systems exhibit less sensitivity to these conditions than others. For example, base material suppliers are continually developing resin systems to meet the demanding electrical properties requirements of high-speed and wireless applications, which include consistent properties over frequency ranges and environmental conditions. In short, different material types can have different responses to changes in frequency, resin content, temperature, and humidity conditions. These responses become more important to understand in high-speed, RF, and wireless applications.

In addition, when selecting a material, it is important not simply to select the material with the lowest dielectric constant or dissipation factor, since there are typically cost-performance trade-offs to be made. In general, the lower the dielectric constant and dissipation factor, the more costly the material, and very often the more difficult it is to process.

In summary, some general relationships include the following:

- The dielectric constant generally decreases with increasing resin content.
- The dissipation factor often increases with increasing resin content.
- The dielectric constant typically drops as frequency increases.
- The dielectric constant and dissipation factor typically increase as water absorption rises.

**FIGURE 9.29** Dielectric constant versus frequency.

- The dielectric constant of E-glass is only mildly frequency-dependent and therefore lower resin contents result in less variation across frequencies.
- The dissipation factor generally rises with frequency, but may exhibit maxima at certain frequencies.

### 9.9.4 Electrical Performance of Lead-Free Compatible FR-4 Materials

Most of the FR-4 laminate materials developed for lead-free assembly applications use an alternative resin chemistry in comparison to the conventional dicyandiamide (“dicy”) cured FR-4s. The most common alternatives are commonly referred to as “phenolic” or “novolac” cured materials. Although there is some variation between these materials, as a group they tend to exhibit somewhat different electrical performance, particularly with respect to dielectric loss, or  $D_f$ . For most applications operating in typical frequency ranges, the differences are not significant. However, as operating frequencies increase toward the higher end of “FR-4 applications” and impedance control becomes more critical, these differences can become very significant. Table 9.8 includes two common dicy-cured FR-4 materials (A and C) and two phenolic FR-4 materials compatible with many lead-free assembly applications (B and D). It also includes a lead-free compatible material (E) designed to improve  $D_k$  and  $D_f$  performance in comparison to the “phenolic” lead-free compatible materials. Note that different types of measurement systems can result in different measured values for  $D_k$  and  $D_f$ . Laminate resin contents and other factors also influence these properties. Thus, in Table 9.8 the comparisons between these materials are more important than the absolute values reported for each material. For these comparisons, the same measurement system and resin contents were used.

**TABLE 9.8** Properties of Several Base Material Types

Product	Description	Glass Transition Temp., °C	Decomp. Temp., °C	% Expansion, 50–260°C (40% RC)	$D_k@ 2$ GHz	$D_k@ 5$ GHz	$D_f@ 2$ GHz	$D_f@ 5$ GHz
A	Dicy-cured, 140°C $T_g$ FR-4	140	320	4.2	3.9	3.8	0.021	0.022
B	Phenolic, Mid- $T_g$ FR-4	150	335	3.4	4.0	3.9	0.026	0.027
C	Dicy-cured, High- $T_g$ FR-4	175	310	3.5	3.8	3.7	0.020	0.021
D	Phenolic, High- $T_g$ FR-4	175	335	2.8	3.9	3.8	0.026	0.026
E	Non-Dicy, Non-Phenolic	200	370	2.8	3.7	3.7	0.013	0.014

In Table 9.8, the improved phenolic FR-4 materials are clearly not quite as good in terms of electrical performance at higher frequencies as the conventional dicy-cured materials, particularly with respect to  $D_f$ . However, material E exhibits thermal properties at least as good as the phenolic materials. In addition, the electrical performance of material E is even better than the conventional dicy-cured materials, especially in terms of  $D_f$  performance. Figures 9.30 and 9.31 provide higher frequency  $D_f$  and  $D_k$  data for several lead-free compatible FR-4 materials in comparison to a standard dicy-cured, high- $T_g$  FR-4, using a split-post resonant cavity test method. It also includes data for the non-dicy/non-phenolic material. Note that there is a wide range of  $D_f$  values for the phenolic materials, and to a lesser extent some variation in  $D_k$  values

**FIGURE 9.30** D<sub>f</sub> versus frequency for lead-free compatible FR-4 materials.

as well. In comparison, the non-dicy/non-phenolic material offers lower and more stable D<sub>f</sub> properties and a slightly lower D<sub>k</sub>.

Furthermore, Table 9.9 provides several laminate constructions for a common phenolic material, along with resin content and D<sub>k</sub> data at 2 and 5 GHz. Note how different constructions and resin contents can vary in D<sub>k</sub> values. Table 9.10 provides the same construction data with D<sub>f</sub> data at 2 and 5 GHz. Tables 9.11 and 9.12 provide this same data for the non-dicy/non-phenolic material with additional data at 10 GHz.

**FIGURE 9.31** D<sub>k</sub> versus frequency for lead-free compatible FR-4 materials.

**9.10 ELECTRICAL PERFORMANCE OF LOW  $D_k/D_f$  LEAD-FREE COMPATIBLE MATERIALS**

However, for performance at very high frequencies, lower  $D_k/D_f$  materials are preferred. While low  $D_k/D_f$  materials have been available for many years, the advent of lead-free assembly has complicated material selection, and in these applications not only are the laminate  $D_k$  and  $D_f$  properties critical, but their thermal properties are just as important. Critical material properties for lead-free assembly compatibility will be discussed in a subsequent chapter. Figures 9.32 and 9.33 provide  $D_f$  and  $D_k$  data for three different low  $D_k/D_f$  materials that are also compatible with lead-free assembly.

**FIGURE 9.32**  $D_f$  versus Frequency for Low  $D_k/D_f$ , Lead-Free Compatible Materials.

**FIGURE 9.33**  $D_k$  versus Frequency for Low  $D_k/D_f$ , Lead-Free Compatible Materials.

Table 9.13 provides  $D_k$  and  $D_f$  data for the very low  $D_k/D_f$  material by construction and resin content. This sample of constructions illustrates how these properties vary with resin content in addition to frequency. For a full list of constructions available for any product, it is recommended that the manufacturer’s data sheets be consulted.

**TABLE 9.13** Laminate Constructions and  $D_k$  Data For A Low  $D_k/D_f$  Material

Thickness (in.)	Construction	Resin Content %	$D_k$ @ 2 GHz	$D_k$ @ 5 GHz	$D_k$ @ 10 GHz	$D_f$ @ 2 GHz	$D_f$ @ 5 GHz	$D_f$ @ 10 GHz

### 10.1 INTRODUCTION

---

The European Union's Restriction of Hazardous Substances (RoHS) directive has had a profound impact on all levels of the electronics industry supply chain, including the base materials used in printed circuit boards (PCBs). While debate over the net environmental benefits of this initiative continues, it is clear that all levels of the supply chain must deal with the implications. The July 2006 deadline for the first group of products that must comply has come and gone, and deadlines for other product groups are established. Indeed, many of the product groups with exemptions that allow for more time to comply are being forced to transition ahead of schedule due to component availability and constraints within the assembly services industry. The product groups granted initial exemptions are generally those with the most stringent reliability requirements, and many involve complex PCB designs that even further complicate the issues with respect to base materials. This chapter will present the key issues related to base materials, important properties with respect to lead-free assembly compatibility, and examples of material evaluation. Further discussion of material selection is presented in Chap.11.

---

### 10.2 ROHS BASICS

---

RoHS restricts the use of:

- Lead (Pb)
- Cadmium (Cd)
- Mercury (Hg)
- Hexavalent chromium (Cr<sup>VI</sup>)
- Polybrominated biphenyl (PBB)
- Polybrominated diphenyl ethers (PBDE)

The first four substances are metals used for a variety of applications, whereas the last two are generally used as flame retardants in plastic materials. It is important to note that these halogenated flame retardants are not generally used in laminate materials for printed circuits. In addition, bromine (Br), the halogen used in these flame retardants, is itself not restricted.

Chapter 7 discussed flame retardants in more detail. The key point to be made here is that the most common flame retardant used in base materials, tetrabromo-bisphenol-A (TBBPA), is not restricted by RoHS. Furthermore, in FR-4 materials, TBBPA is generally reacted into one of the epoxy resins, and thus does not exist as a free-standing molecule, but is incorporated into the molecular backbone of the resin system.

The metals that are restricted are not used in base materials either. So from the standpoint of compliance, most laminate materials are acceptable. The key issue is the restriction on the use of lead, and the implications that this has for assembly of components onto PCBs. Eutectic tin/lead (Sn/Pb) has been the primary solder alloy used in assembly of printed circuits, and has a melting point of 183°C. Peak assembly temperatures using eutectic tin/lead commonly reach 230–235°C. With the elimination of lead from electronics assembly, alternative solder alloys have been developed. These lead-free alloys have higher melting points. Tin/silver/copper (Sn/Ag/Cu) alloys, also called ‘SAC’ alloys, are the most common lead-free solder alternatives, with the most common of these alloys having melting points around 217°C and peak assembly temperatures of up to 260°C. Assembly rework temperatures can be even higher. It is the increase in temperature to which PCBs are exposed to that is the primary issue with respect to base materials. In other words, the issue for base materials is not compliance with the restriction on the banned substances, but compatibility with the manufacturing processes and temperatures used.

### 10.3 BASE MATERIAL COMPATIBILITY ISSUES

---

The question of base material compatibility is very complex. This is the result of several factors. First, PCB design and construction have a significant impact on the base material properties required. Thin, low-layer-count PCBs may have different requirements than very thick, high-layer-count PCBs. Copper weights, aspect ratios, and other design features also have an impact. End-use application and the associated requirement for long-term reliability and electrical performance also impacts the decision-making process. The requirements for a cell phone, video game, or even a computer motherboard are very different than those for high-end servers, telecommunications gear, avionics, and critical medical and automotive electronics. Finally, not all lead-free assembly processes are the same. Some designs experience peak temperatures of around 245°C, whereas others experience peak temperatures of up to 260°C, or even higher in some cases. Some PCBs may experience two to three thermal cycles, others up to five, six, or even more depending on how many reworks are allowed. All of this makes it impossible to recommend one base material type for all applications without either underspecifying the laminate material and risking defects during assembly or later on in the field, or overspecifying the material and paying too much for the material or limiting availability.

Beyond the complexity introduced by the PCB design and construction, there are fundamentally two issues:

- Surviving lead-free assembly processes without defects
- Maintaining the required level of long-term reliability for the given application

The critical base material properties required for each are summarized here, and discussed in more detail later in this chapter. The impact on the base material components is discussed in Section 10.4.

#### 10.3.1 Surviving Lead-Free Assembly without Defects

The primary defects related to base materials that can occur during lead-free assembly include measling, blistering, or delamination. These defects are related to the thermomechanical properties of the base material as well as the interaction of these properties with any

absorbed moisture that may be contained within the PCB during assembly, which can be volatilized as the PCB is heated. Fundamentally, these defects represent either the creation of voids within the PCB due to the volatilization of moisture, retained solvents, other organic components including the by-products of resin decomposition, or the loss of adhesion between the fundamental base material components: glass cloth, resin system, and copper. The adhesion loss and subsequent blistering or delamination may be the result of pressure from volatilized components, mismatches between component thermal expansion rates, degradation of the components at the interfaces, or combinations of these factors. Figure 10.1 is an example of delaminations within a PCB after lead-free assembly processing. This PCB used a standard dicyandiamide (dicy) cured, high- $T_g$  FR-4 base material. The left and right-side images in this figure are from the same area of the PCB, but photographed with different lighting to highlight the specific interfaces where delamination occurred.

**FIGURE 10.1** PCB delamination after lead-free assembly.

The key base material properties that relate to survivability in lead-free assembly processes include:

- Decomposition temperature ( $T_d$ )
- Coefficients of thermal expansion ( $CTE_s$ )
- Moisture absorption
- Time to delamination

Time to delamination, or T260 time, which is the time it takes for a sample to delaminate when held at an isotherm temperature of 260°C, is not a fundamental base material property, but is a functional test related to the other material properties. In multilayer PCBs, this property can be affected by the quality of the innerlayer copper surface preparation and multilayer lamination quality, among other things.

### 10.3.2 Lead-Free Assembly and Long-Term Reliability Issues

The second fundamental issue for base materials and PCBs is understanding the impact to long-term reliability assuming a PCB has survived assembly. Other things being equal, the long-term reliability of a PCB assembled in a lead-free process with higher temperatures is not as good as a PCB assembled in a tin-lead assembly process with lower temperatures. The magnitude of the difference is dependent on many factors, but they include the type of base

material used. The key properties of the base material with respect to long-term reliability include:

- CTEs
- Glass transition temperature ( $T_g$ )
- Decomposition temperature ( $T_d$ )
- Moisture absorption

Additionally, the specific construction of the PCB in terms of resin content, the types of fiberglass cloth used, and the adhesion and long-term thermochemical compatibility between the resin system and copper which is plated within vias can have a significant impact on long-term reliability. Some of these factors relate to the impact they have on CTEs, both in the z-axis as well as in the x- and y-axes. For example, using a very high resin content prepreg layer adjacent to a very low resin content layer increases the stress at the interface of these layers due to the differences in thermal expansion that result from the differences in resin-to-glass concentrations. The higher temperatures of lead-free assembly result in a greater absolute level of expansion or stress at these interfaces, which can lead to blistering or delamination. The distribution of the glass filaments within the resin system can have a similar effect. Within a given layer or prepreg, if there are “resin-rich” versus “glass-rich” areas, the differences in thermal expansion between these areas cause stresses that can lead to delamination, or at the interface with a plated-through hole (PTH) will result in points of stress-strain discontinuity resulting from differences in the z-axis expansion values. It is not uncommon to see cracks in the PTH copper begin at these points and ultimately lead to failure.

Section 10.5 discusses the material properties relevant to both surviving lead-free assembly as well as ensuring long-term reliability. Although the test methods used to assess long-term reliability are beyond the scope of this chapter, where relevant, a brief description will be provided to help explain performance differences. However, before discussing these properties in more detail, Section 10.4 presents some of the concerns related to the components used to make base materials.

#### **10.4 THE IMPACT OF LEAD-FREE ASSEMBLY ON BASE MATERIAL COMPONENTS**

---

The higher temperatures of lead-free assembly have an impact on each of the three main components of laminate materials: the resin system, the glass cloth, and the copper foil. Table 10.1 summarizes the key issues for each of these main components.

#### **10.5 CRITICAL BASE MATERIAL PROPERTIES**

---

Substantial work describing the impact of lead-free assembly temperatures on base materials and finished PWBs has been gathered.<sup>2,3,4,5,6,7</sup> These works have identified the critical base material properties that must be considered when selecting a material for lead-free assembly applications, though work on this subject is continuing. Table 10.2 provides a summary of these properties.

A very critical point that must be emphasized with respect to these issues is that although laminate manufacturers can easily make improvements in one property, doing so often can adversely affect other important properties. For example, it is relatively easy to formulate a resin system with a very high time to delaminate in conventional T260 or T288 tests, or to engineer a resin system with a very high decomposition temperature. However, this is often

**TABLE 10.1** Primary Lead-Free Issues for Base Material Components

Component	Lead-Free Assembly Impact	Potential Solutions	Related Considerations
Resin System	<ol style="list-style-type: none"> <li>1. Peak assembly temperatures can reach point where resin decomposition begins.</li> <li>2. Higher temperatures result in increased thermal expansion and stress on plated holes as a result.</li> <li>3. Vapor pressure of absorbed moisture is much higher at lead-free assembly temperatures; can lead to blistering/delamination.</li> <li>4. "Phenolic" lead-free compatible materials are often not as good for electrical performance, especially <math>D_r</math>.</li> </ol>	<ol style="list-style-type: none"> <li>1. Formulate resin system with higher decomposition temperatures.</li> <li>2. Formulate for lower coefficients of thermal expansion.</li> <li>3. Evaluate materials for moisture absorption/release characteristics; drying processes in PCB fabrication and/or assembly.</li> <li>4. Evaluate non-dicy/non-phenolic laminate materials.</li> </ol>	<ol style="list-style-type: none"> <li>1. Reformulation can adversely affect electrical properties and manufacturability.</li> <li>2. Can also impact mechanical properties and manufacturability.</li> <li>3. PCB storage conditions during manufacturing and prior to assembly are much more important, especially humidity conditions.</li> <li>4. Cost/performance trade-off. New materials now available that offer more choices.</li> </ol>
Fiberglass Cloth	Thermal and mechanical stress on resin-to-glass bond. Volatilized components can also stress this bond.	Cleanliness, moisture resistance, and choice of proper coupling agent for resin adhesion are more important.	Loss of resin-to-glass adhesion through thermal cycling could impact CAF resistance.
Copper Foil	Thermal and mechanical stress on resin-to-copper bond.	Copper nodularization and roughness, treatments for improved adhesion, i.e. coupling agents.	Roughness impacts signal attenuation, especially at high frequencies. <sup>1</sup>

achieved at the expense of mechanical properties and can make the material more difficult to use successfully in conventional PWB manufacturing processes, or without sacrificing design flexibility. Interactions between these and other material properties such as hardness, modulus, and fracture toughness with the processes used in PCB fabrication can greatly influence the reliability of a PCB during and after assembly. For example, an increase in decomposition temperature with a simultaneous decrease in fracture toughness does little good if the PCB exhibits cracking or fracturing during scoring processes or similar defects during the mechanical drilling of tight pitch holes for PTHs. Therefore, achieving the best balance of properties to meet the needs of the OEM, Electronic Manufacturing Services company (EMS), and PWB manufacturer is absolutely critical.

### 10.5.1 The Historical Focus on $T_g$

Chapter 6 explained how and why  $T_g$  has historically been one of the properties used to classify base materials, while Chap. 8 provided additional information on the measurement of  $T_g$ . In short, the historical focus on  $T_g$  as an indicator of reliability is probably the result of its effect on total z-axis expansion. However, because of differences in CTE values, even the relationship

**TABLE 10.2** Critical Base Material Properties for Lead-Free Assembly Applications

Property	Definition	Issue
Decomposition Temperature, $T_d$	Measurement of weight loss from resin system degradation as a function of temperature. $T_d$ is typically defined as the point at which 5 percent of the original mass is lost to decomposition, but other levels can also be reported, e.g. 1 percent, 2 percent, or “onset.”	Resin decomposition can result in adhesion loss and delamination. A 5 percent level of decomposition is severe, and intermediate levels are important for assessing reliability since peak temperatures in lead-free assembly can reach onset points of decomposition. A high $T_d$ by the 5 percent definition does not guarantee performance. Conversely, a low $T_d$ by the 5 percent definition is not necessarily bad if the onset temperature of decomposition is high enough.
Glass Transition Temperature, $T_g$	Thermodynamic change in polymer from a relatively rigid, glassy state, to a softened, more deformable state.	Several properties change as the $T_g$ is exceeded, including the rate at which a material expands versus temperature. Modulus also decreases significantly as $T_g$ is exceeded.
Coefficients of Thermal Expansion, CTEs	Rate of change in physical dimension (in x-, y-, or z-axis) as a function of temperature, expressed as a coefficient of thermal expansion. Can also be expressed as a percentage expansion over a given temperature range.	Resin system CTE values above $T_g$ are much higher than below $T_g$ . Z-axis expansion induces stress on plated vias. The higher temperatures of lead-free assembly result in more total expansion for a given material. Several mature lead-free-compatible materials incorporate inorganic fillers that reduce CTE values. X- and y-axis CTEs are also important for reliability at component and layer interfaces.
Moisture Absorption	Tendency of a material to absorb moisture from the surrounding environment. Can be assessed by more than one method, including water soak or in an increased pressure and humidity environment.	Vapor pressure of water is much higher at lead-free assembly temperatures. Absorbed moisture can volatilize during thermal cycling and cause voiding or delamination. PWBs that initially pass lead-free assembly testing may exhibit defects after storage in an uncontrolled environment as a result of moisture absorption. This should be considered when evaluating materials and PWB designs.
Time to Delamination	Not a fundamental property; measurement of the time for delamination to occur at a specific temperature, e.g. 260°C (T260) or 288°C (T288).	This property is related to decomposition temperature and adhesion between material components. Thermal expansion and moisture absorption can also influence results. In multilayer PWBs, the treatment of the internal copper surfaces is also critical, among other factors.

between  $T_g$  and thermal expansion requires further analysis. Figure 10.2 illustrates the relationship between  $T_g$  and thermal expansion for the products in Table 10.3.

From Fig. 10.2, products with the same pre- and post- $T_g$  CTE values (A and C, for example; note that above  $T_g$  the lines are parallel) differ in total expansion based on their  $T_g$  values. For example, the conventional 175°C  $T_g$  material (C) exhibits less total expansion than the conventional 140°C  $T_g$  material (A) because the onset of the higher post- $T_g$  rate of expansion is delayed by 35°C. However, the 175°C material with a lower CTE value (D) exhibits much less total expansion than the conventional 175°C  $T_g$  material even though the  $T_g$  values are the same. Furthermore, the 150°C  $T_g$  material with reduced CTE values (B) exhibits approximately the same total expansion (3.4 percent) as the conventional 175°C  $T_g$

**FIGURE 10.2** The impact of  $T_g$  and CTE values on total expansion.

material (3.5 percent). However, with a decomposition temperature that is significantly higher, this mid- $T_g$  FR-4 material is much more compatible with lead-free assembly than the conventional 175°C  $T_g$  material.

### 10.5.2 The Importance of Decomposition Temperature

Although glass transition temperature ( $T_g$ ) and z-axis expansion have been a primary focus of attention over the years, only with the introduction of lead-free assembly has the decomposition temperature ( $T_d$ ) gained significant attention. The decomposition temperature has always been important in terms of reliability, yet most people have used  $T_g$  as a proxy for material reliability. One reason for this is that other things being equal, a higher- $T_g$  results in less total thermal expansion, and therefore less stress on plated vias. What wasn't discussed is that it is common for conventional dicy-cured, high- $T_g$  FR-4 materials to exhibit somewhat lower decomposition temperatures than conventional dicy-cured, 140°C  $T_g$  FR-4 materials. This is highlighted by the fact that most conventional 140°C  $T_g$  FR-4 materials exhibit longer T260 times than conventional high- $T_g$  FR-4 materials. To highlight the importance of  $T_d$ , examine Fig. 10.3.

The traditional dicy-cured, high- $T_g$  FR-4 materials we have become familiar with have  $T_d$  values in the range of 290–310°C. Traditional 140°C  $T_g$  FR-4 materials are generally somewhat higher, with a typical example of a material with a  $T_d$  of 320°C shown in Fig. 10.3. In the typical tin-lead assembly environment, peak temperatures do not reach the point where decomposition is significant for either the traditional or enhanced products. However, in the lead-free assembly environment, peak temperatures reach the point where a small but significant level of decomposition can occur for the conventional materials, but not for the enhanced products.

**TABLE 10.3** Properties of Some Common FR-4 Base Materials

Product	Description	Glass Transition Temp. (°C)	Decomposition Temp. (°C)	% Expansion, 50–260°C (40% Resin Content)
A	Conventional Dicy-Cured 140°C $T_g$ FR-4	140	320	4.2
B	Phenolic™ Mid- $T_g$ FR-4	150	335	3.4
C	Conventional Dicy-Cured High- $T_g$ FR-4	175	310	3.5
D	Improved High- $T_g$ FR-4	175	335	2.8

**FIGURE 10.3** Decomposition curves for a traditional and improved FR-4 material.

This seemingly small level of decomposition in the conventional products can have extremely significant effects on reliability, especially if multiple thermal cycles are experienced.

On the other hand, as long as the temperatures experienced during assembly and rework do not exceed the temperature at which decomposition begins, there may not be further benefit to higher decomposition temperatures. In addition, the resin system modifications often made to increase  $T_d$  can sometimes lead to other problems, such as brittleness or hardness of the resin system that negatively impacts PCB manufacturability (as in drilling, scoring, and routing) or fracture toughness in tight pitch PTH areas. As not all lead-free-compatible materials use the same resin systems, great care should be used in selecting a material that balances the requirements of the OEM, assembler, and PCB fabricator. A simple review of a material data sheet or IPC slash sheet is not sufficient to guarantee success. Involvement with the base material supplier to understand fully the capabilities of a material and the processing required for success is even more important for lead-free applications. To expand on this, examine Figs. 10.4 through 10.6, which were also presented in Chap. 8.

First, note the slope of the decomposition curve in Fig. 10.6. By the 5 percent decomposition definition, this material has a  $T_d$  of 405°C. However, looking at 1 percent and 2 percent values, the temperatures are 336°C and 367°C, which are significantly lower than a reported 5 percent value of 405°C. This is not to say that a 1 percent  $T_d$  of 336°C is bad. In fact, this material has exhibited exceptional reliability in lead-free applications. However, it does point to the need to understand decomposition levels other than the 5 percent level. In contrast, the material in Fig. 10.5 has a 5 percent  $T_d$  of 330°C with 1 percent and 2 percent  $T_d$ 's of 326°C and 328°C, respectively. In this case, there is a very small difference between the 1 percent, 2 percent, and 5 percent values, and this material has also proven to have excellent performance in a broad range of lead-free assembly applications. Last, the standard high- $T_g$  material in Fig. 10.4 exhibits a 5 percent  $T_d$  of 305°C with 1 percent and 2 percent values of 297°C and 301°C. This is also a small range of values, but in this case the absolute values are lower and begin to approach the range of temperatures that can be experienced, at least locally, in a printed circuit board that undergoes lead-free assembly and rework. Materials such as this have not performed with adequate reliability to be considered for anything but the simplest lead-free applications. In addition, if PCBs made with these materials are stored in uncontrolled environments and are allowed to absorb even a modest level of moisture, the combination of lower  $T_d$ 's with the higher vapor pressure of water at lead-free temperatures can lead to catastrophic defects in assembly or severely degraded long-term reliability.

To take this a step further, examine the materials listed in Table 10.3. These are four FR-4 materials, with material C being the same material as shown in Fig. 10.4, and material D being

**FIGURE 10.4** Decomposition curve for a standard dicy-cured high- $T_g$  FR-4.

the same as the material in Fig. 10.5. The impact of decomposition temperature when these materials are exposed to multiple thermal cycles to different peak temperatures is highlighted in Figs. 10.7 and 10.8. Figure 10.7 graphs cumulative weight loss (decomposition) for these materials when cycled repeatedly to a peak temperature of 235°C. Clearly, there is little impact on

**FIGURE 10.5** Decomposition curve for a phenolic high- $T_g$  FR-4.

FIGURE 10.6 Decomposition curve for an alternative high-T<sub>g</sub>/high-T<sub>d</sub> material.

resin decomposition when the peak temperature reaches 235°C. Figure 10.8 presents the same results when the peak temperature is increased to 260°C. The increase in temperature to 260°C has a severe impact on resin decomposition for the traditional FR-4 materials as they experience multiple thermal cycles, especially the conventional high-T<sub>g</sub> material (product C). The rapid degradation in material C after only a few thermal cycles highlights why this material is not recommended for lead-free assembly applications. Indeed, as more data are gathered, thermal cycling seems to have a much greater impact than even one cycle to a very high temperature, even if the cycling occurs for a long time. As an example, review Fig. 10.9, which plots decomposition versus time at different isotherm temperatures for a standard dicycured high-T<sub>g</sub> FR-4 material (C in Figs. 10.7 and 10.8). In Fig. 10.9 it can be seen that relatively low levels of decomposition are experienced for extended time periods even at the 260°C and 275°C isotherm temperatures. This same material, C in Fig. 10.8, exhibits rapid decomposition when cycled up to 260°C and cooled to room temperature multiple times.

FIGURE 10.7 Decomposition through multiple cycles to 235°C.

FIGURE 10.8 Decomposition through multiple cycles to 260°C.

### 10.5.3 Moisture Absorption

As pointed out in Table 10.2, the vapor pressure of water at lead-free assembly temperatures—260°C, for example—is much higher than at eutectic tin-lead assembly temperatures such as 230°C. Figure 10.10 plots the vapor pressure of water, in both mm Hg and psi, versus temperature. At 230°C the vapor pressure of water is near 400 psi. At 260°C, it is close to 700 psi. Therefore, any absorbed moisture within a PCB during assembly can have a much greater impact in lead-free assembly, as the greater pressure stresses the adhesion between the base material components and can also create small voids within the resin system.

This means that much more care must be used in selecting materials for their moisture absorption properties. However, all common base materials absorb some level of moisture.

FIGURE 10.9 Decomposition versus time at different isotherm temperatures.

FIGURE 10.10 Vapor pressure of water versus temperature.

So the storage of these materials, both during manufacturing of the PCB as well as prior to assembly, must also be examined. Additional drying or baking steps may be needed in some applications to drive off any absorbed moisture prior to exposure to high temperatures. Additionally, it can be difficult to correlate actual performance with the moisture absorption data commonly found on material data sheets. One reason for this is that it may not be just the moisture absorption that is important, but the rate at which moisture can be driven from the material as well. As an illustration, consider the data in Fig. 10.11.

These materials were conditioned for 60 minutes in 15 psi steam and then solder shocked for 20 seconds at 288°C. Their moisture absorption was measured and compared to their

FIGURE 10.11 Moisture absorption versus solder shock resistance for several materials.

FIGURE 10.12 Percent weight change after a five-day ambient moisture test and 125°C bake.

performance in the solder shock testing. The particular halogen-free material shown in this graph exhibits a very high level of moisture absorption and does indeed exhibit poor solder shock resistance. However, with the exception of only one material, all the other materials exhibited good solder shock resistance in this test, even though their moisture absorption levels ranged from less than 0.2 percent to just over 0.4 percent. The one other material that exhibited some level of defects had an intermediate level of moisture absorption, around 0.3 percent. The point is that it is very difficult to draw conclusions about material performance based on reported levels of moisture absorption. Additional reliability testing relevant to the application being considered is needed to make good decisions on material compatibility.

With respect to moisture absorption and the subsequent drying or baking of PCBs, consider the tests summarized by Figs. 10.12 and 10.13. In each test, several different types of base material were evaluated, including dicy-cured and phenolic-cured FR-4 materials, as well as low  $D_k/D_f$  and halogen-free materials. Figure 10.12 shows moisture absorption data for samples that were dried, then soaked in water at room temperature for five days, measured, and then baked at 125°C for 24, 96, and 120 hours. Samples from this test were then submitted to 35°C and 85 percent RH for seven days, measured, and then baked at 125°C for 24 and 48 hours. The results of this second test are shown in Fig. 10.13. Although these graphs show that the different types of materials may absorb somewhat different amounts of moisture, in each case the moisture was

FIGURE 10.13 Percent weight change after seven days at 35°C/85 percent RH moisture test and 125°C bake.

able to be driven off by baking. Beyond this, little correlation could be found between the relative levels of moisture absorption and performance in lead-free assembly applications. Although the materials tested here that showed relatively low levels of moisture absorption have performed well in lead-free assembly applications, some that showed relatively high levels of moisture absorption in these tests have also performed well. The materials in this group that have not done well in lead-free applications fell somewhere in the middle in terms of relative moisture absorption. Thus, although moisture absorption is a critical property, it must also be evaluated within the context of other properties.

#### 10.5.4 Time to Delamination

The time to delamination, and how it is measured, was discussed in further detail in Chap. 8. This test method involves placing a sample of laminate or PCB in a thermomechanical analyzer (TMA) and heating the sample to a specific isothermal temperature, most commonly 260°C (T260) or 288°C (T288). The time it takes for the sample to delaminate is then measured and reported. Figure 10.14 is an example of a complex backplane PCB that was subjected to T260 testing. This PCB used a conventional dicy-cured high- $T_g$  FR-4 material and delaminated before reaching 2 minutes. Note the charring and degradation of the resin system. Alternate resin systems, including alternate types of FR-4 materials, can offer significantly improved performance. Figure 10.15 compares time-to-delamination performance at different temperatures for four different resin systems: two dicy-cured FR-4s and two that use an alternate type of curing mechanism. Note that the materials using an alternative curing mechanism

40 Layer FR4 PWB  
TMA T-260 Sample

**FIGURE 10.14** Delamination and resin decomposition after T260 testing.

FIGURE 10.15 Time to delamination versus temperature for different resin systems.

offer much longer times to delamination at each temperature, although all systems exhibit much shorter times as the temperature is increased.

Times to delamination also vary based on the type of sample measured. Laminates with the copper foil removed generally exhibit longer times than laminates with copper foil. Clad laminates in turn exhibit longer times than multilayer PCBs. Figure 10.16 provides data on clad versus unclad samples for several material types in T260 and T288 testing. In multilayer PCBs, usually the interface between the resin and the internal copper surfaces will fail first. Time to delamination in multilayer PCBs is affected by the quality of the surface treatment of

FIGURE 10.16 T260 and T288 testing on clad and unclad samples of several material types.

the internal copper layers, the quality of the multilayer lamination processing, as well as the type and condition of the bonding prepreg.

Time to delamination testing of multilayer PCBs has become a common test for lead-free assembly compatibility. However, several factors beyond the base material type can have an influence on performance. So care needs to be taken in assessing why a particular PCB might exhibit a low time to delamination. On the other hand, if a particular type of base material exhibits low times to delamination, little can be done in PCB manufacturing to improve performance. In short, a given material offers a certain performance entitlement. Whether this performance level is realized in the finished PCB is dependent on several factors, primarily related to PCB manufacturing processing.

### 10.5.5 The Impact of Lead-Free Assembly on Other Properties

Exposure to assembly temperatures can have a significant effect on the properties of base materials, including the  $T_g$  and modulus properties of the material. This is particularly true if the material is exposed to multiple thermal cycles. In addition, the magnitude of the effect is dependent on the specific peak temperature experienced. Figures 10.17 and 10.18 compare the effect of multiple thermal cycles on dynamic mechanical analysis (DMA)  $T_g$  for various material types when cycled to 235°C (Fig. 10.17) and 260°C (Fig. 10.18). When cycled repeatedly to 235°C, none of these materials exhibits a significant change in DMA  $T_g$ . However, when cycled repeatedly to 260°C, the dicy-cured materials show significant degradation in the measured DMA  $T_g$ , especially the high- $T_g$  dicy-cured material.

Figures 10.19 and 10.20 present similar data for measurements of the percent change in DMA modulus through multiple thermal cycles. Note that even when cycled to a peak temperature of 235°C, the high  $T_g$  dicy-cured FR-4 material exhibits a consistent decline in DMA modulus. The 140°C  $T_g$  dicy-cured material exhibits a decrease only after several cycles.

FIGURE 10.17 DMA  $T_g$  versus multiple thermal cycles to 235°C.

**FIGURE 10.18** DMA T<sub>g</sub> versus multiple thermal cycles to 260°C.

When cycled to a peak temperature of 260°C, both of the dicy-cured FR-4 materials exhibit rapid declines in DMA modulus. In all of these cases, the non-dicy (phenolic) FR-4 materials show little impact whether cycled to 235°C or 260°C. If anything, they exhibit very slight increases in T<sub>g</sub> and modulus.

**FIGURE 10.19** Percent change in DMA modulus versus multiple thermal cycles to 235°C.

FIGURE 10.20 Percent change in DMA modulus versus multiple thermal cycles to 260°C.

## 10.6 IMPACT ON PRINTED CIRCUIT RELIABILITY AND MATERIAL SELECTION

In addition to the works already cited, there have been excellent studies on the impact of lead-free assembly, specifically on PWB reliability.<sup>8,9,10</sup> These works present statistical analyses showing the impact of lead-free assembly on PWB reliability and reach important conclusions regarding the base materials. Although there is not perfect agreement among all published works, the differences typically are the result of a different focus—for example, whether the focus is on complex, thick PWBs with stringent reliability requirements versus relatively less complex PWBs with shorter intended field lifetimes or less stringent reliability requirements. Conclusions include:

- A minimum decomposition temperature is critical for lead-free assembly compatibility, although higher  $T_d$ 's are not *always* better. Trade-offs with other properties, such as manufacturability, fracture toughness, and so on, make achieving the right balance of properties critical.
- $T_g$  and CTE values are important because of the effects on thermal expansion, especially in thicker PWBs.
- Most conventional (dicy-cured) high- $T_g$  FR-4 materials are generally not compatible with lead-free assembly, or can be used successfully only in a very limited range of applications.
- Conventional 140°C  $T_g$  materials may still be suitable for PWB designs with limited thickness and reliability requirements, particularly when intermediate peak temperatures are used in assembly. This is largely the result of these materials having slightly higher decomposition temperatures than the higher- $T_g$  equivalents.
- Mid- $T_g$  FR-4 materials with high decomposition temperatures are viable products for many lead-free assembly applications involving intermediate-complexity PWB designs.
- Materials with a sufficiently high-decomposition temperature, high- $T_g$ , and reduced CTE values are suitable for the broadest range of applications, including complex PWBs assembled at 260°C peak temperatures.

- Balancing material properties with PWB manufacturability is critical. Materials that exhibit excellent properties have failed because of difficulties experienced when fabricating the PWB, such as fracturing in drilling, routing or scoring, difficulty in texturing drilled holes for copper plating, resin recession, or hole wall pull-away during thermal stress.

### 10.6.1 Example of Material Types and Properties versus Assembly Reliability

To highlight a couple of these conclusions, consider the following test. First, multilayer PWBs made from the materials in Table 10.3 were processed through Infra-Red (IR) reflow cycles at different peak temperatures. The PWB was a 10-layer, 0.093-in. (2.6 mm) thick board “designed to fail,” meaning the copper weights and patterns, construction, and resin contents were chosen so that the board would be more sensitive to thermal cycles. In addition, the dwell time at the peak temperature was 1.5 minutes. This allowed differences in material performance to be detected more clearly. Figure 10.21 graphs the percentage of boards surviving six reflow cycles without any evidence of blisters, measles, or delamination.

FIGURE 10.21 Survival after six reflow cycles at different peak temperatures.

Notably, the first material to exhibit defects is the conventional dicy-cured, high- $T_g$  FR-4 material. This material began to exhibit defects when the peak temperature reached 240°C. At a peak temperature of 260°C, the conventional dicy-cured FR-4 materials, both the 175°C  $T_g$  and the 140°C  $T_g$  products, all exhibited evidence of defects. On the other hand, the materials with higher decomposition temperatures, both the 150°C  $T_g$  and the 175°C  $T_g$  products, all survived six cycles to 260°C.

### 10.6.2 Example of Material Types and Properties versus Long-Term Reliability

In another test, three high- $T_g$  materials were evaluated through Interconnect Stress Test (IST) testing.<sup>11</sup> This particular test provided insight into the effect of thermal expansion and decomposition temperature on long-term reliability, as assessed by the IST method. The IST test method uses an electric current to heat test coupons that contain a network of plated through holes. The test samples are generally preconditioned several times to simulate exposure to

**TABLE 10.4** Materials Evaluated through IST Testing

Product	Description	Glass Transition Temp. (°C)	Decomposition Temp. (°C)	% Expansion, 50–260°C (40% Resin Content)
C	Conventional High- $T_g$	175	310	3.5
D*	High- $T_g$ /High- $T_d$	175	335	3.4
D	High- $T_g$ /High- $T_d$ / Reduced CTE	175	335	2.7

assembly processes, and then cycled back and forth between an elevated temperature, most commonly 150°C, and room temperature. The samples are cycled in this manner until failure occurs, with failure generally being defined as a change in measured resistance of 10 percent. The materials evaluated in this example are described in Table 10.4.

Note that the  $T_g$  values of these materials are the same, but differences exist in decomposition temperatures and thermal expansion values. Product D\* is similar to product D except that it has a higher level of thermal expansion. Product D\* exhibits approximately the same thermal expansion as Product C, but Product D\* has a higher decomposition temperature. Product D has both a high decomposition temperature and a very low level of thermal expansion. The PWB tested was a 14-layer, 0.120-in. (3.1 mm) thick multilayer with 0.012-in. (0.30 mm) diameter plated through holes. The average copper plating in the via was 0.8 mil (20.3 micron), although 1.0 mil (25.4 micron) had been requested. Figure 10.22 charts the average number of cycles to failure (10 percent resistance change in the plated via net) for each material type at each preconditioning level: as is (no preconditioning), three cycles to 230°C, six cycles to 230°C, three cycles to 255°C, and six cycles to 255°C.

Clearly, the two materials with improved decomposition temperatures exhibit much better performance than the conventional high- $T_g$  product. Also, in comparing product D to product D\*, it appears that the lower thermal expansion of product D does offer improvement in the number of cycles to failure, but this improvement is smaller in comparison to the improvement due to the higher decomposition temperature, at least for this PWB design. The benefit of reduced thermal expansion becomes more important as the thickness of the PWB increases. In addition, the technique used to reduce the CTE values in this case also provides benefits in PWB manufacturability.

**FIGURE 10.22** IST results for three 175°C  $T_g$  materials.

### 10.6.3 Understanding the Potential Impact on Electrical Performance

Most of the FR-4 laminate materials developed for lead-free assembly applications use an alternative resin chemistry in comparison to the conventional dicyandiamide (dicy) cured FR-4s. The most common alternatives are commonly referred to as phenolic or novolac cured materials. Although there is some variation between these materials, as a group they tend to exhibit somewhat different electrical performance, particularly with respect to dielectric loss, or  $D_f$  (dissipation factor). For most applications operating in typical frequency ranges, the differences are not significant. However, as operating frequencies increase toward the higher end of FR-4 applications and impedance control becomes more critical, these differences can become very significant. Table 10.5 includes the same materials as Table 10.3, but also shows the differences in dielectric constant ( $D_k$ ) and dissipation factor ( $D_f$ ). It also includes a lead-free-compatible material designed to improve  $D_k$  and  $D_f$  performance in comparison to the phenolic lead-free-compatible materials. Note that different types of measurement systems can result in different measured values for  $D_k$  and  $D_f$ . Laminate resin contents and other factors also influence these properties. So when examining Table 10.5, the comparisons between these materials are more important than the absolute values reported for each material. For these comparisons, the same measurement system and resin contents were used.

**TABLE 10.5** Properties of Several Base Material Types

Product	Description	Glass Transition Temp. (°C)	Decomp. Temp. (°C)	% Expansion, 50–260°C (40% RC)	$D_k$ @ 2 GHz	$D_k$ @ 5 GHz	$D_f$ @ 2 GHz	$D_f$ @ 5 GHz
A	Conventional 140°C $T_g$ FR-4	140	320	4.2	3.9	3.8	0.021	0.022
B	Improved Mid- $T_g$ FR-4	150	335	3.4	4.0	3.9	0.026	0.027
C	Conventional High- $T_g$ FR-4	175	310	3.5	3.8	3.7	0.020	0.021
D	Improved High- $T_g$ FR-4	175	335	2.8	3.9	3.8	0.026	0.026
E	Non-Dicy, Non-Phenolic	200	370	2.8	3.7	3.7	0.013	0.014

From this table it is clear that the improved phenolic FR-4 materials are not quite as good in terms of electrical performance in the range of 2–5 GHz as the conventional dicy-cured materials, particularly with respect to  $D_f$ . However, material E exhibits thermal properties at least as good if not better than even the improved materials discussed up to this point. In addition, the electrical performance of material E is even better than the conventional dicy-cured materials, especially in terms of  $D_f$  performance. This non-dicy, non-phenolic material is an attractive material for use in applications requiring not only lead-free compatibility, but electrical performance superior to the phenolic materials that have been adopted in existing lead-free designs.

## 10.7 SUMMARY

While most base materials comply with the RoHS directive, the question of compatibility with lead-free assembly processes is a more complex issue. The material properties that are important for lead-free assembly compatibility include:

- Decomposition temperature ( $T_d$ )
- Coefficients of thermal expansion (CTEs)

- Glass transition temperature ( $T_g$ ) (especially because of the impact on thermal expansion)
- Moisture absorption
- Time-to-delamination performance, which is not a fundamental material property, but is a simple method used to assess thermal stability of a composite material at different temperatures

While laminate manufacturers can easily make improvements in one of these properties, it is not as easy to make improvements without affecting other properties, including properties important for ease of manufacturing in the PCB fabrication process. Achieving the optimal balance of properties that consider the requirements of each level of the supply chain—from OEM to EMS to PCB fabricator—is crucial for success in lead-free assembly applications.

Conventional dicy-cured FR-4 materials, especially the high- $T_g$  dicy-cured materials, are significantly impacted by lead-free assembly temperatures, and are generally not recommended for lead-free applications. Alternative resin systems, especially the phenolic-cured FR-4 materials, have gained widespread acceptance in these applications, and where both thermal performance and electrical performance are critical, non-dicy, non-phenolic materials are also available. Chapter 11 discusses material selection in lead-free applications in more detail.

# CHAPTER 11

---

# SELECTING BASE MATERIALS FOR LEAD-FREE ASSEMBLY APPLICATIONS

---

**Edward J. Kelley**

*Isola Group, Chandler, Arizona*

---

## 11.1 INTRODUCTION

---

Chapter 10 discussed the impact of lead-free assembly on printed circuit boards (PCBs) and base materials, and also discussed many of the critical base material properties relevant to performance in lead-free applications. These properties included:

- Decomposition temperature ( $T_d$ )
- Glass transition temperature ( $T_g$ )
- Coefficients of thermal expansion (CTEs)
- Moisture absorption
- Time to delamination, such as T260 and T288 tests

Also, the need to achieve the right balance of properties with ease of use in the PCB fabrication process, in addition to the requirements of assemblers and original equipment managers (OEMs), was highlighted.

This is the result of the impact that PCB fabrication can have on the performance of the material and finished PCB during assembly and in end-use application. A given material type offers a certain level of performance in the finished PCB. However, this level of performance may or may not be realized, depending on how the materials were processed during fabrication. This makes it extremely complicated to make general recommendations on what material should be used in a given application. However, this chapter describes an approach that has been used quite successfully in addressing this question. But first, some of the PCB fabrication and assembly issues that can affect performance are outlined.

---

## 11.2 PCB FABRICATION AND ASSEMBLY INTERACTIONS<sup>1</sup>

---

The reliability of the assembled PCB in the end-use application is a function not only of the base materials selected, but how the materials were processed during PCB fabrication and component assembly. Different base material types may require different processing conditions in

order to achieve the best results in the finished product. In reviewing these items, understand that these are general considerations that should be evaluated within the context of the specific fabrication and assembly processes and with regard to the specific materials being considered. The specific requirements for long-term reliability must also be considered. So while it is not possible to give exact, optimal processing conditions for all applications, the items that follow represent parameters that should be considered as products are converted to lead-free assembly.

**11.2.1 PCB Fabrication Considerations**

As just stated, selecting the appropriate base material for a given application is only one of several key issues when converting to lead-free assembly. Several factors related to PCB fabrication are also critical.

**11.2.2 Moisture Absorption**

As discussed in Chap. 10, a given level of moisture absorption can be much more serious in lead-free assembly applications than it is for conventional tin-lead assembly applications. This is due to the increase in water vapor pressure at the higher temperatures of lead-free assembly. Figure 11.1 is a graph showing the vapor pressure of water versus temperature. At lead-free assembly temperatures, the pressure is much higher, which causes substantially more stress within the laminate and on the interfaces within the PCB, including resin-glass, resin-oxide, resin-copper, and resin-resin interfaces. As a result, additional drying or baking processes may be needed to drive off moisture prior to processes involving thermal cycles.

**11.2.2.1 PCB Construction and CTE Values.** While all PCB constructions contain some level of CTE mismatch between each of the layers, the total amount of expansion and stress at the interfaces are greater in lead-free applications due to the higher temperatures involved. So even though the CTE values may be the same for a given construction, transitioning a part from standard tin-lead assembly to lead-free assembly results in greater levels of stress within the PCB. In some cases, this increased stress can lead to defects such as delamination, especially if combined with the increased stress resulting from any absorbed moisture. These thermal expansion-related stresses can be most severe in hybrid constructions where two or more different types of base material are used in the same construction, particularly if the

**FIGURE 11.1** Vapor pressure of water versus temperature.

**TABLE 11.1** X- and Y-axis CTE Values for Some Common Glass Styles

Glass Style	X-axis CTE (ppm/°C)	Y-axis CTE (ppm/°C)
106	22.2	22.2
1080	16.9	19.4
2113	15.3	15.9
2116	14.7	14.9
1652	14.1	14.1
7628	12.1	15.9

CTE values of the two material types are very different. However, even if the same type of material is used throughout the PCB construction, care in selecting the specific glass styles and resin contents should be exercised. This is due to the differences in x-y CTEs between the various glass styles and resin contents that can be used. Adjacent layers with very different CTE values lead to increased levels of stress at higher temperatures, with the possibility of adhesion loss and delamination as the result. Table 11.1 provides x- and y-axis CTE values for some common glass styles to highlight the possible differences. When possible, you should consider choosing glass styles with the smallest differences in CTE values for adjacent layers.

**11.2.2.2 Oxide and Oxide Alternative Processes.** During PCB fabrication, the internal copper surfaces are generally chemically treated to improve the adhesion between the resin system and the copper layer. Two primary types of processes are used. The first involves an oxidation of the copper surface to micro-roughen the surface, usually followed by a reduction step to improve chemical resistance of this layer in subsequent processes. The second type of process is referred to as an oxide alternative, or oxide replacement process. These processes generally use etching chemistries, which also roughen the copper surface to provide greater surface area for resin bonding, and often use proprietary chemistries designed to further enhance adhesion and chemical resistance. In short, compatibility of the resin system with the oxide or oxide alternative is critical for any application, but becomes even more important in lead-free assembly applications due to the increased stress on the resin to innerlayer copper bond.

Typical validation of this bond includes assessing the peel strength between the oxide or oxide alternative treated copper and the resin system, along with time-to-delamination testing such as T260 and T288 testing. Samples prepared for these tests should use representative prepreg materials and be laminated using the same press cycles used for actual PCB fabrication.

The potential for moisture absorption in these processes is the other critical consideration. Oxide and oxide alternative treatments can be compromised if exposed to high temperatures, or even moderate temperatures for extended times. Oxidation of these surfaces during postdrying or baking can lead to adhesion or chemical resistance problems in subsequent processes. On the other hand, moisture absorbed by the laminate materials during these processes can impact the quality of multilayer lamination and subsequent performance during thermal cycles. In short, it is important to dry the innerlayers as much as possible after these processes while staying within the guidelines provided by the oxide and oxide replacement chemistry supplier.

**11.2.2.3 Multilayer Lay-Up Prior to Lamination.** In addition to the oxide and oxide alternative processing discussed in the previous section, the hold time between this process and multilayer lay-up and lamination is also important. This is due not only to the possibility of oxidation of the innerlayer surfaces, but to the potential for moisture absorption by the exposed resin surfaces on the innerlayer, for the reasons already discussed. This hold time should be minimized, and the storage of the innerlayers prior to lay-up should be in a temperature- and humidity-controlled environment to reduce the likelihood of absorbing moisture. Typical environmental conditions for this storage are 68°F or 20°C, and a maximum of 50 percent relative humidity (RH), although lower humidity levels are recommended.

Similarly, the prepreg materials used in constructing the multilayer PCB must be stored in a temperature- and humidity-controlled environment. This is due not only to the potential for moisture absorption, but also because the shelf life and performance of the prepreg can be significantly impacted by temperature and humidity conditions prior to use. This can often be a subtle point, but it is a critical one, especially as lead-free applications demand greater performance from the base materials. Again, storage conditions generally should be no worse than 68°F or 20°C and 50 percent RH for typical FR-4 materials, although some high-performance materials can be even more sensitive and perform better if stored in even cooler or drier environments. Some of the high-performance materials may even require vacuum desiccation prior to use. This is a fairly common practice for polyimide materials, for example. Finally, storage of the multilayer books prior to lamination should ideally be done in a controlled environment, with the hold time between lay-up and lamination also minimized.

**11.2.2.4 Multilayer Lamination Processing.** Multilayer lamination cycles must be designed around the specific material being used. However, there are some general recommendations that can be applied to most materials:

- **Pre-lamination vacuum** Expanding on the discussion of moisture absorption, it is important to apply a vacuum to the lamination books prior to ramping up the temperature and curing the resin in the prepreg. This removes moisture that could volatilize during the lamination cycle. Drawing a vacuum can also remove other volatile components such as residual solvents in the prepreg materials. This is an often overlooked factor that can be vitally important. Recommended vacuum times can depend on the actual moisture levels of the materials used, but generally range from 15 to 30 min. It is important during this time that the materials are not heated too much. In addition, as mentioned in the previous section, some materials, such as polyimides, are often vacuum-desiccated prior to lay-up.
- **Heat rise and pressure application** For a given type of resin system, it is important to understand the rheology of the resin in the prepreg as a function of the rate of temperature rise. This, along with the proper application of pressure, ensures adequate filling of the internal circuitry and good wet-out of the resin into the fiberglass filaments. Complete wet-out of the internal circuitry and good resin flow on the oxide or oxide alternative surface are important for reliability in subsequent thermal cycles.
- **Stress relief pressure profiles** It is important to have sufficient pressure on the lamination book, as the resin in the prepregs are heated and begin to flow into the innerlayer circuit patterns. The actual pressure needed can vary with the type of material being used and the level of vacuum achieved during the process. However, after the resin cures to a certain point and stops flowing, a reduction in pressure can help reduce the levels of stress in the multilayer PCB. This can improve reliability in subsequent thermal cycling. The reduction in pressure is typically to the range of 50 to 75 psi.
- **Cool down rate** After the product has been held at the proper temperature for the proper period of time, which will depend on the type of material used, the rate at which the product is cooled is also important. In general, slower cooldown rates will minimize warpage and residual stress in the finished product. However, slower cooldown rates can adversely impact productivity, so a reasonable balance must be identified. In many cases, a slow cooldown through the  $T_g$  of the resin system, followed by a somewhat faster cooling rate after the product cools below  $T_g$ , represents a good balance of performance and productivity.

**11.2.2.5 Drilling.** Many of the materials designed for compatibility with lead-free assembly require optimization of drilling parameters. Phenolic and other high-performance resin systems can have higher modulus values and be harder than conventional dicy-cured FR-4 materials.

Undercut drill bits generally provide better hole quality with these materials. Other drill process variables must also be examined, and include:

- Maximum hit counts
- Drill chip loads (feeds and speeds)
- Infeed and retract rates
- Drill resharpenings
- Stack heights
- Vacuum levels
- Entry and backer material types

**11.2.2.6 Desmear Processing.** Many of the resin systems developed for lead-free assembly compatibility, including the phenolic-type materials, are more chemically resistant than the conventional dicy-cured materials. However, most can still be processed using conventional chemical desmear processes. Adjustments may be needed in the times and/or temperatures used for solvent swelling and permanganate desmear processes, and the supplier of these chemistries should be consulted when transitioning to lead-free compatible materials. The processing guidelines provided by the laminate material supplier will also typically provide recommendations for desmear processing. For some advanced products, plasma desmear may be recommended.

**11.2.2.7 Surface Finishes.** If a lead-free Hot Air Solder Leveling (HASL) process is used, the higher temperatures required by the lead-free alloys should be considered when selecting the base material. This will be discussed in Section 11.3 as well. The common alternatives to HASL, which are growing in use as lead-free assembly is adopted, typically do not involve a bake process or significant thermal cycle. Although this is good in terms of the reduced thermal cycling exposure to the base material, it also results in one less opportunity for moisture to be removed from the PCB prior to assembly. This should be considered when deciding whether a drying step is needed prior to assembly.

### 11.2.3 PCB Assembly Considerations

Although a complete discussion of assembly variables is beyond the scope of this chapter, a few key points need to be outlined with respect to material selection and lead-free assembly variables. First, as has been pointed out several times, the storage conditions of the PCB prior to assembly should be examined. Moisture absorption in the PCB prior to assembly can have a significant impact, and in severe cases can lead to delamination within the PCB. Storage in a controlled environment is encouraged, and drying of PCBs prior to assembly may also need to be considered. One of the challenges in drying PCBs prior to assembly is avoiding any negative impact to the surface finish that could adversely affect solderability. Consulting with the supplier of the surface finish supplier is strongly suggested before defining these drying processes. However, Table 11.2 offers some general recommendations for drying steps prior to assembly based on the type of surface finish.

**TABLE 11.2** Drying Recommendations Prior to Assembly Based on Surface Finish Type

Final Finish	Temperature	Time (hr)	Comments
Tin	125°C	4	Higher temperature may reduce solderability
Silver	150°C	4	Silver may tarnish, but solderability should not be affected
Nickel/Gold	150°C	4	No issues arise with extended bake on nickel/gold finish
Organic Coating	105°C	2	Extended bake cycles may negatively impact multiple heat cycle assembly processes

Development of the assembly profile is important not just for the obvious requirements of component assembly, but also to ensure that the PCB is not damaged as a result of the thermal exposures. These objectives often compete with each other. Profiles vary with PCB thickness, copper distribution, component densities, and other factors. Defining these profiles to meet both objectives can be a very complex process. But with respect to the impact on the PCB and the base materials, care should be exercised in defining the heat ramp rate, the time the PCB is exposed to the peak temperature, and the cooldown rate. Minimizing temperature gradients across the PCB is important in reducing the stresses that arise from thermal expansion. Unequal copper distribution across the PCB and differences in component mass across the PCB can lead to “hot spots” that can approach decomposition temperatures or create areas of stress resulting from thermal expansion differences. These hot spots or severe temperature gradients can be exacerbated by trying to speed up the process by setting the reflow oven zone temperatures very high. You can reduce these hot spots and thermal gradients by setting up “soak” profiles where the PCB is allowed to stabilize at specific temperatures before heating to the peak temperature.

Cooldown rates must also be controlled for similar reasons. Cooling too fast can lead to significant temperature gradients and induce thermal expansion related stresses that can result in blisters, delamination, or pad cratering, which is fracturing in the PCB base material that propagates underneath a copper pad on the surface of the PCB. Finally, rework procedures must be examined and controlled more strictly in lead-free applications. Control of the rework temperature and time that the PCB is exposed to this temperature is critical. Since rework involves local heating of a specific area of the PCB, the issue of temperature gradients can be even more severe.

For all of these reasons, it is strongly recommended that manufacturers perform studies to assess compatibility among the base material, the PCB fabrication process, and the assembly process. First article qualifications when transitioning specific PCB designs to lead-free assembly are strongly recommended. Success with one PCB design does not necessarily mean that other designs can use the same material or fabrication process successfully. In short, lead-free assembly processes are significantly more demanding on the PCB and base materials used and require extensive engineering work to validate compatibility with the assembly process and the requirements for long-term reliability.

### **11.3 SELECTING THE RIGHT BASE MATERIAL FOR SPECIFIC APPLICATIONS<sup>2,3</sup>**

---

A very common request from PCB fabricators, electronic manufacturing services (EMS) companies, and OEMs is whether a given material is compatible with lead-free assembly. Although everyone is looking for a simple answer, the solution becomes complex because of the range of PCB designs (board thicknesses, layer counts, aspect ratios, via pitch, and so on) as well as the differences in lead-free assembly processes, such as the specific peak temperature and number of thermal cycles a PCB will experience. Previous sections also outlined how the PCB fabrication process and assembly process can influence compatibility. In addition, people usually want to use the least expensive material that is suitable for a given application. So although it is easy to specify an advanced product for lead-free compatibility, the approach taken here is to balance cost and performance. In an attempt to simplify this discussion, this section describes a material selection tool that has been developed to suggest what materials should be considered for a given application.

This tool is based on data such as that presented in Chap. 10, in the references, as well as empirical results from prototype and production experience with lead-free assembly applications. The experience of several people with “hundreds of years” of combined experience has been leveraged in designing these tools. However, no such tool can address every specific application with 100 percent confidence. In addition, the capabilities of various PCB fabrication

Color code	Application recommendation
Green	Material generally recommended for typical applications of this type
Yellow	Material may be acceptable for applications of this type, but is not generally recommended
Red	Not recommended

FIGURE 11.2 Color code key.

processes can also impact the performance of the finished PCB. So although these tools are based on considerable data and experiences from a number of sources, they are intended to serve as a general guide for typical applications, and as such, it remains the user’s responsibility to confirm acceptability of any material recommended. This is particularly true with respect to long-term reliability requirements. For example, the field reliability requirement for a cell-phone PCB is going to be very different for a very complex high-end computer or telecommunications infrastructure PCB.

The intent in developing this tool was to come up with a simple method for dealing with this multitude of variables in PCB design and assembly. Figure 11.2 shows the basic color-coding selected for this. Figure 11.3 shows an example of the actual chart format. In the horizontal axis it divides PCBs into thickness categories, and in the vertical axis it differentiates them by the number of reflow processes.

This format forces definition of a “typical” PCB design for each range of thickness shown on the x-axis. Although this is very difficult and “exceptions to the rules” are evident as soon

FIGURE 11.3 Example of a chart format.

FIGURE 11.4 “Typical” PWB features for the selection tool.

as a “typical” definition is provided, these definitions represent fair descriptions of a broad range of products. In addition, you will see that an attempt is made to define a procedure for accommodating the exceptions. Figure 11.4 outlines the “typical” features for PCBs in each thickness range in the charts.

To accommodate the exceptions to these criteria, a method was developed to “adjust” the selection tool based on specific design features or processing conditions. The basic concept for these adjustments is shown in Fig. 11.5, and the specific adjustments are shown in Fig. 11.6.

For the purposes of illustration, the materials outlined in Table 10.5, presented here as Table 11.3.

Figure 11.7 shows the charts for product A with two different assembly temperature ranges, 210 to 235°C for tin-lead assembly and 235 to 260°C for lead-free assembly.

**FIGURE 11.5** Concept for adjustments to material selection.

As you can see when these charts are presented side by side, the range of designs for which this product is deemed suitable decreases as the assembly temperature increases. This should be expected based on the earlier discussion of material properties. The other key point is that there may still be a group of products, albeit more limited, where standard 140°C  $T_g$  material may be adequate and the most cost-effective option. This may help clarify some of the confusion about whether standard FR-4 materials are lead-free-compatible or not. For specific designs with specific requirements for reliability, the answer is yes. For other designs, applications, or reliability requirements, the answer is no. The value of this tool is that it attempts to define the range of PCB designs where specific materials should be considered.

Figure 11.8 presents similar charts for product C, which is the higher- $T_g$  conventional FR-4 material. This is where the conversation gets very complicated. In Table 11.3, you can see that the decomposition temperature for this product is 310°C, which is the lowest of the materials described. On the one hand, the higher- $T_g$  of this product helps reduce the total amount of z-axis expansion and therefore stress on plated vias. On the other hand, the lower decomposition temperature makes this material the most sensitive to higher assembly temperatures. In fact, the temperature range of 235 to 260°C is a very broad one for this product. Limited success may be seen when assembling at the low end of this range, but as temperatures increase, especially toward the high end of this range, this product is simply not recommended, due to the potential for resin decomposition and resultant defects. In fact, for these reasons and the potential interactions with PCB fabrication and assembly processes, not to mention the potential for moisture absorption to further impact performance, standard high- $T_g$  FR-4 materials should not be considered at all for lead-free applications. Products such as B, D, and E are significantly more robust in these applications and offer attractive cost-performance relationships. In summary, you should exercise extreme caution when considering a conventional high- $T_g$  FR-4 for a lead-free application and should discuss these issues with your laminate material supplier. In contrast, consider the charts for products B, D, and E in Figs. 11.9, 11.10, and 11.11, respectively.

**PWB Adjustments for tool reference**

Please consult the “PWB Design considerations” section before using this tool

Layers	If greater than typical consider moving up and right on charts
Micro vias	For PWBs thicker than 1.60 mm (0.062 inches) additional evaluation may be required
Cu Wt	If greater than 2 Oz (70 $\mu\text{m}$ ) consider moving up and right on charts
RC	If greater than maximum range consider moving right on charts
Aspect ratio	If greater than maximum range consider moving right on charts
Retained Cu	If greater than maximum consider moving up and right on charts
PTH Cu ( $\mu\text{m}$ )	If less than typical consider moving up and right on charts
Surface finish	If HASL or reflowed solder consider moving up on chart for each cycle (treat as an additional reflow cycle)
Multiple lamination cycles	If multiple lamination cycles consider moving up on chart for each additional cycle (treat as an additional reflow cycle)
Mixed materials	If mixed material use lowest performing material as reference and consider moving up and right on that chart
Blind and buried vias	If yes consider moving up and right on charts
External planes	If yes consider moving up and right on charts

D	Phenolic High- $T_g$ FR-4	175	335	2.8	3.9	3.8	0.026	0.026
E	Non-Dicy, Non-Phenolic	200	370	2.8	3.7	3.7	0.013	0.014

**FIGURE 11.7** Charts for product A (140°C T<sub>g</sub> conventional FR-4).

Product B, while having a T<sub>g</sub> of 150°C, is better suited for lead-free assembly than product C, with its 175°C T<sub>g</sub>. This is due the fact that product B has a decomposition temperature approximately 25°C higher than product C. In addition, as shown in Table 11.3, products B and C exhibit approximately the same total amount of thermal expansion in the range from 50 to 260°C. The charts for the different peak temperatures are shown to be the same for product B in Fig. 11.9. This is partly due to the limited experience to date with this product in thick PWB designs. In addition, at lower peak temperatures, the number of reflow cycles that this product

**FIGURE 11.8** Charts for product C (175°C T<sub>g</sub> conventional FR-4).

**Peak reflow temperature**

can withstand can go beyond six for thinner PCBs. If the two charts extended beyond six cycles, more differences would be seen.

Product D, with a high decomposition temperature and very low level of thermal expansion, is suitable for the broadest range of applications. This is illustrated in Fig. 11.10. Product E offers not only a high decomposition temperature and very low thermal expansion, but also significantly improved electrical performance. Combining these recommendations allows us

**FIGURE 11.12** Summary of recommendations in lead-free assembly for materials A through D.

**11.4 EXAMPLE APPLICATION OF THIS TOOL**

A simple example helps illustrate the practical application of this tool. This example is based on a real PCB design that was being converted to a lead-free assembly process. Some key features of the PCB as they relate to how it differed from a “typical” PWB as defined in Fig. 11.4, and the recommended adjustments suggested, are shown in Table 11.4.

**TABLE 11.4** Example of a PWB Being Converted to Lead-Free Assembly

PWB Design Feature	Attribute	Recommended Adjustment
Thickness	1.60 mm (0.062 inches)	—
Number of Reflows	3	—
Material	Conventional 140°C T <sub>g</sub> FR-4	—
Surface Finish	Lead Free HASL (HASL not Typical)	Treat as an additional reflow cycle
Layer Count	10 (<=8 Typical)	Consider moving up and right on chart

Figure 11.13 shows the results of making the adjustments suggested, and shows that this material is not recommended for this application. Figure 11.12 recommends that product B be used in this application, and empirical evidence has shown that when the standard 140°C T<sub>g</sub> material was used, some level of assembly-related defects was observed. When product B was used, no assembly-related defects were experienced.

**FIGURE 11.13** Example of practical application of the selection tool.

## 11.5 DISCUSSION OF THE RANGE OF PEAK TEMPERATURES FOR LEAD-FREE ASSEMBLY

As was discussed in Chap. 11 in the context of decomposition temperatures, lead-free assembly temperatures represent a very critical range for many base materials. In the selection charts discussed in Sections 11.3 and 11.4, the lead-free temperature range is given as 235 to 260°C. Although some lead-free applications may fall outside this range, the bulk will likely fall within it. However, with respect to the impact on base materials, 235 to 260°C is a broad range. While this represents a range of only 25°C, for some materials an increase of only 10°C could be the difference between success and failure. Much more data must be gathered before more specific recommendations can be made, but Table 11.5 provides some very general guidance when selecting FR-4 materials such as those discussed in Sections 11.3 and 11.4 for two different ranges of lead-free assembly peak temperatures. All the other variables discussed up to this point must be considered as well, so once again, it is recommended that the user validate the material recommendations suggested here.

**TABLE 11.5** General Recommendations by Lead-Free Peak Temperature Range

Category	230 to 245°C Peak Temperatures	246 to 260°C Peak Temperatures
Conventional 140°C T <sub>g</sub> FR-4s	May be suitable for PCBs of limited thickness and complexity where a limited number of thermal cycles will be experienced.	Generally not recommended, but may be suitable for low-technology applications where a limited number of thermal cycles will be experienced.
Conventional High-T <sub>g</sub> FR-4s	Generally not recommended; even though initial results may be positive, extended storage in an uncontrolled environment prior to assembly could lead to problems.	Not recommended.
Phenolic Mid-T <sub>g</sub> FR-4s	Suitable for a broad range of applications because of the higher decomposition temperature and overall thermal expansion being similar to standard high-T <sub>g</sub> materials.	Suitable for a broad range of applications because of the higher decomposition temperature and overall thermal expansion being similar to standard high-T <sub>g</sub> materials. Consider higher T <sub>g</sub> versions for thicker, more complex PCBs.
Phenolic High-T <sub>g</sub> FR-4s	Compatible in the broadest range of designs and applications. Recommended when long-term reliability is critical.	Compatible in the broadest range of designs and applications. Recommended when long-term reliability is critical.

## 11.6 LEAD-FREE APPLICATIONS AND IPC-4101 SPECIFICATION SHEETS

Revision B of the IPC-4101 specification was released in June 2006. The committee responsible for this specification worked hard to add material specification sheets that included some of the properties discussed in Chaps. 10 and 11 in regards to lead-free assembly. Table 11.6 summarizes some of the new specification sheets that include properties such as decomposition temperature, z-axis expansion, and time-to-delamination values.

**TABLE 11.6** New Specification Sheets in IPC-4101B

Slash Sheet	Min. $T_g$	Filled/Unfilled	$T_d@5\%$	T260	T288	T300	Pre- $T_g$ CTE	Post- $T_g$ CTE	CTE% 50–260°C
/101	110	Filled	310	30	5	NA	60	300	4.0
/121	110	NA	310	30	5	NA	60	300	4.0
/99	150	Filled	325	30	5	NA	60	300	3.5
/124	150	NA	325	30	5	NA	60	300	3.5
/126	170	Filled	340	30	15	2	60	300	3.0
/129	170	NA	340	30	15	2	60	300	3.5

It is important to understand that these requirements apply to laminate materials and not the PCBs manufactured from them. Furthermore, the time-to-delamination requirements are for unclad samples. All of the variables outlined in Section 11.2 regarding printed circuit fabrication and assembly must also be considered when specifying a material. It is also critical to understand that no one property will guarantee success in lead-free applications. When faced with uncertainty, the natural tendency is to overspecify each property. Not only could this cause the user to pay too much for a material, but overspecifying specific properties can also lead to functional problems. These problems can be the result of the interaction between advanced materials and the PCB fabrication processes required to manufacture reliable PCBs.

Take decomposition temperature,  $T_d$ , as an example. Section 10.2.2 discussed the importance of  $T_d$  with respect to lead-free assembly compatibility. Although the 5 percent level of decomposition has been the standard reported value, the point was made that this is a very high level of decomposition from the standpoint of PCB reliability. It is important to understand when decomposition begins and how close this temperature is to actual assembly and rework process temperatures. A material with a reported  $T_d$ , based on the 5 percent level, of 325°C may perform just as reliably, or even more reliably, than a material with a 5 percent  $T_d$  value of 340°C, depending on what the decomposition characteristics are in the lead-free assembly and rework temperature ranges. Specifying materials with significantly higher  $T_d$  values may not improve reliability, and may potentially add cost and difficulty to the manufacturing process if the higher  $T_d$  material is more difficult to process—for example, if the lamination times are longer, or if it is harder to drill or score. Although future specification sheets may include  $T_d$  values based on lower levels of decomposition, it is very important to understand these properties in some detail and specify the appropriate material for a given application.

In summary, experience to date indicates that specification sheets 99 and 124 are suitable for a very broad range of applications. For lead-free applications, the user should consider these as the baseline. Simple low-technology PCBs or those that do not have stringent long-term reliability requirements may successfully use the materials covered by sheets 101 or 121, whereas very advanced products may need more stringent requirements, such as those covered by sheets 126 and 129. Finally, always check for the most recent revision of IPC-4101, as new specification sheets will be added as more experience is gained and data are gathered.

## 11.7 ADDITIONAL BASE MATERIAL OPTIONS FOR LEAD-FREE APPLICATIONS

Sections 11.3 through 11.6, including Table 11.6 on the IPC-4101B specification sheets, focused on FR-4 type base materials. These are still the most commonly used material types by far. Chapter 6 touches on the history of FR-4 materials and the development of improved versions of FR-4 as requirements have changed. In addition, several non-FR-4 materials compatible with

**TABLE 11.7** Range of Material Types Compatible with Specific Lead-Free Applications

Resin Type	T <sub>g</sub> by DSC, °C	T <sub>d</sub>	T260 (min.)	T288, (min.)	% Expansion, 50–260°C	D <sub>k</sub> @2 GHz	D <sub>k</sub> @ 10 GHz	D <sub>f</sub> @2 GHz	D <sub>f</sub> @ 10 GHz

Low D <sub>k</sub> /D <sub>f</sub> Blend/RF	220	350	>30	>10	3.6	3.0–3.6	3.0–3.6	<0.0045	0.0045
Polyimide	260	415	>30	>30	1.5	3.9	3.9	0.017	0.018

lead-free assembly are also available. These include polyimide materials, well known for their thermal reliability and low D<sub>k</sub>/D<sub>f</sub> materials. Table 11.7 indicates the range of material types compatible with specific lead-free applications and their various properties. As discussed throughout this chapter, not all materials are compatible in all applications. However, the properties included in this table should help identify candidate materials for evaluation.

## 11.8 SUMMARY

The question of whether a given laminate material is compatible with lead-free assembly can be very complex due to the many variables in PCB design and manufacturing. In addition, there are variations in lead-free assembly processes. Specifically, peak temperatures, dwell times at peak temperatures, heatup rates, cooldown rates, and rework processes can all vary and complicate this decision. As stated earlier, the temperature range from 235 to 260°C is critical for laminate materials; some materials may be moderately successful at the low end of this range but fail at the higher end. Additional work investigating these assembly-related variables is under way. The existing tools for base material selection for lead-free assembly continue to be developed and improved as more data are collected and analyzed.

Critical base material properties with respect to lead-free assembly applications include:

- **The decomposition temperature** Some minimum value is needed, but above that minimum level, higher values are not *always* better.
- **Thermal expansion properties** Improved materials have reduced levels of thermal expansion.

- **Glass transition temperature** A higher glass transition temperature delays the onset of rapid thermal expansion and therefore reduces total expansion within a temperature range.
- **Moisture absorption** In particular, if PWBs are stored in an uncontrolled or humid environment prior to assembly, drying of boards prior to assembly or selection of a material less prone to moisture-related problems should be considered.
- **Time to delamination** T260 and T288 values are a simple way to screen materials for compatibility with lead-free assembly. However, testing at higher temperatures or requiring excessive times may not be necessary.

Balancing these properties with the level of reliability required along with PWB manufacturability and assembly concerns is vital.

## 12.1 INTRODUCTION

---

Copper-clad laminate materials (single- or double-sided) are the base material for almost all printed circuit boards (PCBs). The properties of these materials have a large influence on the quality of the final product and therefore need to be understood and tested prior to release/manufacturing.

### 12.1.1 Impact of RoHS and Lead-Free Requirements

With a change toward RoHS-compliant “lead-free” assembly processes, laminate materials and complete printed circuit boards are facing a set of increased challenges:

- **Laminates** Materials have to survive the increased thermal stress of repeated lead-free assembly cycles. Due to the higher melting temperature of lead-free solders, a peak temperature during reflow of 260°C must realistically be expected (30°C to 40°C higher than eutectic soldering profiles). Most printed circuit boards will be required to withstand at least five such assembly cycles, but that number may increase to six and higher for more complex assemblies. A rule of thumb states that a 10°C increase of temperature doubles the reaction energy starting degradation or decomposition of the resin compound. The increased peak temperature therefore requires new or improved laminate materials with a higher decomposition temperature and enhanced thermal stability. New laminate test methodologies are also needed to assess the impact of the higher assembly temperatures.
- **PCB reliability** There should not be any degradation in the reliability of the printed circuit boards after assembly compared to boards assembled using traditional soldering profiles. When the same laminate material is used, plated through holes will see an increase in thermal expansion stresses after an equal number of assembly cycles with higher peak temperatures. This means that if the same laminate is used, the reliability margin of the PCB has decreased. To achieve comparable reliability of boards after both eutectic or lead-free soldering, a change

in the base material is most likely. Additional PCB reliability concerns include innerlayer bonding, conductive anodic filament (CAF) growth, and dielectric strength, particularly with reduced dielectric thicknesses.

- **PCB performance** In addition to the preceding reliability challenges posed by lead-free assembly processes, it also has to be guaranteed that all other performance characteristics of the printed circuit board stay the same. This includes dielectrical properties such as dielectric constant  $D_c$  (which influences impedance), dissipation factor  $D_f$ , and thermomechanical properties such as copper peel strength, glass transition temperature, or coefficient of thermal expansion (CTE). These properties should not be affected by the assembly processes applying higher temperatures.

### 12.1.2 Material Evaluation Process

In almost all cases, the laminate manufacturer will provide a set of data for its specific materials. This datasheet is a good starting point and can certainly be used to evaluate laminates at an early state of a project. Often, though, it will be necessary to perform additional tests in the PCB facility to verify or complement the manufacturer's data to ensure that the laminate materials meet the requirements of manufacturing and assembly processes.

This chapter introduces the most important laminate properties and their characterization methods and has been revised to reflect RoHS-compliant manufacturing process and temperature requirements. It will serve as a quick reference guide for the printed circuit board specialist as well as an introduction to laminate testing for those who are new to the field. Laminate properties according to industry standards such as the National Electrical Manufacturers Association (NEMA) and IPC will be introduced. Then the actual test methods will be discussed in the form of a best-practice guide. This guide will help the PCB specialist make quick decisions during the testing process. Methods to test mechanical, thermomechanical, and electrical properties of printed circuit board materials will be described. The focus will be on how the tests are performed, what the results actually mean in today's manufacturing environment, and how relevant the obtained test data are. In addition to the raw base material testing, the chapter will introduce a best-practice qualification guide to assess interactions between manufacturing processes and laminate properties.

## 12.2 INDUSTRY STANDARDS

---

A number of different industry standards can be used to evaluate copper-clad laminate properties. Many of the test methods for similar properties are very comparable, though, and in the end the materials engineer must decide which standard to use as a basis for his or her characterization. In some cases, it may even be necessary to define a new characterization method to qualify a laminate material for a specific customer application or a particular requirement.

### 12.2.1 IPC-TM-650

This document is the most comprehensive and most widely used compilation of copper-clad laminate test methods. It is administered by IPC (Association Connecting Electronic Industries) and available in print or online.\*

---

\*Available at <http://www.ipc.org/html/testmethods.htm>.

Most of the test methods described in this chapter are based on the test manual IPC-TM-650. It contains industry-approved test techniques and procedures for chemical, mechanical, electrical, and environmental tests on all forms of printed wiring and connectors. An IPC test method is a procedure by which the properties or constituents of a material, an assembly of materials, or a product can be examined. These test procedures do not contain acceptability levels for specific properties.

### 12.2.2 IPC Specification Sheets

IPC publishes a wide variety of technical specification sheets for PCB and printed circuits assembly (PCA) products. A few are important in this context:

- **IPC 4101, “Specifications for Base Materials for Rigid and Multilayer Printed Boards,” Rev. B 06/06** This document contains specification sheets for laminate materials used to manufacture PCBs for commercial and military applications. The minimum requirements for key material properties can be found in these specification sheets.
- **IPC 4103, “Specification for Plastic Substrates, Clad or Unclad, for High Speed/High Frequency Interconnections,” 01/02** This document contains specification sheets for Teflon (polytetrafluoroethylene, or PTFE) and other laminate materials used to manufacture PCBs for high-speed or high-frequency applications.
- **IPC 4104, “Specification for High-Density Interconnect (HDI) and Microvia Materials,” 05/99** This document contains specification sheets for materials used in HDI and microvia applications.

### 12.2.3 ASTM

The American Society for Testing and Materials (ASTM) develops standard test methods and specifications that are in some cases related to laminate materials. They will be referenced as appropriate. More information can be found online.\*

### 12.2.4 NEMA

NEMA publishes standards on laminated thermosetting materials. The last published version is the LI 1-1998 Standard for Industrial Laminated Thermosetting Products, which includes the latest information concerning the manufacture, testing, and performance of laminated thermosetting products. Most copper-clad laminate materials are named according to NEMA grades, but it is important to understand that NEMA grades represent only material categories and not one individual material. One of the most commonly known material grades is FR-4, which is often thought of as a specific laminate material. This is not the case, however, as each NEMA grade represents a material class defined by properties that fall into a certain class. Thus, properties of different laminate materials from different suppliers that fall into the same class (FR-4, for example) may not be identical. More information can be found online.\*\* (For a more detailed discussion of FR-4, see Sec. 6.4.)

**TABLE 12.1** NEMA Grade Material Designations and Properties

NEMA grade	Resin system	Reinforcement	Description
XXXXPC	Phenolic	Paper	Phenolic paper, punchable
FR-2	Phenolic	Paper	Phenolic paper, punchable, flame-resistant
FR-3	Epoxy	Paper	Epoxy paper, cold punchable, high insulation resistance, flame-resistant
CEM-1	Epoxy	Paper-glass	Epoxy paper core and glass on laminate surface, flame-resistant
CEM-2	Epoxy	Paper-glass	Epoxy paper core and glass on laminate surface
CEM-3	Epoxy	Glass matte	Epoxy non-woven glass core and woven-glass surface, flame-resistant
CEM-4	Epoxy	Glass matte	Epoxy non-woven glass core and woven-glass surface
FR-6	Polyester	Glass matte	Polyester non-woven glass, flame-resistant
G-10	Epoxy	Glass (woven)	Epoxy woven glass, not flame-resistant
FR-4	Epoxy	Glass (woven)	Epoxy woven glass, flame-resistant
G-11	Epoxy	Glass (woven)	High-temp epoxy, woven glass, not flame-resistant
FR-5	Epoxy	Glass (woven)	High-temp epoxy, woven glass, flame-resistant

### 12.2.5 NEMA Grades

Table 12.1 shows technical and industrial laminate grades as they apply to the most important printed circuit board materials.

## 12.3 LAMINATE TEST STRATEGY

Laminates contain different reinforcement materials (woven/non-woven glass/organic fibers, expanded PTFE, etc.), resin types (phenolic, epoxy, cyanate ester, polyimide, BT, etc.), resin formulations (blended, functionality, etc.), hardeners (dicyanodiamide [dicy], phenol-novolak, cresol-novolak, p-aminophenol, isocyanurate, etc.), and sometimes filler particles (ceramic or organic). The ratio of all of these individual components can vary widely. To define a test strategy for laminates, it is important to understand the different main components of the materials as well as the conditions during manufacturing, as these will have a large influence on their properties and quality.

The evaluation and qualification of a laminate material can be a quite complex task and the new requirements for lead-free processing have specifically increased the focus on the thermal characteristics of laminate materials. A number of different qualification test methods are available to the materials engineer. However, very often not all of them are relevant or necessary for the final product. At the same time, the materials engineer faces pressure to produce quick results driven by shorter development cycles and increasing product and process requirements. The organization of the test methods described in this chapter follows a proposed best-practice guide aimed to help perform full material evaluations efficiently and at the same time address the new requirements of lead-free processing. The sections allow quick decisions, especially when a number of materials are being evaluated at the same time.

### 12.3.1 Data Comparison

The first step in every material evaluation is data comparison and assessment. This step may already allow the elimination of some material candidates without performing actual tests.

The first and most important thing to understand is the state of the material that is being considered. Is it an established material formulation that has a solid history at other manufacturing locations, or is it a newly developed material that has not seen mass production yet?

New developments often do not come with complete data sheets that allow an early assessment, whereas the laminator can often provide one for established materials.

Cost is another important factor. The laminator can provide guidance about volume pricing for the new material.

Other considerations are the history of the supplier, in terms of having met previous commitments and whether the material is already in high-volume production. If it is a new material that has not yet been ramped to high volume, if no more than one PWB manufacturer is using it, and if no second source can be identified, then these facts may be a red flag when considering the material for use.

### 12.3.2 Two-Tier Test Strategy

The qualification procedure proposed in this chapter follows a two-tier test strategy that enables quick decisions during a material qualification program. The first set of tests is easy to perform and focuses on key properties that should be evaluated when testing a new laminate material. Failure to pass any of them will likely result in rejection of a material for manufacturing. If multiple materials are being evaluated, the first tests will allow the easy elimination of the least probable candidates.

The second set of tests is an expanded set of qualification tests that focuses on all key properties that are commonly evaluated for laminates. However, the final decision about a qualification test plan for a new laminate should always be driven by product-level requirements, which means that additional laminate tests as well as board-level tests may need to be added to the set of tests described in the following section.

## 12.4 INITIAL TESTS

---

This first set of tests is most commonly performed when starting a material evaluation and qualification project. The tests can be performed easily and give some early indications of whether the material exhibits any major problems.

### 12.4.1 Surface and Appearance

This test is one of the very first tests to happen as the new material arrives in the shop. The laminate is inspected for its appearance and visual quality. Often the materials engineer will be able to assess the quality of the product without applying specification guidelines. Even packaging and shipping materials should be used to assess the laminator's overall quality control.

IPC-TM-650 method 2.1.2 and method 2.1.5 define procedures for how to inspect the surface and appearance of copper-clad laminates. These standards should be applied only to surface areas that are pertinent to the finished board. More than 90 percent of the copper will usually be removed during manufacturing, and a new material should not be discarded solely for cosmetic reasons. On the other hand, for areas that will contain edge card connector pads or very fine-line traces, these surface standards must be applied.

The specifications categorize the longest permissible dimensions of any copper pits and dents and define a point value-based rating system (as shown in Table 12.2).

**TABLE 12.2** Longest Permissible Dimensions

Longest dimension (mm)	Point value
0.13–0.25	1
0.26–0.50	2
0.51–0.75	4
0.76–1.00	7
Over 1.00	30

**TABLE 12.3** Material Class

Class	A	B	C	D	X
Total point count	<30	<5 All dents <0.38 mm	<17	0	Requirements agreed upon

The total point value for an area of 300 mm × 300 mm of laminate determines the material class (as shown in Table 12.3).

In addition to copper pits and dents, the specifications contain procedures on how to inspect for scratches, wrinkles, and inclusions.

#### 12.4.2 Copper Peel Strength

The copper peel strength of copper-clad laminates is an indicator for a variety of their performance characteristics. It indicates the bond strength of the copper circuitry of a double-sided printed circuit construction after manufacturing and any successive assembly or repair cycles. To assess the copper bond strength of the outerlayer circuitry of a multilayer construction accurately, it is necessary to take a close look at the exact build-up and copper foil used in the construction and to build specific test vehicles that are similar to the original stack-up. Copper peel strength measurements have grown increasingly important as circuit traces and pads are becoming smaller. In addition, this test allows an assessment of any potential weaknesses in multilayer constructions and identifies the interface that might delaminate first after thermal stress. The higher the initial bond strength of a material, the better. For all characterizations after thermal stress in the temperature range of lead-free assembly, it is also important to look at the decrease of bond strength. This is especially important for applications that require multiple reflow operations and one or more repair cycles.

The test method is specified in IPC-TM-650, method 2.4.8, and the applicable test patterns are specified in IPC TM-650, method 5.8.3. Figure 12.1 shows an actual test pattern using a sample 100 mm × 100 mm coupon with 4-mm-wide copper strips.

The material being tested should be processed using the same fabrication steps that will be applied for the actual product. IPC-TM-650, method 2.4.8, recommends a specimen size of 50.8 mm × 50.8 mm (2.0 in. × 2.0 in.) and a minimum sample size of two for both the warp and fill (X and Y) direction of the laminate. The end of the test strip is peeled off so that a tensile

**FIGURE 12.1** Test pattern used for a copper peel strength test.

tester can clamp it. The load cell should be calibrated to account for the weight of the clamp. The copper foil strip is then peeled from the material at a rate of 2 in. per min. The measured value is dependent on the copper thickness. The thicker the copper foil, the more force is required to deform it plastically. The value is also dependent on the angle at which it is being pulled. Therefore, it is always important to specify the thickness of the copper foil tested and to maintain a peeling force radius of 90° during the test. The minimum load is determined as specified and the peel strength is calculated using Eq. 12.1:

$$\text{lb/in} = L_M/W_S \quad (12.1)$$

where  $L_M$  = Minimum load  
 $W_S$  = Measured width of peel strip

Copper bond retention after exposure to soldering or touch-up temperatures is measured as outlined in IPC-TM 650, method 2.4.8, condition B. The test samples are covered with silicone grease before floating them on the solder pot at 288°C for 5 to 20 sec. to avoid solder contamination on the test strip. After allowing the samples to cool down to room temperature and removing the grease, the test is performed in the same way as previously described. It is important to inspect the specimen for any blistering or delaminations prior to testing (see also the discussion of solder shock testing in Section 12.5.2) as this may interfere with the test procedure and may indicate that the laminate material has problems with solder shock resistance.

Another factor that can influence the adhesion strength of the copper foil is exposure to processing chemicals during manufacturing. Details about this test method can be found in IPC-TM 650, method 2.4.8, condition C. This test is usually performed only if specific requirements at the end-product level call for it or if the material during manufacturing exhibits low copper bond retention properties.

Minimum copper peel strength values for unstressed material should be 1 N/mm or higher. The acceptable values after thermal stress are 0.8 N/mm and 0.55 N/mm after process solutions. Measurements taken at elevated temperature (125°C) should yield a minimum value of 0.7 N/mm. The authors recommends using the preceding values as guidelines and validating acceptable minimum values with actual product requirements.

### 12.4.3 Solder Shock

The solder shock test is one of several methods to assess the thermal resistance of copper-clad laminates. It is easy to perform and represents another key test during the early assessment of a material. There are a number of different methods to choose from, which will be described in detail in Section 12.5.2. During the initial assessment of the material, it is important to choose at least one of the described test methods to make certain that the material meets the minimum requirements, especially if the material is used in higher-temperature lead-free assembly processes. Aside from solder shock testing of bare laminate material, it is also recommended that the PCB engineer consider PCB-level temperature shock as well as repeated reflow testing with a particular focus on resin-reinforcement delaminations. This will ensure that not only the raw material but also the completed PCB will be able to withstand the required temperature regime.

### 12.4.4 Glass Transition Temperature ( $T_g$ )

A further important data point within the initial assessment is the determination of the glass transition temperature ( $T_g$ ). Different test methods are described in more detail in Section 12.5.2. For the first assessment, one method should be selected. When choosing the method, it is important to make sure that the test procedure is compatible with the material in test

(for some materials, the glass transition can be determined only using dynamic mechanical analysis [DMA]). A minimum of two samples should be tested. If a data sheet of the material is available, the measured value should correspond with the manufacturer's data (within the measurement accuracy of the equipment). The values of  $T_{g1}$  and  $T_{g2}$  (measured on the same sample) should not be more than  $7^{\circ}\text{C}$  apart. If  $T_{g2}$  is significantly below the  $T_{g1}$  measurement, this may be a strong first indication that resin system degradation has started during the measurement procedure. It is recommended to confirm this finding using the  $T_d$  measurement procedure.

#### 12.4.5 Thermal Decomposition Temperature ( $T_d$ )

The determination of the thermal decomposition temperature ( $T_d$ ) completes the initial assessment. This is a new test methodology, and both ASTM and IPC test procedures are available. IPC-TM-650, method 2.3.40, is called "Procedure to Determine the Thermal Decomposition Temperature  $T_d$  Using Thermo Gravimetric Analysis (TGA)," and the ASTM methodology is called "Standard Test Method for Rapid Thermal Degradation of Solid Electrical Insulating Materials by Thermo Gravimetric Analysis." In both cases, the test methodology is based on thermogravimetric analysis (TGA) of a laminate specimen that is heated with a set ramp rate assessing the onset and process of decomposition. At first, the thermoset laminate resin passes the glass transition point where the polymer changes from a rigid, brittle, and "glasslike" state to a softer and more rubberlike material. As the material is heated further, the three-dimensional cross-linked structure begins to break down and individual bonds in the polymer structure open. As decomposition continues, gaseous decomposition products are set free, which can be detected as a loss of mass of the sample in test. This usually goes hand in hand with visible damage to the sample (delamination and/or strong discoloration) and significant changes in the mechanical properties of the laminate.

A dry test specimen of 2–20 mg is heated at  $5^{\circ}\text{C}/\text{min}$  to  $150^{\circ}\text{C}$  and then held at that temperature for 15 min. This ensures that the sample is completely dry and establishes the base weight used to characterize the weight loss. Then the sample is heated at  $5^{\circ}\text{C}/\text{min}$  up to a temperature of  $800^{\circ}\text{C}$  and the weight loss is continually recorded. The temperature at which a 5 percent weight loss of the sample is detected is defined as the  $T_d$ .

Although this test methodology is a good gauge of the thermal stability of laminate materials, the method and results must be evaluated carefully to ensure that correct conclusions are drawn from the results. For example, the results of this test are dependent on the surface/volume ratio of the specimen in test-specimens of the same weight, but different surface areas will show different results. The sample with the large surface area loses weight at a faster rate and therefore shows a lower  $T_d$ . Samples with a large percentage of nondecomposing filler or reinforcement material will also behave differently as the measured weight change is based only on the resin content of the sample. This again will lead to a seemingly higher measured  $T_d$ , which may lead to erroneous conclusions. Finally, the process of decomposition is as important as the determined value of  $T_d$  and a comparison of the onset of weight loss may also be a valuable parameter to assess when comparing laminate materials using this methodology.

In general, a higher  $T_d$  value is desirable for materials that are being selected for lead-free assembly processes as this indicates that the laminate withstands the higher assembly temperatures with an increased margin.

Figure 12.2 shows an example of different  $T_d$  measurements for three different laminate materials. It shows the typical decomposition rates for some sample materials and also highlights how the assessment of a material can change if different criteria are chosen. If the IPC value of 5 percent weight loss is chosen, then M3 is superior to M1 and M2. But if the materials engineer decides that the onset of weight loss (decomposition) is critical for the application, then M3 is the worst performing material. The authors recommend using materials with a high onset temperature as well as a high 5 percent decomposition temperature.

**FIGURE 12.2** Example of different  $T_d$  measurements for three different laminate materials. ( $T_d$  Graph Courtesy of Helmut Kroener, Multek.)

## 12.5 FULL MATERIAL CHARACTERIZATION

The following set of characterization methods summarizes the most commonly used test methods to qualify copper-clad laminates for manufacturing. It is intended to guide the materials engineer through the laminate qualification process. Yet it can only serve as a best-practices guide, as the final set of qualification methods will vary for each material and should always be driven by its specific application.

### 12.5.1 Mechanical Tests

Commonly used mechanical tests include tensile tests, flexural strength tests, and copper peel strength tests.

**12.5.1.1 Modulus and Tensile Strength (Tensile Test).** The test method to determine modulus and yield stress for copper-clad laminates described in this section is based on ASTM D 882, “Standard Test Methods for Tensile Properties of Thin Plastic Sheeting.” Other relevant industry standards are IPC-TM-650, method 2.4.19 (for flexible laminate materials), and IPC-TM-650, method 2.4.18.3 (for deposited organic free films). Elastic modulus and yield stress are always determined by the same method.

The elastic modulus is the indicator value for the stiffness and strength of a composite material under load, whereas the yield stress indicates the maximum load the material can take in x/y direction before it brakes. The modulus is the more important of the two values. It is used to differentiate materials and their actual strength during qualification testing. The elastic modulus is also one of the key properties of a material that need to be understood when performing computational modeling of packages and printed circuit board assemblies.

In many applications, materials with different properties are combined, which leads to thermomechanical stresses that cause fatigue or interfacial failures. Computational modeling is often used when there is not sufficient time or resources available to perform actual product test, but fast reliability assessments are needed.

The standard test specimen for this test consists of a strip of laminate material 152.4 mm (6 in.) long and 12.7 mm (0.5 in.) wide. A minimum of 10 samples should be prepared and all copper must be removed before testing. It is important that only samples with identical thickness and glass stack-up be tested, as this will allow a meaningful comparison of the materials in the test. The test engineer also must ensure that both the warp and fill direction of the laminate composite are measured and documented separately.

After the samples are cut, they need to be inspected for any fractures, delamination, or roughness along the edges and if necessary they need to be sanded. The cross-sectional area of each specimen is calculated from the width and thickness in the measurement area. Then the individual samples need to be conditioned at 23°C (73.4°F) and 50 percent relative humidity (RH) for 24 hours. Although most specifications recommend conditioning of the material prior to cutting and preparation of the samples, the authors recommend first cutting the specimens to size and then conditioning them. This ensures more uniform properties of the individual samples.

The tests are performed using a standard tension and compression apparatus, which can be operated at a controlled rate of crosshead movement. The load-extension curve should be recorded and the specimen tested until it breaks. If extensometers are used, it is necessary to minimize the stress on the sample at the contact points of specimen and indicator.

The tensile strength is calculated by dividing the maximum load at break by the original minimum cross-sectional area. The unit is megapascals (MPa). Dividing the elongation at break by the initial gauge length and multiplying it by 100 will calculate percent elongation. When extensometers are employed, only the length of the section between them is used; otherwise, the distance between the grips represents the initial gauge length. Young's modulus is calculated by drawing a tangent to the linear portion of the stress-strain curve, selecting any point on this tangent, and dividing the tensile stress at that point by the corresponding strain. The unit is gigapascals (GPa). For all calculations, the values for 10 samples should be recorded and the average calculated.

In addition to the absolute values for the different mechanical properties, the stress-strain curve gives the materials engineer information about the elastic and plastic portion of the deformation in the laminate samples. The elastic (linear) part of the deformation is restorable, whereas plastic changes in the materials are not. Figure 12.3 shows a typical stress-strain curve.

**12.5.1.2 Flexural Strength.** The test method to determine the flexural strength of copper-clad laminates is based on ASTM D 790 ("Flexural Properties for Un-Reinforced and Reinforced Plastics and Insulating Material") and IPC-TM-650, method 2.4.4B ("Flexural Strength of Laminates at Ambient Temperatures"). The test method described in the preceding section to determine the modulus in tensile mode does have the inherent problem that the glass reinforcement and its properties have a large influence on the results. This may be avoided when testing copper-clad laminates in flexural mode. Here the attributes of the resin system have a greater influence on the outcome of the test. When comparing the test results of different laminate materials, it is important to compare only data that were generated using the same test method.

This test also requires that the copper be completely removed from the laminate material by means of standard etching processes. The specific size (length and width) of the samples and test parameters (test span and speed) are dependent on the thickness of the laminate and can be found in IPC-TM-650, method 2.4.4. See Fig. 12.4 for a typical flexural strength measurement curve.

The samples are conditioned to room temperature. They are then centered on the supports of the standard tension and compression test apparatus with the long axis of the specimen perpendicular to the loading nose and support. The samples are loaded at the defined speed

FIGURE 12.3 Typical stress-strain curve.

FIGURE 12.4 Typical flexural strength measurement curve.

and tested until they break. The load at breakage should be recorded. Use Eq. 1.2 to calculate the flexural strength.

$$S = 3PL/2bd^2 \quad (12.2)$$

where S = Flexural strength (psi)  
 P = Load at breakage (lb.)  
 L = Span (in.)  
 B = Width of specimen (in.)  
 D = thickness (in.)

**12.5.1.3 Copper Peel Strength (Before and After Thermal Stress).** Test methods are described in Section 12.4.2 and results can be transferred to this point in the evaluation. To complete the data, perform additional tests if necessary after specific thermal stress (solder dip, reflow with different peak temperatures, and/or different dwell times) or after exposure to plating solutions.

## 12.5.2 Thermomechanical Tests

Properties that are tested thermomechanically include  $T_g$ , CTE, thermal resistance, solder dip resistance, and solder float resistance.

**12.5.2.1 Glass Transition Temperature  $T_g$  (DSC, TMA, and DMA).** The resin systems used in today's copper-clad laminates are almost all three-dimensionally cross-linked thermoset polymers. This means that the materials are manufactured (in a curing reaction) into a hard final product and cannot be remelted many times the way thermoplastic polymers can. In many cases, different resin systems are blended to create a material with specific properties. The functionality of the individual resins and their ratio in the blend define the properties of the thermoset. The degree of cure of the hardened thermoset resin system can be described by characteristics such as percent of uncured monomer and heat of final cure or by mechanical properties such as hardness, modulus, and yield stress. But one of the most commonly used characteristics to describe the degree of cure and cross-link density of a thermoset polymer is the glass transition temperature ( $T_g$ ).

The simplest definition of the  $T_g$  of a laminate is to call it the temperature at which the mechanical properties of a laminate change (deteriorate) rapidly. It is at this temperature that the polymer changes from a rigid, brittle, and "glasslike" state to a softer and more rubberlike material. However, this should not be confused with the melting point of a crystalline substance or the extreme softening of a thermoplastic polymer. In a thermoset material at  $T_g$ , the relative mobility of the cross-linked polymer molecules changes. Below  $T_g$ , they are immobile and the material is rigid; above  $T_g$ , the relative mobility of the molecules increases and slight movements are possible, which leads to a loss of mechanical strength in the material. Although all of the methods described in this section enable us to determine a specific glass transition temperature for laminate materials, it also needs to be emphasized that the glass transition in thermoset resins is not a single defined temperature. It usually occurs within a temperature range (for some resin systems, the range can span as much as 100°C), and the  $T_g$  is determined within this range.

In addition, the difference between  $T_g$  and  $T_d$  must be pointed out here.  $T_g$  is the temperature at which mechanical properties of the material change, whereas  $T_d$  is the temperature where the material starts to irreversibly degrade. If one wants to assess a laminate's capability to withstand high-temperature lead-free processing temperatures,  $T_d$  is the more relevant measure.  $T_g$  is relevant when assessing loss of mechanical strength which can lead to PCB warpage, bowing, and increased z-axis expansion, which in turn can have a significant impact on PCB reliability.

There are a number of different measurement techniques to determine the  $T_g$ . The most commonly used methodologies are thermal analysis techniques. Other techniques are available (such as spectral analysis and electrical characterization), but their use is limited and therefore they will not be discussed here. The three thermal analysis methods that will be discussed in this section are as follows:

- Differential scanning calorimetry (DSC)
- Thermomechanical analysis (TMA)
- Dynamic mechanical analysis (DMA)

All of these techniques measure slightly different property changes in the laminate material and therefore the values that are obtained will be different. They usually will follow this simple rule of thumb:

$$T_g (\text{DMA}) > T_g (\text{DSC}) > T_g (\text{TMA})$$

*12.5.2.1.1  $T_g$  by Thermomechanical Analysis (TMA).* Thermomechanical analysis measures dimensional changes in a material as it is heated from room temperature to a preset final temperature. The change in length (width or height) of the specimen with the change in temperature determines the CTE of the material. At  $T_g$ , the expansion coefficient of the material changes and it is this property change that is used to determine the  $T_g$  by TMA.

The test procedure is specified in IPC-TM-650, method 2.4.24C. The specimen should have a minimum thickness of 0.51 mm and at least two samples taken from random locations in the material need to be tested. Any copper cladding needs to be removed by etching. The treatment of the copper foil leaves a negative imprint on the laminate surface, which can lead to problems during the measurement right below the actual glass transition temperature. Therefore, the surface of the specimen should be sanded lightly prior to testing. The edges of the sample should also be smooth and burr-free. Use care to minimize stress or heat on the specimen.

The samples need to be preconditioned for 2 hours at 105°C (221°F), then cooled to room temperature in a desiccator. The actual measurement should be started at a temperature no higher than 35°C (95°F); an initial temperature of 23°C is recommended. Unless otherwise specified, a scan rate of 10°C (18°F) per min. is commonly used. The temperature ramp needs to be continued at least 30°C (54°F) above the anticipated transition region. The  $T_g$  is defined as the temperature at which the two tangent lines for the thermal expansion coefficient intersect. Figure 12.5 shows an example of a typical TMA scan. The material has a  $T_g$  of 136.7°C.

It is recommended to retest the same sample after allowing it to cool down to room temperature to determine whether the measured value for  $T_{g2}$  is comparable to the measured value of  $T_{g1}$ . If  $T_{g1}$  is significantly lower than  $T_{g2}$ , then this could be an indication that the sample material was not fully cured when it was tested the first time. If  $T_{g1}$  is significantly higher than  $T_{g2}$ , that could indicate that the sample material has already started to decompose and was approaching  $T_d$ . The authors recommend further testing if these measurements differ by more than 5°C.

*12.5.2.1.2  $T_g$  by Differential Scanning Calorimetry (DSC).* Differential scanning calorimetry measures the difference in heat absorption or emission from a test specimen in comparison to a reference sample (usually nitrogen gas). This makes the technique applicable to determine a variety of property changes in polymer materials. It can detect the exothermic cure reaction, crystallization energy, and residual reactivity in polymers, as well as endothermic melting points. For epoxy-based resin systems, DSC is a well-suited technique as these materials go through a crystalline transition at  $T_g$  and this property change can be used to determine the glass transition. For other resin systems that are more amorphous and have a  $T_g$  that occurs over a wider range (such as polyimides), the detection may be more difficult by DSC than TMA.

FIGURE 12.5 Typical TMA scan.

The test procedure is specified in IPC-TM-650, method 2.4.25C. The specimen should be a solid piece weighing between 15 mg and 25 mg. In the case of very thin materials, multiple pieces may be used. The specimen should be of the size and configuration that fits within the sample pan of the DSC equipment. All of the specimen preparation needs to take place before preconditioning to avoid any moisture influence prior to testing. Sample edges should be smoothed and burrs removed by light sanding or an equivalent method to achieve proper thermal conduction. Use care to minimize stress or heating of the specimen. Even though the IPC test method allows samples to be tested with copper cladding, the authors recommend testing only without copper cladding. This increases the relative mass of polymer in the DSC sample pan and leads to a better signal and detection of  $T_g$ .

The samples need to be preconditioned for 2 hours at 105°C (221°F), then cooled to room temperature in a desiccator for at least a half-hour prior to testing. Place the specimen in a standard aluminum sample pan with an aluminum lid. For reference purposes, a cover lid crimped onto the sample pan should be used. Start the scan at a temperature at least 30° lower than the anticipated onset of  $T_g$ . Unless otherwise specified, a scan at a rate of 20°C/min (36°F/min) is recommended and the temperature ramp needs to be continued at least 30°C (54°F) above the anticipated transition region. The glass transition temperature is determined using the heat flow curve. In many cases, the DSC equipment will have applicable software installed to determine  $T_g$ . A tangent line is fit onto the curve above the transition region, and a second tangent line is fit below the transition region. The temperature on the curve halfway between the two tangent lines, or  $1/2 \delta C_p$ , is the glass transition point  $T_g$ . Figure 12.6 shows an example of a DSC scan where the material has been scanned twice. The  $T_g$  of the first scan was 192.9°C. The second scan yielded a slightly higher value of 195.3°C (likely caused by additional curing of the material).

## DSC

FIGURE 12.6 Example of a DSC result.

12.5.2.1.3  $T_g$  by Dynamic Mechanical Analysis (DMA). Dynamic mechanical analysis applies an oscillatory stress or strain on the sample while the temperature is increased during the experiment. The ability of the material to elastically store the mechanical strain energy changes during the heat cycle as it changes its viscoelastic behavior from glassy to rubbery. This property change determines the glass transition temperature by DMA.

The test procedure is specified in IPC-TM-650, method 2.4.24.2. The test specimen should consist of a strip of laminate material compatible to the measuring equipment. For all samples with woven reinforcement, it is necessary to make sure that the specimens are cut parallel or perpendicular to the woven structure. The analysis is based on an assumption of constant specimen geometry; therefore, the test specimens must be stiff enough not to deform plastically during the experiment. All copper needs to be etched off.

While the IPC-method recommends preconditioning of the samples at 23°C and 50 percent RH for at least 24 hours prior to testing, the authors recommend preconditioning similar to that employed for TMA or DSC measurements. Samples are baked for 2 hours at 105°C (221°F), then cooled to room temperature in a desiccator for at least a half-hour prior to testing. The sample is mounted in the fixture making sure that it is perpendicular to the clamps. Both clamps are tightened using torque screwdrivers to ensure that the sample does not slip during the measurement and that no stresses have built up around the sample that could negatively influence the results. The sample is loaded with a frequency of 1 Hz (6.28 radian/sec) while it is heated in dry nitrogen or dry air at a rate of no faster than 2°C per min. The temperature ramp needs to be continued at least 50°C above the transition region. The glass transition temperature is defined as the temperature corresponding to the maximum in the  $\tan \delta$  versus temperature curves at a frequency of 1 Hz.  $\tan \delta$  is calculated from Eq. 12.3.

$$\tan \delta = E''/E' \quad (12.3)$$

FIGURE 12.7 Typical DMA scan.

where  $E''$  = loss modulus  
 $E'$  = storage modulus

Figure 12.7 shows an example of a typical DMA scan. The material has a  $T_g$  of 193.17°C.

**12.5.2.2 Coefficient of Thermal Expansion (CTE).** The CTE describes the property of materials to expand as they are being heated. Because of the reinforced composite construction of most laminates, the CTE in x and y direction is usually different from the CTE in z direction. By convention, the x direction corresponds to the warp direction of the reinforcement, whereas the y direction corresponds to the fill direction of the fabric. The z direction is the direction perpendicular to the plane of the laminate. The difference between the values is caused by the reinforcement, which severely restrains the expansion in x and y, whereas the resin can expand unrestrained in the z direction.

For copper-clad laminate materials used in printed circuit boards, the CTE in x, y, and z direction is of great importance. The x and y direction is critical because of all the components that will be mounted on the final printed circuit board. The greater the mismatch between the laminate material and the soldered components, the higher the risk that temperature changes will lead to solder fatigue and eventually to a reduction in the reliability of the board. The z direction is of equal importance because the expansion of the laminate during thermal cycles will lead to stresses in the copper plating (CTE of 17 ppm/K) of the plated through or buried holes in the board. A low z-axis CTE and high  $T_g$  are therefore generally desirable for increased through hole reliability.

A number of different measurement techniques are available to determine the CTE of copper-clad laminates. The most commonly used is TMA following IPC-TM-650, method 2.4.24C, as described in Section 12.2.1. When determining the CTE of a laminate, the temperature scan must start at a temperature sufficiently lower than the specified temperature range

for which the CTE is being determined to allow the heat rate to stabilize. The typical scan rate is also 10°C (18°F) per min. and the scan should be continued to at least 250°C (482°F). Because the expansion properties of the material change at  $T_g$ , there are usually two CTE values that are being reported: the CTE below  $T_g$  is commonly referred to as  $\alpha_1$ , and the CTE above  $T_g$  as  $\alpha_2$  (see Eq. 12.4).

$$\text{CTE: } \alpha = \Delta L / \Delta T \text{ ppm/K} \quad (12.4)$$

where  $\Delta L$  = change in length  
 $\Delta T$  = change in temperature  
 K = degrees Kelvin

In the TMA scan example (Fig. 12.5), the material has a z-axis CTE ( $\alpha_z$ ) of ~65ppm/K and a z-axis CTE ( $\alpha_z$ ) of ~150ppm/K.

The CTE in x and y direction can also be measured by TMA, although care must be taken during the preparation of the sample to avoid any influence of reinforcement material on the TMA probe. The results are strongly dependent on the properties of the reinforcement fabric.

Another method to determine the x- and y-axis CTE of laminate materials employs strain gauges. This method is described in IPC-TM-650, method 2.4.41.2. Many details need to be taken into consideration when making use of this method. The strain gauges need to be calibrated for the specific temperature range and the adhesive used to attach them needs to be stable over the whole range. Special care needs to be taken during specimen preparation and gauge attachment. It is recommended to run one heat cycle prior to the actual measurement to remove any residual stresses. More details can be found in IPC-TM-650.

**12.5.2.3 Thermal Resistance.** The thermal resistance of laminate materials is one of the key properties, especially in light of the lead-free processing conditions. It is the most important indicator of the performance of printed circuit boards during assembly operations. As already mentioned in the Sec. 12.1, most printed circuit boards will be required to withstand at least five reflow cycles with a peak temperature in the range of 260°C, but that number may increase to six and above for more complex assemblies. During exposure to these process temperatures, the laminate cannot delaminate or begin decomposition. Another important factor that can be assessed with thermal resistance tests is the performance of the laminate in printed circuit board applications that expose the board to high-operating temperatures. Several different test methods should be considered when qualifying laminates.

**12.5.2.3.1 Solder Dip Resistance.** The test method is described in IPC-TM-650, method 2.4.23. The original purpose of this test technique was to assess the solderability of the laminate surface, but today it is often used to assess the ability of laminate materials to withstand the temperatures in a molten solder bath. It is important to note that the original IPC methodology has not been revised in a long time and the current version may not reflect the actual temperature requirements of lead-free processing. The authors still feel that this method is a very good assessment and differentiation technique for laminate materials and recommend that either solder pot temperatures or exposure times are increased if the laminates are intended for use in lead-free assembly processes. Performance factors that are being considered are resistance to softening, loss of surface resin, scorching, delamination, blistering, and measing.

The material will be tested in three different surface configurations: (1) a surface upon which no metal cladding was ever applied (if possible), (2) a surface with the metal cladding removed by standard etching processes, and (3) a surface with metal cladding as received. The sample size for all specimen is 1 1/4 in. × 1 1/4 in. thickness and three samples are required for each surface configuration. All samples are tested using the same procedure.

Preclean the samples by immersing them for 15 sec. in 10 percent hydrochloric acid (HCl) (by volume) and then rinse in water. The HCl should be at a temperature of 60°C (140°F). Dry the specimen quickly to avoid excess oxidation of the sample. Dip the sample into a flux agent and allow draining for 60 sec. before proceeding with the solder dip. Stir and then skim the surface of the molten solder with a clean stainless steel paddle to ensure that the solder

is of uniform composition and at a temperature of 245°C (473°F). Immerse the specimen edgewise into the molten solder. The insertion and withdrawal should be at a rate of 1 in. per sec. and the dwell time in the solder should be 4 sec. Upon withdrawal, allow the solder to solidify by air-cooling while the specimen is in a vertical position. Thoroughly remove the flux.

The samples are examined for any evidence of discoloration or surface contaminants, loss of surface resin, softness, delamination, interlaminar blistering, or measles. The specimens having metal cladding also need to be examined for blistering or delamination of the metal foil from the laminate material.

**12.5.2.3.2 Solder Float Resistance.** This test addresses the thermal resistance of the laminate material floating on the solder bath. Because this method subjects the sample to a thermal gradient across the z-axis of the material similar to an actual wave solder operation, the results of this test are particularly important and—as mentioned previously—either solder pot temperatures or exposure times should be increased if the laminates are intended for use in lead-free assembly processes.

The test method follows IPC-TM-650, method 2.4.13. At least two samples need to be tested for each material and they should be taken from random locations. For double-clad laminate, the copper foil needs to be removed from the backside of each specimen by using standard etching processes. The test samples need to be preconditioned in an air circulating oven at 135°C for one hour to remove any excess moisture that could lead to premature failures. After preconditioning, the specimens can be held in a desiccator at room temperature. After attaching the sample to the solder float test fixture, float it for 10 sec., foil side down, on the surface of the molten solder at a temperature of 260°C (for method A) or 288°C (for method B). Then remove the sample and tap the edges to remove any excess solder. Thoroughly clean and visually examine the sample for blistering, delamination, or wrinkling.

In case more than one material is being qualified and no failures are being observed after testing for 10 sec. or if the goal is to determine the weakest point in the laminate and test to failure, then the authors recommend increasing the solder float time incrementally or repeating the test with the same sample until failures are observed.

**12.5.2.3.3 T260 (TMA).** Aside from testing materials in solder baths, there is one other technique to verify the thermal resistance of laminates. This test method is described in IPC-TM-650, method 2.4.24.1, and is used to determine the time to delamination of laminates and printed boards using a TMA system (see also section 12.5.2.1.1).

The sample requirements are identical to the ones for determination of the  $T_g$  by TMA. A minimum of two specimens should be tested, which can be taken from random locations of the material. Materials are tested as received; the metal cladding is not removed. The samples are preconditioned for 2 hours at 105°C (221°F), and then cooled down to room temperature in a desiccator. The TMA temperature ramp should start from an initial temperature no higher than 35°C (95°F) at a scan rate of 10°C/min. After the scan reaches the specified isothermal temperature, hold at that temperature (onset) for 60 min. or until failure. The time to delamination is determined as the time from the onset of the isotherm to failure. Failure is defined as any event or deviation of the data plot where the thickness is shown to have irreversibly changed. On occasion, some materials will delaminate before the isotherm is reached. In this case, the temperature at the time of failure is recorded. For epoxy laminates and similar materials, the recommended isothermal temperature is 260°C (500°F). For materials intended for lead-free processing and for polyimides and other high-temperature materials, increasing the isothermal temperature to 288°C (550°F) is recommended.

### 12.5.3 Electrical Characterization

Electrical properties include  $D_c$  and  $D_v$ , surface and volume resistivity, and dielectric strength breakdown.

**12.5.3.1 Dielectric Constant ( $D_c$ ) and Dissipation Factor ( $D_f$ ).** The dielectric constant (also known as permittivity,  $D_c$ , and  $\epsilon_r$ ) is defined as the ratio of the capacitance of a capacitor with a given dielectric (laminate) to the capacitance of the same capacitor with air as the dielectric. It is a measure of the ability of a material to store electrostatic energy and determines the relative speed that an electrical signal will travel within that material. The higher the  $D_c$ , the slower the resulting signal propagation speed will be. The signal speed is inversely proportionate to the square root of the dielectric constant. It is not an easy property to measure or to specify, because it depends not only on the material properties and the resin-to-glass ratio, but also on the test method, test signal frequency, and the conditioning of the samples before and during the test. It also tends to shift with temperature. Still,  $D_c$  values are important for computer simulations that are used to predict the performance of impedance-controlled high-end multilayer constructions, especially when new laminate materials are considered. See Fig. 12.8 for a schematic representation of the test.

**FIGURE 12.8** Dielectric constant test.

Related to the dielectric constant is the dissipation factor ( $D_f$ ) or loss tangent. This is a measure of the percentage of the total transmitted power that will be lost as electrons dissipate into the laminate material. See Fig. 12.9 for a schematic representation of the test.

**FIGURE 12.9** Dissipation factor test.

Several test methods are specified in IPC-TM-650 to determine the dielectric constant and the dissipation factor (methods 2.5.5, 2.5.5.1, and 2.5.5.2). Both methods 2.5.5 and 2.5.5.2 test laminate material with fully removed copper. At least three samples need to be tested because of the large influence of the dielectric thickness on the determined value. Method 2.5.5.1 employs samples with an etched pattern. All of these measurements are based on the capacitance of the corresponding sample. With this capacitance and the area and thickness of the sample capacitor it is possible to calculate the dielectric constant.

The dissipation factor is determined with methods 2.5.5.1 and 2.5.5.2. In one case, the value can be read from the equipment display (Agilent Technologies Mdl 4271A); in the other, it can be calculated from the measured sample conductance and capacitance and the measuring frequency.

**12.5.3.2 Surface and Volume Resistivity.** Electrical resistivity of laminate materials is differentiated between specific surface resistance and volume resistance. The surface resistance  $\sigma$  characterizes the electrical resistance between two conductors along the surface of the laminate material. The volume resistance  $\rho$  describes the electrical resistance between two layers of conducting copper along the z-axis of the laminate material. The higher the values for both of these electrical properties, the better, as this ensures proper isolation of individual copper conductors in the printed circuit board.

Both resistance values are determined according to IPC-TM-650, method 2.5.17. All resistance measurements are done with equipment capable of measuring up to  $10^{12}$  megohm while applying 500 volts direct current to the test specimen (Agilent Technologies 16008A). The sample's size is 101.6mm  $\times$  101.6mm for laminates thicker than 0.51 mm and 50.8 mm  $\times$  50.8 mm for laminates below 0.51 mm thickness. The test pattern according to method 2.5.17 should be applied to the samples using standard photo and etch processes.

All measurements are performed by applying 500 volts direct current. The voltage needs to be applied to the samples for 60 sec. before taking the resistance reading to allow the test structures to stabilize. The surface resistance is determined between the outer ring electrode and the inner solid electrode. The volume resistance is determined between the solid front and back electrodes after changing the connecting cables appropriately. The values for volume and surface resistivity can be calculated from the measured resistance values as shown in Eqs. 12.5 and 12.6.

Volume resistivity  $\rho$  (meg-ohm-cm)

$$\rho = (R \cdot A) / T \quad (12.5)$$

where R = Measured resistance in meg-ohms  
 A = Effective area in square cm  
 T = Average thickness of specimen in cm

Surface resistivity  $\sigma$  (meg-ohms)

$$\sigma = (R \cdot P) / D \quad (12.6)$$

where R = Measured resistance in meg-ohms  
 P = Effective perimeter of electrode in cm  
 D = Width of test gap in cm

**12.5.3.3 Dielectric Strength Breakdown.** The dielectric strength of a laminate material is its ability to resist electrical breakdown. The dielectric strength defines a specific voltage that the laminate resists for a specified time whereas the dielectric breakdown voltage defines the maximum voltage at which the laminate fails. These properties can be measured perpendicular to the reinforcement (z-axis) or parallel to the reinforcement (x-y axis). The more important value is the z-axis strength because more and more thin prepreg and laminate cores are being used in high-end multilayer applications. The minimum thickness in the laminate is defined as the shortest distance between the copper treatment peaks that needs to resist the desired test voltage. The values for dielectric strength vary with test setup, temperature, humidity, frequency, and wave shape, but are, if tested under controlled conditions, comparable between materials.

The test method following IPC-TM-650, method 2.5.6.2, describes the determination of the perpendicular electric strength of laminates. Four specimens should be tested. The sample size is recommended to be 4 in.  $\times$  4 in. with any copper cladding removed. Unless otherwise specified, the samples need to be conditioned for 48 hours in distilled water at 50°C. After that, the samples are immersed in ambient temperature distilled water for a minimum of 30 min. to allow the samples to achieve temperature equilibrium without a substantial change in moisture content. The test is performed at ambient temperature (23°C). Relative humidity is not significant as the tests are performed under oil. Samples are inserted into the high-voltage test equipment and tested to failure at a 500volts/sec. increase. The results are reported in volts/mil.

The test method (see Fig. 12.10) following IPC-TM-650, method 2.5.6, describes the determination of the parallel electric strength of laminates. Four specimens should be tested: two in machine direction, and two in the transverse direction for reinforced materials. The samples size is recommended to be 3 in. long by 2 in. wide with any copper cladding removed. Two holes 0.188 in. in diameter are to be drilled along the centerline of the 3 in. dimension and midway between the edges in the 2 in. dimension, with a spacing of 1 in. center to center. Conditioning and test setup in oil is identical. Electrodes are inserted in the holes and the samples are tested to failure at a 500volts/sec. increase. The results are reported in kilovolts (KV).

**FIGURE 12.10** Dielectric strength breakdown

## 12.5.4 Other Laminate Properties

Other laminate properties to consider include flammability and water absorption.

**12.5.4.1 Flammability.** The flammability of laminate materials is classified according to Underwriters Laboratories (UL) specifications. All of the tests are performed using a standard test setup under an exhaust hood using a Bunsen burner as a source for the flame. The categories are as follows:

- **UL-94-V-0** Specimens must extinguish within 10 sec. after each flame application and within a total of less than 50 sec. after a total of 10 flame applications. No samples are to drip

flaming particles or exhibit glowing combustion that lasts for more than 30 sec. after the second flame test.

- **UL-94-V-1** Specimens must extinguish within 30 sec. after each flame application and within a total of less than 250 sec. after a total of 10 flame applications. No samples are to drip flaming particles or exhibit glowing combustion that lasts for more than 60 sec. after the second flame test.
- **UL-94-V-2** Specimens must extinguish within 30 sec. after each flame application and within a total of less than 250 sec. after a total of 10 flame applications. Samples may drip flaming particles or burn briefly, but no specimen may exhibit glowing combustion that lasts for more than 60 sec. after the second flame test.

In most cases, the laminator will provide results for these tests routinely. In the case of new materials for which the laminator has not supplied any flammability data, it may be a good idea to check this property. This does not require an elaborate test setup, and you can get a first indication by igniting a sample specimen under an exhaust hood using a lighter.

**12.5.4.2 Water Absorption.** Depending on their specific molecular composition, every laminate material will absorb a certain amount of water. This will happen not only during the many wet processing steps in printed circuit board manufacturing but also as a result of exposure to normal environmental conditions. The absorbed moisture may change the properties of the laminate and increase the risk of blistering and delaminations during high-temperature processes such as reflow soldering.

The test method, according to IPC-TM-650, method 2.6.2.1, determines the amount of water that is absorbed by a laminate material sample when immersed in water for 24 hours. The test is easy to perform and the results for different laminates are readily comparable.

The test samples for this test need to be 2 in. long by 2 in. wide. The thickness is not specified but should not vary widely when more than one material is characterized. The edges of the samples need to be sanded smooth and copper cladding is to be removed using standard etching processes. The samples are preconditioned in a drying oven for 1 hour at 105°C (221°F), cooled down to room temperature in a desiccator, and weighed immediately after removal. Then the samples are placed in distilled water at 23°C. It is important to place the samples on their edge to maximize the laminate area exposed to water. After 24 hours, the samples are removed, dried with a dry cloth, and immediately weighed. The moisture absorption is reported in percent weight increase.

## 12.5.5 Additional Tests

In addition to the previously described test methods, many more can be found in IPC-4101 and in the test methods manual IPC-TM-650. All of these tests address laminate properties that may have a significant impact on the performance of the final product. The final decision as to which qualification tests to include or exclude always needs to be made on a case-by-case basis depending on the performance requirements for the printed circuit board.

At the same time, there are a number of laminate qualification tests that rarely will be performed in the printed circuit manufacturing facility. In many cases, the laminate supplier will perform a number of qualification tests itself and share the results with its customers. This may in many cases be sufficient, especially after a close relationship between the supplier and the PCB manufacturer has been established.

## 12.5.6 Prepreg Testing

During the qualification of a new laminate material, it may also become necessary to perform prepreg-specific tests to verify its quality. The most commonly tested properties of prepreps are resin content, flow during multilayer processing, and gel time. Details about additional properties and all corresponding test methods can be found in IPC-4101.

## 12.6 CHARACTERIZATION TEST PLAN

Table 12.4 summarizes all of the test procedures.

**TABLE 12.4** Laminate Characterization Test Plan

1. Step	Data comparison	Unit	Test result			
	Material available in production volume	yes/no				
	Material cost	\$/m <sup>2</sup>				
	Material data sheet available	yes/no				
2. Step	First test runs in small volume	Unit	Test method	Conditioning	Data sheet	Test result
	Surface and appearance		IPC-TM-650, method 2.1.2 & 2.1.5	As received		
	Copper peel strength laminate Condition A	N/mm	IPC-TM-650, method 2.4.8	As received		
	Copper peel strength laminate Condition B	N/mm	IPC-TM-650, method 2.4.8	Solder pot 288°C/10s		
	Solder shock laminate 288°C/10s	Pass/fail	IPC-TM-650, method 2.4.23	As received		
	Solder shock laminate 288°C/60s	Pass/fail	IPC-TM-650, method 2.4.23	As received		
	Glass transition temperature (DSC, TMA, or DMA)	°C	IPC-TM-650, as applicable	As received

## 12.7 MANUFACTURABILITY IN THE SHOP

During the qualification of a new material, it is also crucial to run the laminate through the production processes to check whether they are compatible. Table 12.5 summarizes all the steps that are necessary to control.

The first process step is innerlayer processing. Here, a change in stiffness of the new laminate material can have a significant impact on the processability in horizontal manufacturing lines. This is especially important for thin cores. A change in the copper quality of the new laminate may impact the adhesion of the innerlayer photoresist and can also affect the copper etch rates. During automatic optical inspection (AOI), it is necessary to verify the contrast between copper circuitry and laminate and adjust the AOI settings if necessary. In case of necessary innerlayer repairs, the settings for the welding process may need adjustment to avoid thermal damage of the laminate and ensure reliable interconnects. The last step during innerlayer processing is copper blackoxide. Here, it is necessary to verify the compatibility of the employed blackoxide (reduced/nonreduced or alternative) to the base material to obtain a sufficient innerlayer bond strength of the multilayer product. The dimensional stability of the innerlayers must be measured after the multilayer cycle to adjust the innerlayer scaling factors of the new material.

The next step after multilayer lamination and edge routing is drilling. A change in the thermomechanical properties of the laminate may impact the quality of the drilled holes, and adjustments to drill speeds or desmear settings may be necessary. After metallization and plating, the adhesion of the copper in the plated through hole as well as reliable contacts to all innerlayers must be verified.

**TABLE 12.5** Summary of Production Steps

Compatibility with innerlayer (IL) process steps
Preclean
Resist lamination
Exposure
Develop, Etch, Strip
Punching
IL-Automatic optical inspection
IL-Repair/outerlayer (OL)-repair
Blackoxide/oxide alternatives
Compatibility with multilayer process steps
IL drying
Lay up
Press cycle
Edge routing
Dimensional stability check
Compatibility with process steps from drill to electroless copper
Drilling
Brush/Pumice/Debur
Desmear/Plasma Desmear/Other
Electroless copper or similar process
Compatibility with soldermask process step
Compatibility with different finish metallization processes
Electroless Ni/Au
Immersion Sn
Immersion Ag
Compatibility with routing process

The adhesion of soldermask may also change as well when a new material is introduced. This is especially critical in combination with any metal finish process steps (such as electroless Ni/immersion Au, immersion Sn, and immersion Ag). In addition to having a negative impact on soldermask adhesion, these processes in combination with new laminates can also lead to nonselective metal plating or skip plating. One of the last manufacturing steps that should be evaluated during the introduction of a new laminate material is board routing and scoring. Here the use of a new base material with changed stiffness or different reinforcement may lead to necessary process adjustments.

### 13.1 CLASSES OF PCB DESIGNS

---

Printed circuit boards (PCBs) or printed wiring boards (PWBs) can be divided into two general classes which have common characteristics based on their end functions. These two classes have very different materials and design requirements and functions and, as a result, need to be treated differently throughout the design and fabrication processes. The first class contains analog, RF, and microwave PCBs such as are found in stereos, transmitters, receivers, power supplies, automotive controls, microwave ovens, and similar products. The second contains digital-based circuitry such as is found in computers, signal processors, video games, printers, and other products that contain complex digital circuitry. Table 13.1 lists many of the characteristics of each class of PCBs.

**TABLE 13.1** Characteristics of RF/Analog versus Digital-Based PCBs

RF, microwave, analog PCB	Digital-based PCB
Low circuit complexity	Very high circuit complexity
Precise matching of impedance often needed	Tolerant of impedance mismatches
Minimizing signal losses essential	Tolerant of lossy materials
Small circuit element sizes often essential	Small circuit element sizes desirable
Only 1 or 2 layers	Many signal and power layers
High feature accuracy needed	Moderate feature accuracy needed
Low/uniform dielectric constants needed	Dielectric constant secondary

#### 13.1.1 Characteristics of Analog, RF, and Microwave PCBs

As can be seen from Table 13.1, the materials, design, and fabrication needs of this class of PCBs are markedly different from those of PCBs commonly referred to as digital.

- Circuit complexity is low because most components used have two, three, or four leads. This is due to the high usage of resistors, transistors, capacitors, transformers, and inductors.

- Traces, pads, and vias often act as inductors, capacitors, and coupling elements in the actual circuit. Their shapes may have a material effect on overall circuit performance. For example, the lead inductance and capacitance in a transistor collector circuit wire may act as the resonant components for an RF amplifier or it may degrade performance if it is unwanted. Figure 13.1 shows the impedance of traces as a function of their capacitance.

**FIGURE 13.1** Trace capacitance vs. trace impedance, based on  $L_0 = 8.5$  nH/in. (Prepared by Ritch Tech, 1992.)

- Two traces running side by side may be used to couple a signal from one circuit to another as is done in directional couplers of microwave amplifiers. (This same coupling in a digital circuit may result in a signal getting into a neighboring circuit causing a malfunction.)
- A series of conductors running side by side may function as a band-pass filter. Proper performance of filters, as well as most other wideband RF circuits, depends on all frequencies traveling with equal speed through the structures. To the extent that this is not true, frequencies that arrive later distort the signal being processed. This is called *phase distortion*.

Figure 13.2 illustrates the dielectric constant of various PCB materials as a function of frequency. Notice that some materials exhibit a dramatic decline in dielectric constant as frequency increases. The speed with which a signal travels through a dielectric is a function of the dielectric constant. Figure 13.3 illustrates signal velocity as a function of dielectric constant. From these two graphs it can be seen that using a dielectric material with a nonuniform dielectric constant in RF applications may result in severe phase distortion because the higher-frequency components arrive at the output before the lower frequencies.

- A trace in a power supply circuit may be expected to carry several amps without significant heating or voltage drop. Its resistance may even be used as a sense element to detect current flow. Similarly, handling large currents with insufficient copper in a trace may result in a voltage drop that degrades circuit performance. Figure 13.4 illustrates trace resistance of a copper trace as a function of its width and thickness. Figures 13.5 and 13.6 illustrate conductor heating as a function of width, thickness, and current flow.
- PCBs used in consumer electronics tend to share lower circuit complexity with RF and analog PCBs. However, the performance demands are far lower. The need for the lowest possible cost offsets this. To achieve the cost objectives, every effort is made to keep all connections on a single side and to form all holes in a single operation by punching. This

FIGURE 13.2 Dielectric constants versus frequency of various PCB materials.

FIGURE 13.3 Signal velocity as a function of dielectric constant. (Prepared by Shared Resources, Inc., 1991.)

eliminates both drilling and plating. The substrate material system is often resin impregnated paper, the lowest-cost substrate system for electronic packaging.

Summarizing, successful RF and analog design depends heavily on the properties of the materials used and on the physical shapes of the conductors and their proximity to each other

FIGURE 13.4 Trace resistance vs. trace width and thickness. (Prepared by Ritch Tech.)

FIGURE 13.5 Temperature rise vs. current for 1-oz copper.

rather than on the ability to handle very large numbers of circuits simultaneously. Hand routing or connecting of the individual parts coupled with manipulating the shapes of individual copper features are essential parts of this design process. For these reasons, the design tools and design team must be chosen to meet these needs. Physical layout tools that provide convenient graphical manipulation of PCB shapes are a must.

### 13.1.2 Characteristics of Digital-Based PCBs

Compared to RF and analog PCBs, digital-based PCBs have complex interconnections, but are tolerant of rather wide feature size and materials variations.

**FIGURE 13.6** Temperature rise vs. current for 2-oz copper.

- They are characterized by very large numbers of components, often numbering in the hundreds and sometimes the thousands.
- Digital components often have large numbers of leads, as high as 400 or more. This high lead count stems from logic architectures that have data and address buses as wide as 128 bits or more. To connect PCBs with these wide data buses, digital systems often contain board-to-board connectors with as many as 1,000 pins.
- Digital circuits have increasingly fast edges and low propagation delays to achieve faster performance. Edge rates as fast as 1 ns are now encountered in devices destined for products as common as video games. Table 13.2 lists edge speeds of some commonly used logic families, edge rate being the time required for a logic signal to switch from one logic level to the other (switching speed). Propagation delays, the time required for a signal to travel through a device, are decreasing along with edge rates.

**TABLE 13.2** Typical Logic Family Switching Speeds

Logic family	Edge speed, ns	Critical length, in
STD TTL	5.0	14.5
ASTTL	1.9	5.45
FCTL	1.2	3.45
HCTL	1.5	4.5
10KECL	2.5	7.2
BICMOS	0.7	2.0
10KHECL	0.7	2.0
GaAs	0.3	0.86

- These fast edges and short propagation delays lead to transmission line effects such as coupling, ground bounce, and reflections that can result in improper operation of the resulting PCB. Table 13.2 illustrates the degree to which a fast switching signal will couple into a neighboring line as a function of the edge-to-edge separation and the height of

the signal pair above the underlying power plane. The critical length listed in Table 13.2 is the length of parallelism between two traces at which the coupling levels in Fig. 13.7 are reached.

FIGURE 13.7 Trace-to-trace coupling. (Prepared by Shared Resources, Inc.)

The digital circuits themselves are designed to function properly with input signals that vary over a relatively wide range of values. Figure 13.8 illustrates the signal levels for a typical logic family, in this case ECL. The smallest output signal from an ECL driver is the difference between  $VOL_{max}$  and  $VOH_{min}$  or 0.99 V. The smallest input voltage to a device at which the logic part is designed to work properly is the difference between  $VIL_{max}$  and  $VIH_{min}$  or 0.37 V. The difference between these two levels, the noise margin of 0.62 V is available to counteract losses in the wiring and the dielectric and from other sources such as coupling and reflections. From this it can be seen that digital logic has a high tolerance of losses and higher immunity to noise.

This tolerance of noise and losses makes it possible to have trace features and base materials that introduce substantial losses and distortion while still achieving proper operation. It is this relatively high tolerance of distortion that makes it possible to manufacture economical digital PCBs.

**Summary.** The large number of connections in digital PCBs generally requires multiple wiring layers to successfully distribute power and interconnect all the devices. As a result, the design task is heavily weighted on the side of successfully making many connections in a limited number of routing layers while obeying transmission line rules. The base materials need to have characteristics that result in a PCB that is economical to fabricate and able to withstand the soldering processes while preserving high-speed performance. Compared to RF PCBs, losses in the dielectric tend to be of little concern for digital PCBs. The actual shapes of conductors, pads, holes, and other features have little effect on performance. (For detailed treatment of these topics, see Howard W. Johnson and Martin Graham, *High Speed Digital Design: A Handbook of Black Magic*, Prentice-Hall, New York, 1993.)

The PCB design system and the design skill set for digital PCBs must be optimized to ensure accuracy in making large numbers of connections while successfully handling the high speed requirements of the system. Achieving this in a reasonable amount of time demands the use of a CAD system that contains an automatic router for use in connecting the wires.

TYPICAL 10K ECL LOGIC VOLTAGE LEVELS

MAXIMUM SIGNAL SWING = VOHmax - VOLmin 1.04 V

"1" NOISE MARGIN = VOHmin - VIHmin 145 mV

13.2 TYPES OF PCBs OR PACKAGES FOR ELECTRONIC CIRCUITS

The range of choices for packaging electronic circuits is quite broad. Some of the parameters that influence the choices are weight, size, cost, speed, ease of manufacture, repairability, and function of the circuit. The more common types are listed as follows with a brief description of their characteristics.

*Levels of packaging* are often used when referring to how electronic circuits are packaged. The first level of packaging is the housing of an individual component. This is usually an encapsulating coating, a molded case, or a cavity-type package such as a pin grid array (PGA). The second level of packaging is the PCB or substrate on which individual components are mounted. Third-level packaging is any additional packaging beyond these two. Most often third-level packaging takes the form of a multichip module (MCM) that has bare components mounted in it which is itself mounted on a PCB along with other components.

13.2.1 Single- and Double-Sided PCBs

These PCBs have conductor patterns on one or both sides of a base laminate with or without plated through-holes to interconnect the two sides. These are the workhorses of consumer

electronics, automotive electronics, and the RF/microwave industry. They are the lowest-cost choice for consumer products. Laminate materials range from resin-impregnated paper for consumer electronics to blends of low-loss Teflon™ for RF applications.

### 13.2.2 Multilayer PCBs

These PCBs (see Fig. 13.9) have one or more conductor layers (usually power planes) buried inside in addition to having a conductor layer on each outside surface. The inner layers are connected to each other and to the outer layers by plated through-holes or vias. These are the packages of choice for nearly all digital applications ranging from personal computers to supercomputers. Numbers of layers range from 3 to as many as 50 in special applications. Laminate materials are nearly always some type of woven glass cloth impregnated with one of several resin systems. The resin system is chosen to satisfy requirements such as the ability to withstand high temperatures, cost, dielectric constant, or resistance to chemicals.

### 13.2.3 Discrete-Wire or Multiwire PCBs

This class of PCBs is a variation of the multilayer package. A circuit board is constructed by etching a pair of power layers back to back on a laminate substrate. A layer of partially cured, still sticky laminate is bonded to each side of this power plane structure. Discrete wiring is rolled into this sticky adhesive in patterns that will connect leads or serve as access to surface-mount component pads.

Once all of the wires have been rolled into place, a second layer of laminate is placed over the wires, followed by copper foil sheets. This sandwich is then laminated, drilled, and processed like any multilayer PCB. The resulting PCB has outer layers and power planes much like any multilayer PCB. The principle difference is that the printed wiring signal layers have been replaced by discrete wiring layers. In some cases of very high wiring density, alternating layers of power planes between wiring layers serve as isolation.

Designing a discrete wiring PCB (see Fig. 13.10) involves adding a special discrete-wiring router to a standard PCB design system to generate the files for the machine that rolls the wire into the dielectric. Discrete wiring once provided a faster prototyping alternative to multilayer fabrication. At the present time, both technologies are equally rapid and cost effective during prototyping. However, for modest to high-volume production, multilayer technology is more cost effective than discrete wiring.

### 13.2.4 Hybrids

These circuits are usually single- or double-sided ceramic substrates with a collection of surface-mount active components and screened-on resistors made from metallic pastes. They are most often found in hearing aids and other miniature devices.

### 13.2.5 Flexible Circuits

These circuits are made by laminating copper foil onto a flexible substrate such as Kevlar® or Kapton®. They can range from a single conductor layer up to several layers. They are most often used to replace a wiring harness with a flat circuit to save weight or space. Often, the flexible circuit will contain active and passive components. Common applications are cameras, printers, disk drives, avionics, and video tape recorders.

**FIGURE 13.9** Cross section of 14-layer multilayer printed wiring board, showing a typical inner layer and prepreg material relationship. In this case, to reduce z-axis expansion, the innerlayers are polyimide, while the prepreg material is semicured polyimide. Typical signal, power, and ground layers are also indicated, as well as the thickness of the copper foil for each layer.

**FIGURE 13.10** Cross section of a discrete-wire PCB. (Courtesy of Icon Industries.)

### 13.2.6 Flexible Rigid or Flex-Rigid

As the name suggests, these are combinations of flexible PCBs and rigid PCBs in a single unit. The flexible portion of the circuit is made first and included in the lamination process of the rigid portion of the assembly. This process eliminates wiring harnesses and the associated connectors. Applications include avionics and portable equipment such as laptop computers. As a rule, a flex-rigid assembly is more expensive than an equivalent combination of PCBs and cables.

### 13.2.7 Backplanes

Backplanes are special cases of multilayer PCBs. They tend to contain large quantities of connectors that have been installed using press fit pins. In addition, backplanes are used to distribute large amounts of dc power to the system. This is accomplished by laminating several power planes inside the backplane and by bolting bus bars onto the outside surfaces. Some applications require that active components, such as surface-mount ICs, be soldered to their surfaces. This greatly increases the difficulty of assembly as a result of the need to solder fine-pitch parts to a large, thick PCB.

### 13.2.8 MCMs (Multichip Modules)

Multichip modules are essentially miniature PCBs. Miniaturization is achieved by removing components such as ICs from their packages and mounting them directly to the substrate using wire bonds, flip chip, TAB or flip TAB. The motivation for using an MCM is miniaturization, reduction in weight, or a need to get high-speed components as close to each other as

possible to achieve high-speed performance goals. MCMs usually represent a third level of packaging in a system between packaged components and the carrier PCB. As a result, this additional level of packaging virtually always results in a more expensive, more complex assembly than the equivalent circuits in standard packages. There are several types of MCM package.

**13.2.8.1 MCM-L, Multichip Module Laminate.** This version of an MCM is manufactured from very thin laminates and metal layers using the same techniques employed in the manufacture of standard PCBs. Features such as holes, lands, and traces are much finer and require tooling similar to that used to manufacture semiconductors. This is the least expensive MCM type to design, tool, and manufacture. The same design tools and methodologies used for PCBs can be used.

**13.2.8.2 MCM-C, Multichip Module Ceramic.** This version of an MCM is manufactured by depositing conductor layers on thin layers of uncured ceramic material, punching and backfilling holes with vias, stacking the layers, and firing the total to create a hard ceramic multilayer substrate. This is the second least expensive MCM type to design, tool, and manufacture. It has been the workhorse of IBM's large mainframe computers for at least two decades. The same design tools and methodologies used for PCBs can be used.

**13.2.8.3 MCM-D, Multichip Module Deposited.** This version of an MCM is manufactured by depositing alternating thin films of organic insulators and thin films of metal conductors on a substrate of silicon, ceramic, or metal. The design and manufacturing techniques used for this technology resemble that used to create integrated circuit metallization. The thermal conductivity of the substrate is quite good. Design and fabrication support for MCM-D is limited.

**13.2.8.4 MCM-D/C, Multichip Module Deposited and Cofired.** This version of an MCM is a combination of a cofired, multilayer ceramic substrate containing the common wiring for a family of modules and deposited conductor and insulation layers containing the personality wiring. It has all of the problems of each technology it uses plus problems related to mismatches in temperature coefficient of the two materials systems.

**13.2.8.5 MCM-Si, Multichip Module Silicon.** As the name implies, this MCM technology starts with a silicon substrate like that used to make integrated circuits. Conductor patterns are formed using silicon dioxide (glass) as an insulator and aluminum or a similar metal for the wiring patterns in the same manner as is employed to build an integrated circuit. In fact, the same design tools and fabrication tools used to build ICs are used to build MCM-Si modules.

A significant advantage of MCM-Si is the fact that the substrate is the same material as the ICs that will be attached to it. Therefore, it is thermally matched to the ICs, ensuring reliable contacts over extremes of temperature.

**13.2.8.6 Summary of MCM Technologies.** MCM packaging may be seen as a way to achieve higher performance from a collection of high-speed ICs than can be accomplished by mounting them onto a PCB or as a way to reduce size and weight. In reality, higher levels of integration nearly always result in a more economical solution. For all but low-volume, specialty applications, such as aerospace electronics and specialty processors for very high performance equipment, this has proven to be true for quite some time. This is likely to continue to be so for some time as semiconductor technology continues to improve the density of functionality that can be placed on a single IC. One need only examine the progression of microprocessor performance to see this phenomenon at work.

When a high-performance product requires integrated circuits made with different processing technologies, such as analog and CMOS or ECL and CMOS, integration does not represent

a reasonable alternative to MCMs. Examples of this type of product are high-performance graphics products and video signal processing equipment.

### **13.3 METHODS OF ATTACHING COMPONENTS**

---

A wide range of methods has evolved for attaching components to PCBs. The methods chosen as well as the combinations of methods chosen for a product have a substantial impact on the final cost, ease of assembly, availability of components, ease of test, and ease of rework. The five basic attachment combinations are: through-hole only, through-hole mixed with surface-mount on one side, surface-mount one side only, surface-mount both sides, and surface-mount both sides with through-hole.

#### **13.3.1 Through-Hole Only**

All component leads attach to the PCB by being inserted into holes that pass through the PCB. The components may be secured by wave soldering or by pressing into holes that result in an interference fit (press fit). Assembly involves a component placement operation followed by a wave-soldering operation. This method is still the workhorse of the low-cost consumer electronics industry.

#### **13.3.2 Through-Hole Mixed with Surface-Mount**

Components such as connectors and PGAs are attached to the PCB with through-hole technology. All other components are mounted using surface-mount packages. This is the most common method used to assemble electronics products. Assembly is a two-step process that involves placing all surface-mount parts and soldering them in place with a solder reflow system, then inserting all through-hole parts and soldering them in place in a wave-soldering operation. Alternatively, the through-holes may be hand-soldered if the quantity is small.

#### **13.3.3 Surface-Mount, One Side Only**

This type of package is made up of only surface-mount parts all mounted on the same side of the PCB. Assembly is a one-step process that involves placing all components and soldering them in place using some form of solder reflow.

#### **13.3.4 Surface-Mount, Both Sides**

This type of package contains surface-mount components on both sides. Assembly is a two-step process that involves placing all components on one side and reflow soldering them, followed by placing all components on the other side and reflow soldering them. In addition to more complex assembly operations, designing and testing this type of assembly is much more complex, as parts often share the same area on opposite sides of the PCB, causing conflicts when trying to locate vias and test points.

#### **13.3.5 Surface-Mount, Both Sides with Through-Hole**

As the name implies, this package type contains surface-mount parts on both sides, as well as through-hole parts such as connectors. In most cases, the surface-mount components on one

side are passives, such as bypass capacitors and resistors that can withstand being passed through wave soldering. Assembly is a three-step process that involves placing the surface-mount components on the primary side and reflow soldering them. Once this is complete, the secondary-side surface-mount components are glued in place, the through-hole components are inserted, and the PCB is sent through wave soldering.

Because of the extra operations and exposure of components on the secondary side to molten solder, this type of assembly is prone to many assembly defects. It is important to note that soldering fine-pitch parts on the secondary side using wave soldering results in excessive solder bridging and should be avoided. In addition, active components, such as ICs, may be damaged by exposure to excessive heating.

## 13.4 COMPONENT PACKAGE TYPES

---

Over time, a wide assortment of packages has been developed to house components. Selecting the correct package type for each component is one of the most important parts of the design process. Package types chosen affect ease of design, assembly, test, and rework, as well as product cost and component availability.

### 13.4.1 Through-Hole

This class of component is characterized by parts that have wire or formed leads. These leads pass through holes drilled or punched in the PCB and are soldered to lands on the back side or to plating in the holes. This is the original package type used for electronic components. A major benefit of through-hole components is the fact that every component lead passes all the way through the PCB. Because of this, there is automatic access to any PCB layer to make connections. Further, every lead is available on the bottom of the PCB, so test tooling is easy to construct. With the advent of surface-mount components, through-hole is used primarily for connectors and pluggable devices such as microprocessors mounted in PGA packages.

Through-hole packages are often preferred for ICs and other components that dissipate large amounts of heat, because of the relative ease with which heat-sinking devices can be fitted to them. In addition, it is much easier to provide a socket for a through-hole device. This eases the task of changing programmable parts and microprocessors when it is necessary to upgrade a system.

**Caution:** Integrated circuits in through-hole packages are becoming difficult to find as they are displaced by surface-mount equivalents and should be avoided in new designs unless a secure supply of components is available for the production life of the design.

### 13.4.2 Surface-Mount

This package type is the mainstream choice for packaging electronic components of every type, including connectors. Its principle characteristic is that all connections between a component lead and the PCB or substrate is made with a lap joint to a pad on the surface of the PCB. This has both advantages and disadvantages. On the advantage side, since there are no holes piercing the PCB, wiring space on inner layers and on the reverse side is not consumed with component lead holes. Because of this, it is usually possible to wire a PCB in fewer layers than would be true with through-hole parts. Another and larger benefit is the fact that surface-mount components are always smaller than their through-hole equivalent, making it possible to fit more parts in a given area.

The main disadvantages of surface-mount components stem from the fact that there are no leads to easily grip with instrumentation probes and that there may not be access to the leads

from the reverse side for purposes of production testing. This gives rise to the need to add a test pad to most nets on the back side in order to perform production test. It also gives rise to the need for very expensive, complex adapters in order to provide access to leads on processors and other complex devices to probe their inputs and outputs when performing diagnostic work.

Yet another disadvantage of surface-mount parts stems from their small size. It is more difficult to remove heat from SMT packages than it is for their through-hole equivalent. In some cases, such as high-performance processors, the heat generated by the IC is too high to permit proper operation in an SMT package.

### 13.4.3 Fine Pitch

Fine pitch is a special class of surface-mount components. This class is characterized by lead pitches lower than 0.65 mm (25 mils). These fine lead pitches are usually driven by very high lead count ASICs (160 pins and up) or by the extreme miniaturization requirements of PCMCIA (Personal Computer Memory Card Industry Association) cards, PDAs (personal digital assistants), and other small, high-performance products. The motivation for designating a special fine-pitch-component class of surface-mount parts is the extra difficulty of successfully testing, assembling, and reworking these parts on PCBs, as well as in building PCBs with accurately formed patterns and solder masks to mate with the leads of fine-pitch parts. Fine-pitch parts are the source of most manufacturing defects in a well-run SMT assembly line. The defects stem from lack of coplanarity of the leads, bent leads, insufficient solder on the joints, and poor alignment of the leads to the patterns on the PCB.

Successful manufacture using fine-pitch components involves very tight cooperation among the PCB designer, the PCB fabricator, the component manufacturer, and the PCB assembler/tester. It almost always involves specialized assembly, test, and rework tooling. Design is most often done by convening a series of meetings of the engineering personnel of all these groups to evolve a set of rules, processes, equipment, tooling, and components. These meetings need to start at the product development stage and continue to be held until the proper pad shapes and sizes have been established and the production process is stable.

### 13.4.4 Press Fit

Press fit is a special form of through-hole technology. Components are fastened to the PCB by deliberately designing an interference fit between the component lead and the plated through-hole in the PCB. The principle application of press-fit technology is the attachment of connectors into backplanes. The reason for this is that early backplanes were built by wire wrapping the signal connections onto the connector pins extending out the back of the backplane. Trying to solder the connector pins to the backplane through this field of pins proved difficult, if not impossible. The solution was press fit.

Successful assembly of a press-fit backplane rests in designing a hole size small enough to create a solid connection with the pins while ensuring that the hole is large enough to permit the insertion of the pin without fracturing the hole barrel.

**Caution:** Hot-air leveling the solder on a backplane results in a hole with irregular diameter. This irregularity will almost certainly result in damaged hole plating when the insertion operation is done. Be sure to note on the fabrication drawing of a press-fit backplane that hot-air solder leveling is prohibited. Solder must be plated onto the backplane traces and pads and fused using IR reflow or hot-oil reflow to fuse the lead and tin into a solder alloy.

### 13.4.5 TAB

TAB stands for tape-automated bonding, which is a technique for attaching bare IC die to a printed circuit board. It uses a subminiature lead frame that attaches directly to the bonding

pads of an IC at one end, spreads out to a much larger pitch, and attaches to pads on a PCB. The tape in the title describes the method for carrying the parts prior to assembly, which is a tape with the TAB lead frame and IC built into it. The tape is wound onto a reel for handling. The principle application of TAB components is products such as pagers and portable phones that are made in very high volume and can justify the automation involved in attaching TAB parts to substrates.

#### 13.4.6 Flip Chip

Flip-chip technology involves plating raised pillars of metal on the bonding pads of ICs, turning them upside down, and attaching them to a matching pattern on a substrate. The substrates are most often silicon and precision ceramics. From this description, it can be seen that this is a very specialized packaging method. To succeed, a source of tested good bare die with plated-on pillars must be available. This situation occurs almost exclusively in very high performance supercomputers where the ICs have been specially designed for the application or in very high volume applications such as pagers and cellular phones.

#### 13.4.7 BGA

BGA or ball grid array is a relatively new technology that is a cross between pin grid arrays and surface-mount. High-pin-count IC die are mounted on a multilayer substrate made from ceramic or organic material. The die are connected to the substrate using standard wire-bond techniques and encapsulated in epoxy or another form of cover. The bottom side of the substrate contains an array of high-melting-point solder balls which connect to the wire-bond pads through the multilayer substrate. These balls mate with a matching array of pads on the PCB and are reflow soldered during the same operation as all other surface-mount parts. (See Fig. 13.11.)

The appeal of BGA technology is as an alternative to high-pin-count, fine-pitch SMT ICs. As mentioned earlier, assembling high-pin-count, fine-pitch SMT parts is very difficult, owing to the fragile nature of the component leads. BGAs represent a much more robust package during component-level test and during assembly.

As with most technologies, there are some disadvantages to BGAs. Among these are:

- The solder joints are hidden from view, so inspecting them requires x-rays.
- The solder joints are not accessible for rework, so the soldering process must have a very high success rate.
- Part removal requires special tooling.
- The pattern on the PCB surface is an array of pads that require one via each all the way through the PCB, hampering routing.
- All component leads are concentrated in a much smaller area than the equivalent part in a fine-pitch SMT package. This concentrates the wiring in a small area pierced with many vias. As a result, the BGA PCB will likely have more wiring layers than the equivalent SMT PCB.
- The BGA package is more expensive than the equivalent fine-pitch SMT package, by as much as three times.

#### 13.4.8 Wire-Bonded Bare Die

As the name implies, this method of assembly involves attaching bare IC die directly to a substrate using an adhesive or reflowing solder and connecting the bonding pads to pads on the

**FIGURE 13.11** Typical ball grid array package. (Courtesy of Icon Industries.)

PCB using wire-bond techniques. Virtually all digital watches and many other similar consumer products use this assembly technique. It is very inexpensive when used in very high volume products with only a single IC to connect.

### 13.5 MATERIALS CHOICES

A wide variety of materials has been developed for use in packaging electronic circuits. These can be divided into three broad classes: reinforced organics, unreinforced organics, and inorganics. These are used primarily for rigid PCBs, flexible and microwave/RF PCBs, and multi-chip modules, respectively. The following treatment of the available materials concentrates on the principle materials systems used in PCB design along with the properties that warrant their use. See Chaps. 6 and 8 in this handbook for detailed data provided on loss tangents, temperature of coefficient of expansion, glass transition temperature, and other electrical properties.

IPC, the Institute for Interconnecting and Packaging Electronic Circuits, publishes a comprehensive series of standards that list in detail the properties of all types of laminates, resins, foils, reinforcement cloths, and processes that are candidates for the manufacture of PCBs. These standards start with IPC-L-108B and run up to IPC-CF-152. It is recommended that copies of the applicable standards be obtained at the start of a program in order to ensure a thorough understanding of all important characteristics of the materials being considered for a design.

Properties important to the manufacture of PCBs include (see Table 13.3):

- *Glass transition temperature*  $T_g$ —The temperature at which the coefficient of thermal expansion in a resin system makes a sharp change in rate from a slow rate of change to a

rapid rate of change. A high  $T_g$  is important for PCBs that are very thick to guard against barrel cracking or pad fractures during the soldering operation.

- **Coefficient of thermal expansion  $T_{CE}$** —Surface-mount assembly process subjects the printed wiring assembly to more numerous temperature shocks than typical through-hole processes. At the same time, the increase in lead density has caused the designer to use more and more layers, making the board more susceptible to problems concerned with the base material's coefficient of thermal expansion  $T_{CE}$ . This can be a particular problem with regard to the  $z$ -axis expansion of the material, as this induces stresses in the copper-plated hole, and becomes a reliability concern. Figure 13.12 shows typical  $z$ -axis expansion for a variety of printed circuit base laminate materials.

**FIGURE 13.12** Typical  $z$ -axis expansion via thermal mechanical analysis. (Courtesy of Nelco International Corp.)

- **Relative dielectric constant  $e_r$** —This characteristic measures the effect that a dielectric has on the capacitance between a trace and the surrounding structures. This capacitance affects impedance as well as the velocity at which signals travel along a signal line. (See Figs. 13.3 and 13.4) Higher  $e_r$  produces lower impedance, higher capacitance, and lower signal velocity.
- **Loss tangent,  $\tan(f)$ , or dissipation factor**—A measure of the tendency of an insulating material to absorb some of the ac energy from electromagnetic fields passing through it. Low values are important for RF applications, but relatively unimportant for logic applications.
- **Electrical strength or dielectric breakdown voltage DBV**—The voltage per unit thickness of an insulator at which an arc may develop through the insulator.
- **Water absorption factor WA**—The amount of water an insulating material may absorb when subjected to high relative humidity, expressed as a percent of total weight. Absorbed water increases relative dielectric constant as well as reduces DBV.

### 13.5.1 Reinforcement Materials

The principal reinforcement for PCB substrate materials is cloth woven from glass fibers. A variation of this glass is cloth made from quartz fibers. The resulting material has a slightly lower dielectric constant than ordinary glass, but at a substantial cost premium and a more difficult drilling cycle. Kevlar is an alternate woven reinforcement that results in a lower-weight material system with a lower dielectric constant, also at a higher cost and higher difficulty in processing.

**TABLE 13.3** Properties of Some Common PCB Materials Systems\*

	$T_g$	$e_r$	$\tan(\delta)$	DBV, V/mil	WA, %
Std. FR-4 epoxy	125C	4.1	0.02	1100	.14
Multifunctional epoxy	145C	4.1	0.022	1050	.13
Tetrafunctional epoxy	150C	4.1	0.022	1050	.13
BT/epoxy	185C	4.1	0.013	1350	.20
Cyanate ester	245C	3.8	0.005	800	.70
Polyimide	285C	4.1	0.015	1200	.43
Teflon	N.A.	2.2	0.0002	450	0.01

\* All with E-glass reinforcement, except Teflon.

The original reinforcement material for PCBs was paper or cardboard in some form. Paper impregnated with a resin system is still in use in consumer applications where lowest possible cost is necessary and where performance is not an issue.

### 13.5.2 Polyimide Resin Systems

Polyimide resin-based laminates are the workhorse of electronics that must withstand high temperatures in operation or in assembly or repair. Common applications include down-the-hole well-drilling equipment, avionics, missiles, supercomputers, and PCBs with very high layer count. The principle advantage of polyimide is its ability to withstand high temperatures. It has approximately the same dielectric constant as epoxy resin systems. It is more difficult to work with in fabrication, is more costly than FR-4 systems, and absorbs more moisture.

### 13.5.3 Epoxy-Based Resin Systems

Epoxy resin-based laminates are the workhorse of virtually all consumer and commercial electronic products. There are several variations of this pervasive laminate family, each developed to answer a special need. Among these are standard FR-4, multifunctional epoxy, difunctional epoxy, tetrafunctional epoxy, and BT or bismaleimide triazine blends. Each of these was developed to answer the need for a resin with a successively higher  $T_g$  or glass transition temperature. Multifunctional epoxy is the most commonly used form.

### 13.5.4 Cyanate Ester-Based Resin Systems

This resin system is a recent entrant into the high-performance resin system category. It is said to offer processing characteristics superior to those of the FR-4 blends while offering a higher  $T_g$ .

### 13.5.5 Ceramics

A wide variety of ceramic or alumina substrate materials have been developed for use in hybrids and multichip modules. These materials are the subject of specialized manufacturing processes beyond the scope of this handbook. The reader needing information on this group of materials is advised to contact a major manufacturer of ceramic materials.

### 13.5.6 Exotic Laminates

Kevlar, Kapton, Teflon, and RO 2800 are materials developed for specialty applications. The first two, in the form of thin films, are commonly used as substrates for flexible circuits. The latter two

are the principal dielectrics for microwave and RF circuits. All of these materials can be used with or without reinforcements.

### 13.5.7 Embedded Components Materials

Specialized materials have been developed to allow construction of passive components such as resistors and capacitors into the PCB structure itself. Most of these materials are patented and available from a very small supplier base.

**13.5.7.1 Embedded Resistors.** These are formed by plating a very thin film of nickel or other metal onto a copper foil layer and laminating this foil, plated side in, to an FR-4 or other substrate material. To form a resistor, a window is opened in the copper foil, exposing the underlying nickel resistor layer. A resistor of the appropriate value is formed in the resistance material layer. Contact is made with the resulting resistor by etching connecting pads in the copper foil layer and drilling holes through these pads and plating the holes. (See Fig. 13.13.)

**FIGURE 13.13** The two light diagonal shapes in the figure above are terminating resistors for ECL transmission lines. They are formed directly in the VTT powerplane by etching the copper away from the underlying nickel resistive layer. One end of each resistor is connected to the device terminal using a via and the other end is connected directly to the  $-2.5\text{V}$  plane. (Courtesy of Ohmega Industries.)

Resistive material is available in 25- and 100- $\Omega$ /square values. The principal application of embedded resistor technology is as terminating resistors for ECL transmission lines and as resistors on flexible circuits in products such as cameras and portable tape and CD players. Practical resistor values range from about 10 to 1000  $\Omega$ .

**13.5.7.2 Embedded Capacitance.** This is formed by placing two copper planes close to each other using very thin dielectrics (1.5 to 2.0 mils). The principal application is in the creation of very high quality, high-frequency capacitance between two power planes. This does indeed result in high-quality capacitance, but usually at a high cost resulting from the need to add a pair of extra planes to a PCB in order to create the capacitance (see Fig. 13.14).

FIGURE 13.14 Capacitance per unit area vs. dielectric thickness.

## 13.6 FABRICATION METHODS

A wide variety of fabrication methods has been developed to meet the needs of the electronics industry. The following descriptions are quick summaries of each method intended to acquaint the reader with their advantages and disadvantages and likely applications. Detailed treatments are presented elsewhere in this book.

### 13.6.1 Punch Forming

Punch forming is used in the manufacture of very low cost, single-sided PCBs such as are used in many consumer electronic products. The process involves printing and etching the conductor patterns on one side of a laminate substrate, usually paper-reinforced epoxy. All holes are punched in a single stroke by a die containing a pin and opening for each hole. The PCB outline is formed in a second die that “blanks” it from the panel in which it is processed.

Often, several PCBs will be contained in a single panel sized to travel through the assembly process. After a PCB is punched out of the panel, it is forced back into the vacant hole and is held in place by interlocking fibers along the edges of the PCB. After assembly and testing is complete, each PCB is pressed from the panel. This is known as *crackerboarding* and is aimed at reducing overall manufacturing costs.

### 13.6.2 Roll Forming

Roll forming is a process used to manufacture flexible circuits in very large quantities. This is the lowest-cost method for the manufacture of flexible circuits. However, it involves substantial tooling, so it is applicable only for very high volume products. Examples of PCBs manufactured using this method are printer head connections, disk drive head connections, and the circuits used in cameras and camcorders. The PCBs can be single- or double-sided.

Roll forming resembles newspaper printing in that the process starts with a large roll of copper-clad laminate that is fed through a long process line containing stations which perform each operation on a continuous basis, starting with printing the conductor pattern, etching it, forming the holes, testing, and blanking from the roll itself. The process can include lamination of a cover insulator layer over the conductors as well.

### 13.6.3 Lamination

Lamination is the process by which PCBs of more than two layers are formed. The process begins by etching the conductor patterns of the inner layers onto thin pieces of laminate called *details*. These details are then separated by partially cured laminate called *prepreg* and stacked in a *book* with layers of prepreg on the top and bottom and foil sheets on the outside. This stack is placed into a press capable of heating the combination to a temperature that causes the prepreg resin to reach the liquid state. The liquefied resin flows into the voids in the copper patterns to create a *solid* panel upon cooldown. Once cooled, the panel is sent through the drilling and plating operations much like a two-sided PCB.

Note that some materials, such as polyimide, do not have a prepreg form to act as the glue during lamination. In these cases, a special glue sheet must be used during lamination to fasten the individual layers together.

### 13.6.4 Subtractive Plating

Subtractive plating is a method of forming traces and other conductive patterns on a PCB by first covering a sheet of laminate with a continuous sheet of copper foil. A layer of etch resist is applied such that it covers the copper pattern that is desired. The panel with protective coating is passed through an etcher that removes (subtracts) the unwanted copper, leaving behind the desired patterns. This is the dominant, almost only, method in common usage in the printed circuit industry today.

### 13.6.5 Additive Plating

As the name implies, this method of forming conductor patterns involves beginning with a bare substrate and plating on the conductor patterns. There are two methods for doing this: electroless plating on areas sensitized to accept electroless copper and electroplating by first applying a very thin coating of electroless copper over the entire surface to act as a conductive path, followed by electroplating to full thickness.

Additive plating is seen as a method for reducing the amount of chemicals required to manufacture PCBs, and this is true. However, the process does not yield copper sufficiently robust to withstand the handling of normal assembly and rework. As a result, it is not commonly available in production.

### 13.6.6 Discrete Wire

Discrete wire is a method for forming the wiring layers by rolling round wire into a soft insulating material coated onto the outsides of power plane cores. This method is often referred to as *multiwire*. It is available from only a very small number of manufacturers and offers few advantages over conventional multilayer processing. It is described more fully in Sec. 13.2.3.

## 13.7 CHOOSING A PACKAGE TYPE AND FABRICATION VENDOR

A key part of arriving at a successful design is choosing PCB materials, component-mounting techniques, and fabrication methods that meet the performance needs of the product being designed while achieving the lowest possible costs. Among the decisions that are part of this process are deciding whether to package a product on one large PCB or several smaller PCBs, whether to spread components out to hold the layer count down or increase layers, move components closer together, and design a smaller PCB, whether to package some components in a multichip module that is then mounted on the PCB, as well as other issues.

Part of this decision-making process is arriving at an overall package choice that can be manufactured by the mainstream fabricators and assemblers. Failure to do this will result in excessively high prices and long lead times stemming from the lack of a competitive supplier base from which to choose. At the extreme, where some of the more exotic materials systems are used, there may be as few as one supplier to turn to. In markets where there is substantial price pressure, such as with disk drives and PCs, it is imperative that the design choices be made such that the PCBs can be manufactured at offshore fabricators. Not doing this will place the product at a competitive disadvantage.

### 13.7.1 Trading Off Number of Layers Against Area

Cost of the bare PCB is often a significant contributor to the overall cost of an assembly. As the number of layers in a PCB increases, the cost increases. A standard practice is to spread components out to make room for the connecting wiring as a way to avoid adding additional wiring layers. As might be expected, there is a point at which PCB size grows to where a smaller PCB with more layers yields a more economical solution. Determining where this breakpoint is requires some knowledge about the PCB fabrication process.

Table 13.4 shows typical costs of four-, six-, and eight-layer 18 in by 24 in standard process panels built at offshore manufacturers. This table can be used to calculate the relative cost of PCBs as layer count is increased to reduce area. While the absolute costs in the table are based on Spring 1995 pricing for Pacific Rim fabricators, the percentage relationships between the costs of panels of various layer counts are a good indicator of relative costs for deciding when to increase layer count and reduce area.

**13.7.1.1 Background Information.** Multilayer PCBs of six or more layers are normally built on standard 18 in by 24 in panels using pin lamination. Many four-layer PCBs are built offshore using a process called mass lamination with panels sizes of 36 in by 48 in (four times a “standard” panel). The pricing of individual PCBs is based on how many PCBs fit on a stan-

**TABLE 13.4** PCB Panel Process Cost vs. Layer Count  
Price per panel, \$ U.S., Spring 1995

Number of layers	Panels per mo. 100	Panels per mo. 250	Panels per mo. 1000	Panels per mo. 5000
4 mass lam*	\$260	\$250	\$240	\$231
4 pin lam†	84	80	77	74
6 pin lam†	113	108	104	100
8 pin lam†	147	140	135	130

To determine the number of PCBs that will fit onto a panel, allow 0.125 in between PCBs and allow 0.75-in margin on all four sides. Net areas are 34.5 in by 46.5 in and 16.5 in by 22.5 in.

For gold plating on connector tips, add up to \$2 per PCB.

\* 36 in × 48 in panel.

† 18 in × 24 in panel.

standard panel. Therefore, designers need to choose finished PCB sizes with this in mind (assuming the size is negotiable).

The pricing matrix in Table 13.4 is in price per panel based on the following:

- Solder mask over bare copper, silk screen one side only
- Standard multifunctional FR4 laminate
- 1-oz copper inner layers, ½-oz outer layer foil plated up to 1.5 oz nominal
- Thickness accuracy:  $\pm 10\%$  overall,  $\pm 1.5$  mil any dielectric layer
- No controlled impedance requirement or testing
- 1-mil minimum copper plating in holes
- No vias smaller than 13 mils
- Traces and spaces: 7 mil, 7 mil
- Standard delivery: (no acceleration premium)
- Fabrication site: Pacific Rim Fabricators
- No gold plating
- Tested to CAD netlist

Since PCB fabrication is based on standard panels, the cost of each PCB is affected by how much of each panel is used to form the PCBs built on it and the amount of the panel that is scrapped. Clearly, the more of each panel that is usable, the lower the average cost of each PCB will be. As one chooses the size and form factor of each PCB, attention should be paid to how many will fit onto a standard panel in order to minimize the scrap material created.

### 13.7.2 One PCB vs. Multiple PCBs

One way to keep individual PCB layer counts down is to divide the circuitry among several smaller, simpler PCBs. There is a hidden cost associated with doing this. The hidden cost is spread across several organizations, ranging from the design activity, through manufacturing, and into the sales and service organization. The costs are those associated with handling multiple assemblies, such as managing multiple designs and their documentation, managing the procurement, inventory, testing and stocking of multiple assemblies, and the cost of interconnecting the multiple assemblies. In almost all cases, these costs exceed any savings that might be realized by the creation of multiple assemblies.

# CHAPTER 14

---

## THE PCB DESIGN PROCESS

---

**Lee W. Ritchey**

*3Com Corp., Santa Clara, California*

---

### 14.1 OBJECTIVE OF THE PCB DESIGN PROCESS

---

The objective of the PCB design process is to engineer a PCB, including all of its active circuits, that functions properly over all the normal variation in component values, component speeds, materials tolerances, temperature ranges, power supply voltage ranges, and manufacturing tolerances and to produce all of the documentation and data needed to fabricate, assemble, test, and troubleshoot the bare PCB and the PCB assembly. Doing less than this in any area exposes the manufacturer and user of the PCB assembly to excessive yield losses, excessively high manufacturing costs, and unstable performance.

Achieving the objective involves carefully designing a process that matches the end product, selecting design tools with controls and analytical utilities, and selecting a materials system and components that match.

---

### 14.2 DESIGN PROCESSES

---

Figure 14.1 is a flowchart of the major steps in a complete PCB design process, beginning with specification of the desired end product and continuing through to archiving or storing away the design database in a form that permits subsequent design modifications or regeneration of documentation as necessary to support ongoing production. This process takes advantage of all the computer-based tools that have been developed to assure a “right the first time” design. The basic process is the same for either analog or digital PCBs. The differences in the design process for the two classes of PCBs center around the differences in complexity of these two types of circuits, as mentioned in Chap. 13.

#### 14.2.1 The System Specification

The design team begins a new design by creating a *system specification*. This is a list of the functions the design is to perform, the conditions under which it must operate, its cost targets, development schedule, development costs, repair protocols, technologies to be used, weight and size, and other requirements as are appropriate. A rough definition of each of these variables is necessary at the start to permit proper choices of materials, tools, and instrumentation. For example, a project may involve the design of a portable computer that must weigh less

FIGURE 14.1 PCB design process steps.

than 5 lb, fit into a briefcase, operate on batteries for two hours, have a mean time between failures (MTBF) of 200,000 hours or more, cost less than \$2000, have 4 Mbytes of memory, 240 Mbytes or more of mass storage, and be MS-DOS compatible. This specification serves as the starting point for a new design.

### 14.2.2 System Block Diagram

Once the system specification has been completed, a block diagram of the major functions is created, showing how the system is to be partitioned and how the functions link or relate to each other. Figure 14.2 is an example of this partitioning.

### 14.2.3 Partitioning System into PCBs

Once the major functions are known and the technologies that will be used to implement them are determined, the circuitry is divided into PCB assemblies, grouping functions that must work together onto a single PCB. Usually this partitioning is done where data buses link functions together. Often these buses will be contained on a backplane into which a group of daughter boards are plugged. In the case of a personal computer (PC), partitioning often results in a mother board and several smaller plug-in modules such as memory, display driver, disk controller, and PC card (PCMCIA) interface.

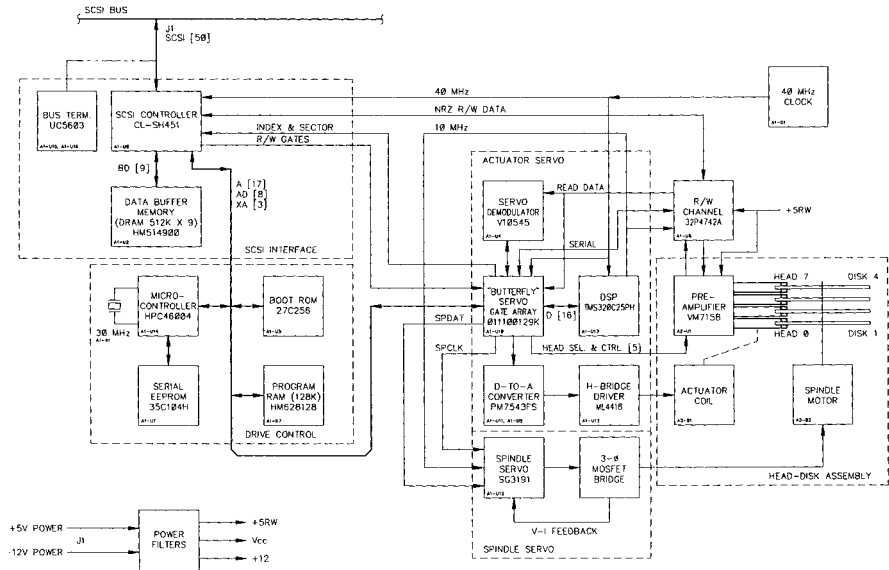

### 14.2.4 Determining PCB Size

As soon as the amount of circuitry and the technology that each PCB must contain is known, the area and size of each PCB may be estimated. Often, the PCB size is fixed in advance by the end use. For example, a system based on VME or multibus technology will have to use the PCB sizes defined by the standard. In this case, system partitioning and component packaging technology will be dictated by what will fit onto these standard PCB sizes.

The finished cost of a PCB often turns on the number of layers and the quantity that will fit onto the standard manufacturing panel sizes. (For most PCB fabricators, this size is 18 in by 24 in with a usable area of 16.5 in by 22.5 in) Sizing PCBs to utilize all or most of the panel area results in the most cost-effective bare PCB. (See Table 13.4.)

### 14.2.5 Creating the Schematic

Once the system function, partitioning, and technologies have been determined, the schematic or detailed connections between components can take place. Schematics and block diagrams are normally created on CAE (computer-aided engineering) systems. These systems allow the designer to draw the schematic on a CRT screen or terminal. The data needed by all of the following steps in the design process is generated by the CAE system from this schematic.

**FIGURE 14.2** This is a block diagram of a digital device (in this case a disk drive) that has been segmented to its assembly levels. The dashed lines represent initial partitioning of the entire product to printed circuit assemblies and also shows the expected interface (connector) requirements.

### 14.2.6 Building Component Libraries

The tools used in the PCB design process must be supplied a variety of information about each part in order to complete each step. This information is entered into a library or set of libraries, one entry per component. Among the pieces of data needed are:

- Type of package that houses the component, e.g., through-hole, QFP, DIP
- Size of component, lead spacing, lead size, pin-numbering pattern
- Function each pin performs, e.g., output, input, power pin
- Electrical characteristics of each pin, e.g., capacitance, output impedance

### 14.2.7 Simulating Design

To be sure a design will perform its intended function over the intended range of conditions, some form of design verification must be done. These conditions may include component value accuracies, range of component speeds, operating and storage temperature ranges, shock and vibration conditions, humidity ranges, and power supply voltage range. Historically, this has been done by building breadboards and prototypes and subjecting them to rigorous testing. As systems and their operation software have grown more complex, this technique has proved to be inadequate. To solve this problem, simulators have been developed that allow a computer to simulate a function without having to build it. These simulators make it possible to perform tests far quicker, more rigorously, and more completely than any breadboard or prototype could ever be expected to.

Defects discovered by a simulator can be corrected in the simulation model with ease and the tests rerun before any commitment to hardware is made.

### 14.2.8 Placing Components on PCBs

Upon successful completion of the logical and gross timing simulation process, the actual physical layout can begin. It begins by placing the components of the design on the surface of the PCB in patterns that group logical functions together. Once this is done, the groups of components are located on the PCB surfaces such that functions that interact are adjacent, components that generate heat are cooled properly, components that interface to the outside world are near connectors, and so on. This placement operation can be done manually by the designer using graphics-based tools or automatically by the PCB CAD system.

### 14.2.9 Sequencing Nets to High-Speed Rules

Most logic families have sufficiently fast rise and fall times and short enough propagation delays to be subject to high-speed problems such as coupling and reflections. To ensure that these high-speed effects do not result in malfunctions, it is necessary to arrange the connections between the loads, terminations, and drivers to control these high-speed phenomena. This arranging of nodes or points in a net is referred to as *sequencing* or *scheduling*. Once the components have been placed on the surface of the PCB, the spatial arrangement of all the nodes on each net is known. At this point, it is possible to determine how to connect the driver to the loads and terminators to form proper transmission lines, ensuring that improper stubs are not created and that the terminator is at the end of the net.

### 14.2.10 Simulating Timing and Transmission Lines Effects

Upon completion of component placement and sequencing the nodes in each net, it is possible to estimate the length and characteristics of each net. This is possible because the  $x$ - $y$  location of each point in a net is known, the order of connections is known, and the fact that the actual wiring must be done in either the  $x$  or  $y$  direction is also known. This length information can be used to model the high-speed switching characteristics of each net and predict the presence of excessive noise and reflections as well as to estimate the length of time required for signal to travel the length of each line, all before actually routing or building the PCB.

This simulation step makes it possible to detect potential malfunctioning signals prior to routing and take steps to fix the problem while the time invested in the design is still modest.

### 14.2.11 Adjusting Sequencing and Placement

If the simulations done in Sec. 14.2.10 reveal excessive time delays or reflection problems, the placement may need to be adjusted to move critical parts closer together or add terminations to nets with excessive reflections. By doing this simulation and adjustment, a design can be assured of meeting the “right the first time” goal so important to high-performance designs.

### 14.2.12 Testing Routability of Placement

At this point, enough analysis has taken place to know that the design will function correctly if routed. However, it may not route in the number of signal layers required by the cost goal. Most CAD systems have tools, such as rats-nest analyzers, that help the designer determine if the design will fit into the allowed signal layers. If it will not, the routability analyzer may give clues on how to revise the component placement to achieve a successful route. Once the placement has been adjusted, the timing and transmission line simulation steps must be repeated to ensure that the set of goals has been met.

### 14.2.13 Routing PCB

This step involves fitting all the connections into the signal layers in the form of copper traces, following spacing and length rules. It usually involves a combination of hand routing special signals and automatically routing the rest.

### 14.2.14 Checking Routed Results

After all the connections have been routed into the signal layers, the actual shape and length of each wire is known, as is the layer(s) on which the wires have been routed and which nets are neighbors. This physical data can be loaded into the timing and transmission line analyzers to do a final check that all design goals have been met. Any violations that are detected can be repaired by hand rerouting as necessary. Once this set of checks has been completed and any adjustments made, the final routed result is checked against the schematic netlist to ensure that there are no discrepancies. A final check is performed on the Gerber data to ensure that the line width and spacing rules have been complied with and that there is no solder mask or silk screen on any pad, as well as that traces and other features that must be protected from solder are covered by solder mask.

### 14.2.15 Generating Manufacturing Files

This step involves generating the photoplotting files, pick-and-place files, bare and loaded board test files, drawings, and bills of material needed to do the actual manufacturing. Typical lists of these files are shown in Tables 14.1 and 14.2.

### 14.2.16 Archiving Design

Once all the manufacturing data has been created, the design database and all of the manufacturing data files are stored on a magnetic tape or other storage media for future use to incorporate changes and for backup in the event that the files and drawings created for manufacturing are lost or destroyed.

**TABLE 14.1** A Typical Collection of Design Files Sent to a PCB Fabricator

File name	File contents
BBBBpCCC.arc*	Arc file of Gerber files containing:
applist.p	List of photoplot apertures for artwork
ly1 thru lyx.ger	Gerber photoplot data for x PCB layers
topmsk.ger	Gerber photoplot data for top solder mask
botmsk.ger	Gerber photoplot data for bottom solder mask
topslk.ger	Gerber photoplot data for top silk screen
botslk.ger	Gerber photoplot data for bottom silk screen
pc_356.out	IPC 356 data for blank PCB netlist testing
name0.rep	Drill allocation report for plated holes
name0.prf	Excellon drill file for all plated holes
name1.rep	Drill allocation report for all nonplated holes
XX.XX.fab	Fabrication drawing in HPGL format, sheet XX of XX

\* BBBBpCCC is the part number of the PCB.

**TABLE 14.2** A Typical Collection of Design Files Sent to a PCB Assembler

File name	File contents
BBBBaCCC.arc*	Arc file of all assembly data containing:
applist.a	Aperture list for plotting paste mask
readme.asy	Readme file describing assembly
tpstmsk.ger	Gerber photoplot data for top paste mask
bpstmsk.ger	Gerber photoplot data for bottom paste mask
BBBB-CCC.dbg	Mfg. output, data format info.
BBBB-CCC.dip	Mfg. output, $x$ - $y$ loc. dip components
BBBB-CCC.log	Mfg. output, component log.
BBBB-CCC.man	Mfg. output, $x$ - $y$ loc. manual insert components
BBBB-CCC.smt	Mfg. output, $x$ - $y$ loc. top smt components
BBBB-CCC.smb	Mfg. output, $x$ - $y$ loc. bottom smt components
BBBB-CCC.unp	Mfg. output, parts not mounted
BBBB-CCC.vcd	Mfg. output
XX_XX.asy	Assembly drawing in HPGL format, sheet XX of XX
XX_XX.fab	Fabrication drawing in HPGL format, sheet XX of XX

\* BBBBaCCC is the part number of the assembly.

### 14.3 DESIGN TOOLS

From the definition of the objective of the PCB design process it can be seen that the process extends from concept all the way through fabrication to assembly and test. Computer-based tools have evolved to automate or improve the speed and accuracy of every step in the process. These tools can be divided into three major groupings based on where they are used:

- CAE (computer-aided engineering) tools
- CAD (computer-aided design) tools
- CAM (computer-aided manufacturing) tools

It is apparent from the names of the tools that they are used in circuit design, physical layout of the PCB, and manufacture of the bare PCB and the PCB assembly.

#### 14.3.1 CAE Tools

CAE tools is the name generally used to refer to the computer-based tools and systems that are employed in the stages of design before the physical layout step or to analyze and evaluate the electrical performance of the final physical layout. These include:

**14.3.1.1 Schematic Capture Systems.** As the name implies, these tools are used by the design engineer to draw a schematic or circuit diagram. The simplest systems are graphical replacements for the classical drawing board, allowing the engineer to place logic and electronic symbols on the surface of the drawing and connect their terminals with lines. More advanced systems perform substantial error checking such as guarding against multiple uses of the same pin or net name. Failure to connect critical pins such as power pins can be done by using information contained in their component libraries about each part. In addition, these systems can generate netlists to be used by simulators and PCB routers and bills of material for use in the manufacture of the PCB assembly.

**14.3.1.2 Synthesizers.** Synthesizers are specialized CAE tools that allow a designer to specify the logic functions that a design is expected to perform in the form of logical operations such as dual full adder, 16-bit-wide register, or other macro functions. The synthesizer will extract the equivalent logic circuit functions from a function library and connect them together as specified by the designer to arrive at a complete logic diagram. This synthesized circuit can then be used as part of a bigger design. Some advantages of synthesizers are that all functions of a given type will be implemented the same way and be error free and that time needed to compose a system schematic is reduced by eliminating the labor required to design repeating circuits.

**14.3.1.3 Simulators.** Simulators are software tools that create computer-based models of a circuit and run them with input test patterns to verify that the circuit will do the intended function when implemented in hardware. Even when run on very large computers, simulators usually run at only a tiny fraction of the speed of the actual circuit. When circuits grow complex, as in a 32-bit microprocessor or digital signal processor, the time required to perform a complete simulation can be very long, sometimes so long that this method of circuit verification becomes impractical. Typical simulation speeds are 1 or 2 s for each machine cycle. A machine cycle may be as little as 2ns or 500 million/s for a system with a 500-MHz clock. This is a 500 million-to-1 slowdown! As circuits have grown more complex and simulation times have become excessive, engineers have been forced to build physical models of a proposed circuit and run actual code against the model as a method of ensuring that the design is accurate. Clearly, this adds both time and cost to the development cycle, both by adding the time needed to build the model and the time needed to locate design errors and fix them. The solution to this problem is circuit emulation.

**14.3.1.4 Emulators.** Emulators or circuit emulators are collections of programmable logic elements, such as PLAs (programmable logic arrays), that can be configured to represent almost any kind of logic circuit. These emulators are commercially available as standard products from several EDA (electronic design automation) companies. The resulting hardware emulation of a circuit can be operated much faster than a software simulation, sometimes as fast as  $\frac{1}{1000}$  of actual final operating speed. Due to this increased speed, the verification of a circuit can take place much faster. In some cases, the emulations are used as substitutes for the actual circuit to verify that the software created to run with the circuit is error free before any commitment is made to final hardware. This technique is used extensively in the design of complex ICs such as microprocessors and custom ASICs. In fact, the Intel Pentium™ microprocessor and its operating system was completely emulated and run successfully on a large hardware emulator prior to making the first silicon.

The use of emulation technology has eliminated the need to iterate or modify designs as errors are detected, saving very large sums of development money as well as development time. In some cases, it has made circuits practical that would not be without it. For example, most supercomputers and other advanced products are built with multilayer ceramic PCBs and MCMs. These packaging technologies do not lend themselves to modification with external wiring to correct errors. As a result, it is necessary to produce entirely new assemblies in order to correct design errors. The same is true for the integrated circuits in the system as well.

**14.3.1.5 Circuit Analyzers.** Circuit analyzers are tools that examine circuits to ensure that they will perform properly over the range of timing variations in circuits and tolerances of components that are expected to be encountered in normal manufacturing. These analyzers do this by constructing mathematical models of each circuit and then varying the values of each component over their expected tolerance ranges. The behavior of the circuit is calculated by its model and the result compared to preestablished limits. Violations are flagged to alert the design engineer. Among the conditions checked for are freedom from excessive signal coupling from neighboring circuits and that transient behavior such as reflections, overshoot and undershoot, and ringing are within proper limits. This type of analysis is often referred to

as worst-case tolerance and timing analysis. It can be run on a design before physical layout begins as well as after layout is completed.

Some examples of circuit analyzers are SPICE and PSPICE. SPICE and PSPICE build mathematical models of each circuit and then perform thousands of complex calculations to predict how the circuit will respond to input signals. Most suppliers of CAD systems also offer their own adaptations of these analysis tools.

**14.3.1.6 Impedance Predicting Tools.** These tools are used to examine the cross section, trace sizes, and materials properties of a PCB to ensure that the resulting circuit impedance is within allowable limits or to interactively adjust these parameters to achieve a desired final impedance. This is an essential step in the design of the PCB itself. Most suppliers of CAD systems intended for high-speed design supply some form of on-line impedance analysis tools as part of their systems.

### 14.3.2 CAD Tools

CAD tools are used to turn the electrical circuit described by the schematic into a physical package or PCB. CAD tools are typically operated by PCB designer specialists who are skilled in the areas of PCB manufacture and assembly rather than by electrical engineers. These tools are fed netlists, component lists, wiring rules, and other layout information by schematic capture or CAE tools. In their simplest form, they allow the designer to create the pad patterns for the component leads and PCB shape and then manually connect the component leads with copper traces. The most sophisticated CAD tools can automatically determine the optimum location of each component on the PCB (autoplacement) and then automatically connect (autorouting) all leads while following high-speed layout rules. This is accomplished by providing the CAD tool with a table of rules specifying which components must be located in groups or near connectors as well as by specifying how much space must be maintained between neighboring traces, the maximum length allowed between points on a net, etc.

The outputs of CAD tools are the information files needed to fabricate, assemble, and test the PCB assembly. These are test netlists, photoplotting files, bills of materials, pick-and-place files, and assembly drawings. CAD tools are made up of circuit routers, placement tools, checking tools, and output file generation tools.

**14.3.2.1 Placement Tools.** Placement tools are used to arrange the components on a PCB surface. Placement tools tend to be part of a complete CAD system rather than a module purchased separately. The inputs to a placement tool are:

- Component list or bill of material
- Netlist or manner in which the components connect to each other
- Shapes, sizes, and spacial arrangement of the component leads
- Shape of the PCB with areas into which components cannot be placed (keepouts)
- Instructions concerning fixed locations for components, such as connectors
- Electrical rules, such as maximum and minimum distance between points on a net
- Thermal rules, such as which parts must be kept apart or near sources of air flow

Placement tools range from completely manual to fully automatic. All have some form of graphical feedback to the designer that assesses the quality of the placement in terms of its ability to be routed or connected in the desired number of signal layers. Most have spacing rules that ensure that the components have enough room between them for successful assembly, rework, and testing.

**14.3.2.2 Routers.** Routers are the part of a CAD system that makes the physical connections between the components as specified by the netlist. A router operates on the PCB netlist

and placement after the placement step has been completed. Routers range from the completely manual, in which case the designer specifies where wires are to be located by using a graphical display and a mouse or light pen, to fully automatic, where a specialized software program takes the netlist, the placement, the spacing rules, and the wiring rules and makes all the decisions necessary to completely connect all components. The principal advantage of manual routing lies in the fact that the designer can tailor every connection to his liking. The principal disadvantage of manual routing is the fact that it is slow and time consuming, often taking several minutes to completely route and check a single net. Automatic or autorouters solve this speed problem. However, the ability to control the detailed shape of each net is limited by the ability of the autorouter to follow wiring rules. Some advanced autorouters are able to comply with very complex wiring rules. A significant problem with autorouters lies in the fact that they may not find ways to successfully route all of the wires. When this occurs, the designer must add more wiring space in the form of more layers or attempt to complete the routing manually. An important feature of a good autorouter is its manual routing option, as it substantially affects the ease with which this often necessary “finishing” operation is completed. Nearly all routers have a suite of checking tools that ensure that the final route matches the netlist and that all of the spacing rules have been followed.

Routers come in several forms and can be purchased as an integral part of a CAD system or as modules to add onto CAD systems. Some router types are:

*Gridded Router.* This type of router operates by placing wires on a predefined grid pattern. The routing surface is divided into a uniform grid that provides a proper gap between traces when wires are routed on every grid line. It is the first form of both manual and autorouter offered with CAD systems. The primary disadvantages of gridded routers are that it is difficult to manage more than one trace width without losing wiring density and it requires end points of nets to be on the routing grid in order to connect to them successfully. Offgrid component connections typically have to be made by hand and checked by hand.

*Gridless Router.* This form of router does not depend on a grid to locate wires on a surface. Instead, it places as many wires in a space as will fit and still maintain the spacing rules established by the design engineer to ensure proper electrical performance while optimizing manufacturability. Multiple trace widths on the same layer are handled easily by this type of router. Once the routing job is completed, the router divides up any unused space equally. The advantage of this technique lies in its ability to optimize manufacturability by keeping spaces as large as possible. The disadvantage of this type of router lies in the fact that it usually depends on a given wiring layer being all horizontal or all vertical—a real disadvantage in SMT applications where components do not need through-holes to connect them but a very powerful router for designs with a very regular array of high-pin-count parts, such as big CPUs and massively parallel processors. This router type is the workhorse of very high complexity digital designs where there is a great deal of regularity and a need to achieve predictable spacings and trace lengths for speed and performance reasons.

*Shape-based Router.* This type of router recognizes shapes already placed in a wiring surface and routes wires to avoid them. Spacing between wires and other objects, such as vias, used to change layers and component pads is maintained as the router places a wire in a space. This router is becoming the workhorse of SMT-based designs.

**14.3.2.3 Checking Tools.** These tools verify that the routed PCB complies with rules such as spacing between traces and trace and holes by comparing the actual spacings found in the finished artwork to rules provided by the designer. They also ensure that all nets are completely connected and are not connected to objects they should not be, such as other nets and mechanical features on the PCB, by comparing the routed results to data supplied by the CAD system. Some checking tools also check to ensure that transmission line rules are followed and that coupling from neighboring traces is within limits. Checking tools are usually an integral part of a CAD system.

**14.3.2.4 Output File Generators.** Once a PCB has been routed and all connectivity verified as accurate, the CAD system holds this information in a neutral form specific to the way

in which its operating system is built. For this data to be useful in manufacturing, it must be converted into forms usable by other equipment such as photoplotters, testers, assembly equipment, and MRP systems. Output file generating routines do this conversion. Most CAD systems are equipped with a limited set of these when shipped. Additional generators or converters must be ordered as add-ons.

### 14.3.3 CAM Tools

CAM tools are CAD systems tailored to the needs of the fabrication process. The output of the PCB design process is a set of CAD files that describes each artwork layer of a PCB, the silk screen requirements, drilling requirements, and netlist information. This information must be modified before it can be used to build a PCB. For example, if a fabricator needs to build several copies of a PCB on a single panel, the fabricator will need to add specialized tooling patterns to the artwork and alter trace widths in order to compensate for etching. Initially, these operations were done manually with a high potential for error and significant labor costs. CAM stations or tools allow the fabricator to do all of these operations automatically and rapidly.

CAM stations can check artwork against spacing rules, breakout rules, and connectivity rules and make corrections if necessary. CAM stations can synthesize netlists (the manner in which points in a design are connected) from the Gerber data for use at bare PCB test, in those cases where no netlist was provided by the customer. In cases where a netlist was provided by the customer, the Gerber synthesized netlist can be compared to the CAD generated netlist as a final way of verifying that the artwork does, in fact, match the schematic—one more safeguard against data corruption anywhere in the translation processes.

## 14.4 SELECTING A SET OF DESIGN TOOLS

---

The task of selecting the proper set of CAE, CAD, and CAM tools for a project or company is often one of the most critical steps in determining project success. To reduce the problems associated with interfacing tools to each other, it is desirable to choose all of the tools from a single vendor. However, very few vendors are able to offer best-in-class tools for every phase of the design process. Further, it is very difficult for a single CAD/CAE system to handle the wide variety of design types that may be required across a very large process or across an entire company. For example, a CAD system with a powerful autorouter is of very little use to a design team laying out single-sided PCBs with many irregular parts such as transformers and power transistors. Conversely, a system tailored to do power supply layout well will fare very poorly on a CPU design with many high-speed buses. Knowing this, how does one select the “right” tool set?

### 14.4.1 Specification

The first step in the tool selection process is to characterize the types of design that the tool set will be required to handle. Next, the level of simulation and design rule checking required to ensure “right the first time” designs must be determined in order to select the right level of simulation and checking tools. For example, performing transmission line analysis on a stereo PCB may be an elegant step but it is a waste of resources. Choosing not to do this level of analysis on a high-speed disk drive PCB may result in a design that is unstable throughout its product life.

Key to success with any tool is the availability of designers qualified to operate it. This pool of designers needs to be assessed for each type of candidate system. If a system or tool is chosen that does not have a pool of qualified operators from which to draw, the result will likely be substantial delays while the necessary expertise is developed or designs that are substandard if the learning time is too short.

### 14.4.2 Supplier Survey

Once these facts are known, a survey of potential tool suppliers must be conducted. Basic elements include:

1. Determining how closely each tool candidate comes to meeting the need and its cost to acquire, set up, and maintain
2. Assessing the long-term viability of the supplier to ensure that the tool does not become an “orphan” should the supplier fail
3. Making a check with other users of the candidate tools to ensure that they perform as advertised

### 14.4.3 Benchmarking

Representative benchmark designs need to be made on each candidate system to assess how well they are done. Depending on the size of the potential sale and the size of the benchmark design, a vendor may do the benchmark free of charge. If not, one should be prepared to pay for this valuable step in the evaluation process. Only after completing all of these evaluation steps is it possible to make an informed selection. Doing less, such as relying on an outsider to recommend tools or taking a vendor’s word for it, carries the risk of owning a tool that delays development or, worse, having to repeat the selection process in the middle of a project.

### 14.4.4 Multiple Tools

Knowing the wide variety of designs that may be encountered and the fact that virtually all CAD and CAE tools have been designed to be very good at some subset of design types, it is unrealistic to expect that a single set of tools from a single vendor will be able to deal with all problems equally well. A company with a wide range of design types, such as a company engaged in the design of computers and instrumentation, should expect to own more than one set of tools, each set optimized to its set of tasks. Trying to force one set of tools onto all types of problems is certain to result in overtooling simple designs and undertooling complex ones.

## 14.5 *INTERFACING CAE, CAD, AND CAM TOOLS TO EACH OTHER*

---

A major argument for buying all of the CAE, CAD, and CAM tools from a single vendor is to ensure that they all play together. In the past, this was a major concern because each vendor had proprietary data formats and there were no industry standard data formats. IPC, IEEE, and other trade associations have evolved standard forms of data interchange between systems. These have been adopted by suppliers, such that it is relatively easy to interface best-in-class tools from different vendors to each other.

## 14.6 *INPUTS TO THE DESIGN PROCESS*

---

### 14.6.1 Libraries

Each CAE and CAD tool uses a series of libraries that contain information describing each component that may be used in a design. These range from a simple description of the physical size of the pads and their relative positions to a full logical model that can be exercised in a simulator. Libraries do not usually come as part of a system. They must be purchased separately or developed one part at a time by the user. Libraries in mature systems can be quite large and

represent a substantial investment in time to develop them. Unfortunately, libraries are usually unique to a given tool and cannot be transferred easily should a new tool be chosen.

**14.6.1.1 Pad Shapes and Physical Features.** The most basic library used by a CAD system describes the physical characteristics of a part in a manner that allows the CAD system to create its mounting holes pattern and pads as well as its silk screen outline and solder mask pattern. This library entry will contain a *pad stack* that describes how large the component lead holes are and the size and shape of the pads that will appear in each type of PCB layer. For example, an outer layer pad will need to be large enough to ensure adequate annular ring, an antipad will be needed in a power plane to ensure that the plated-through-hole barrel does not touch the power plane, or a thermal pad will be necessary to make a connection to the plane in a manner that still allows reliable soldering. These library entries may contain the unique part numbers used by a company to build a bill of materials, in which case, the CAD system will be able to produce a bill of material in ready-to-use form.

Some physical feature libraries also contain information about the nature of a pin, such as whether it is an input, output, or power pin. This data is used by the checking programs to ensure that the points in a net are ordered properly for high-speed performance or to ensure that a net has the correct kinds of pins in it.

**14.6.1.2 Functional Models.** CAE tools that simulate the operation of a PCB require a library of models that describe how each part operates logically. These are functional models. Functional models do not contain information about propagation delay or rise times needed to verify that timing rules are complied with. Functional models are often used to configure emulators.

**14.6.1.3 Simulation Models.** Simulation models are extended versions of functional models. They contain all the functional information as well as detailed information about path delays through a part and rise and fall times. They are used to ensure that worst-case timing conditions result in a properly operating design.

## 14.6.2 PCB Characteristics

One of the sets of data required by the physical layout system is a description of the PCB or its physical characteristics. This includes its size, number and kinds of layers, thicknesses of insulating layers, copper thicknesses, and areas that are not available for parts or traces.

## 14.6.3 Spacing and Width Rules

To ensure compliance with manufacturing and transmission line rules, the trace widths and trace spacings for each layer must be entered into the CAD system. This is typically done in tabular form.

## 14.6.4 Netlists

Netlists describe to the CAD system how the pins of each device connect to each other. Systems that manage routing or layout to high-speed design rules will require netlists that contain instructions on how to handle each net, such as what impedance to use, what spacing to preserve with respect to neighbors, and whether terminations or special ordering is needed.

## 14.6.5 Parts Lists

Parts lists tell the CAD system what type of library entry to use for each part in the design.

---

## CHAPTER 15

---

# ELECTRICAL AND MECHANICAL DESIGN PARAMETERS

---

**Ralph J. Hersey, Jr.**

*Lawrence Livermore National Laboratory, Livermore, California*

---

### 15.1 PRINTED CIRCUIT DESIGN REQUIREMENTS

---

The electrical characteristics of printed board and multichip electrical connection substrates have become a critical functional product definition, and design requirement, for many electrical and electronic products. Until the late 1980s, most printed board designs were printed wiring designs, in that, with the exception of power and ground distribution, component placement and the arrangement of conductive and nonconductive patterns were not critical for functional electrical requirements. This was particularly true for most digital applications. However, since the late 1980s, electrical signal integrity has become a more serious design consideration in order to meet both functional performance and regulatory compliance requirements.

---

### 15.2 INTRODUCTION TO ELECTRICAL SIGNAL INTEGRITY

---

Electrical signal integrity is a combination of frequency and voltage/current, depending on the application. In low-level analog, very small leakage voltages or currents, thermal instabilities, and electromagnetic couplings can exceed acceptable limits of signal distortion. In a similar manner, most digital components can erroneously switch by application of less than 1 V of combined dc and ac signals.

#### 15.2.1 Drivers for Electrical Signal Integrity

Analog and digital signals are subject to many issues that can cause signal distortion and degrade signal integrity. Some of these concern the transmission of the signal, and some the return paths.

**15.2.1.1 Signal Integrity Terms for Both Analog and Digital Signals.** Table 15.1 provides a listing of many of the issues that affect the signal transmission.

**TABLE 15.1** Representative List of Issues for Both Analog and Digital Signals

Rise time	Thermal offset voltage
Fall time	Thermal offset current
Skew	Low-level amplifier
Jitter	High-impedance amplifier
High skew rate	Charge amplifier
Intermodulation distortion	Integrating amplifier
Harmonic distortion	Wideband amplifier
Phase distortion	Video amplifier
Crossover distortion	Precision amplifier

**15.2.1.2 Return Paths.** All electrical signals have a signal conductor and a signal return path. Very frequently, the signal conductor is shown on the schematic and the return conductor is neither shown nor mentioned on the schematic/logic drawing. This can also present a problem with PB CAD (computer-aided design) tools. Some CAD tools are “dumb” in that they will automatically route a transmission line as one of the signal conductors but will not route the necessary signal ground on one of the adjacent conductive pattern layers.

## 15.2.2 Analog Electrical Signal Integrity

The design of some analog printed circuits is a critical balance of all of the known parameters and characteristics of the complete design-through-use product development, manufacturing, assembly, test, and use processes. Analog designs cover all or portions of the complete electromagnetic spectrum, from dc all the way up into the GHz range of frequencies. Active and passive electrical/electronic components and materials have various levels of sensitivity to operating environments and conditions, such as temperature, thermal shock, vibration, voltage, current, electromagnetic fields, and light. In particular, the signal input terminals, voltage connections, and especially analog signal grounds are critical to analog signal integrity.

**15.2.2.1 Sensitive Circuitry Isolation.** One of the key methods to improve analog signal integrity is to isolate or separate the more critical or sensitive portions of the design. Sensitive circuitry may be susceptible to one or more external forces, such as electromagnetic, voltage, and grounding systems, mechanical shock/vibration, and thermal. Sometimes the more sensitive circuitry is repackaged into a separate function module that provides its own isolation and separation from the offending condition. Isolation and separation can be provided by physical separation, electromagnetic and thermal barriers, improved ground practices and design, power source filtering, signal isolators, shock and vibration dampeners, and elevated or lowered temperature controlled environment.

**15.2.2.2 Thermal Electromotive Force.** Below a few millivolts, thermal electromotive forces (EMFs) can have a significant impact on low-level analog signal integrity. Thermal EMFs of a nonsymmetrical sequence of various metal junctions (conductors) or symmetrical sequences of various metal junctions operating at different temperatures will generate and inject undesirable voltage (or induce unwanted currents) into the electrical signal path. This thermocouple effect is desirable in the case of temperature measurements. However, in the case of other low-level measurements it is an undesirable characteristic. Therefore, the requirement for low-signal-level PCDs is to ensure that all components and electrical interconnection networks and corresponding electrical terminations (such as soldered, welded, wire-bonded, or conductive adhesive) are symmetrical and isothermal. Electrical components, such as thin/thick-film resistors of different values (resistance), may have resistor elements

manufactured from different formulations or compositions of materials and will have a designed-in thermal EMF error due to component selection.

### 15.2.3 Digital Electrical Signal Integrity

Each digital logic family of integrated circuits has manufacturer-specified electrical operating parameters and signal transfer characteristics, many of which have become industry standards due to multiple sourcing (manufacturing) of the family of components. The electrical signal integrity requirements for digital ICs are primarily the high and low electrical (voltage/current) requirements for the output, input, clock, set, reset, clear, and other signal names; the signal rise/fall times, clock frequency(s) and setup/hold times; and the voltage and ground connections as are necessary for the control and operation of the IC.

The input, output, and electrical signal transfer parameters and characteristics for digital ICs vary from logic or microprocessor family to family. Signal ICs are a large matrix of components, consisting of the semiconductor substrate materials, such as silicon, silicon/germanium, and gallium arsenide, that make up the various types of transistors. As shown in Table 15.2, the large number of digital IC families available create a complex matrix of design issues and requirements.

**TABLE 15.2** Typical Digital Logic Rise and Fall Times

Logic family	Typical rise/fall time, ns	Logic family	Typical rise/fall time, ns
STD TTL	5	H	6
L	6.5	HCT	8
S	3.5	AC	3
ALS	1.9	ACT	
FTTL	1.2	10K ECL	0.7
BiCMOS	0.7	100ECL	0.5
		GaAs	0.3

The electrical signal integrity of the rise and fall times of electrical signals is a major driver and concern for high-speed and high-frequency printed circuits. Table 15.2 lists some of the typical rise and fall times of some of the popular digital logic families.

## 15.3 INTRODUCTION TO ELECTROMAGNETIC COMPATIBILITY

Electromagnetic compatibility (EMC) is a serious design requirement for both functional performance to design and regulatory compliance requirements. EMC encompasses the control and reduction of electromagnetic fields (EMF), electromagnetic interference (EMI), and radio frequency interference (RFI) and covers the whole electromagnetic frequency spectrum from dc to 20 GHz. Worldwide, the electronics industry has had to pay increasing attention to EMC to comply with both national and international standards and regulations. EMC involves major design considerations that ensure proper function within the electronic component, assembly, or system in order to:

1. Limit the emission (radiative or conductive) from one electronic component assembly, or system, to another.
2. Reduce the susceptibility of an electronic component, assembly, or system to external sources of EMF, EMI, or RFI.

There are three keys to EMC:

1. Design the product so that it produces less stray electromagnetic energy.
2. Design the product so that it is less susceptible to stray electromagnetic energy.
3. Design the product to prevent stray electromagnetic energy from entering or leaving the product.

## 15.4 NOISE BUDGET

---

Good design requires up-front determination of a *noise budget*, which should be included in the product definition requirements. The noise budget is the summation of all of the dc and ac voltages (or currents) that form a boundary within which the component, assembly, or system is designed to function.

$$e_{\text{noise}} = e_{\text{dc}} + e_{\text{ac}} \quad (15.1)$$

where  $e_{\text{dc}}$  = dc electrical noise  
 $e_{\text{ac}}$  = ac electrical noise

The *dc noise budget* consists of the voltage settings (preset) of the power supplies, the operating tolerance of the power supply, and the series dc voltage drops of the voltage distribution system.

The *ac noise budget* consists of the effectiveness of the local bypass capacitor, the amount of decoupling between the load, the bulk decoupling capacitor, and the power distributions system, the local voltage drops in the component's voltage/ground conductors, and the component's input voltage tolerance.

As mentioned in Sec. 15.5.3, many of the operating electrical, mechanical, thermal, and environmental parameters and conditions can have a major influence on the noise budget. With a limited focus on digital designs, additional noises that may need to be considered are EMC radiated and conducted emissions from other electromagnetic equipment and thermally generated voltages (thermocouple effect) due to electrical connections with differing layers of metals operating at different temperatures. The following is a list of most of the electrical voltages that should be considered for a noise margin analysis:

Switching noise*	Changes in supply voltage
Cross-talk*	Changes in junction temperature
Impedance mismatch*	Changes in die ground voltage (IR)
Component wirebond (IR) <sup>†</sup>	Component lead (IR)

## 15.5 DESIGNING FOR SIGNAL INTEGRITY AND ELECTROMAGNETIC COMPATIBILITY

---

### 15.5.1 High Speed and High Frequency

Higher operating speeds and frequencies have had a dramatic effect on electronic packaging technology as a whole, but in particular on PBs and PBAs. Higher operating speeds have

---

\* For digital circuits these three may amount to about 50 to 60 percent of the noise budget.

<sup>†</sup> (IR) voltage drop (current  $X$  resistance).

forced an evolutionary change from traditional PWD methods and practices, which were suitable for lower operating speeds, into the realm of serious PCD. Many of the technical design practices for most digital designs have had to adopt high-frequency analog techniques for design, synthesis, and analysis. In addition, component packaging densities have increased, functional electronic packaging densities have increased, more digital components are of the CMOS family design, and CMOS power dissipation increases with operating frequency, the end result being that thermal management has become more of a concern to PBD and other electronic packaging design personnel.

## 15.5.2 Leakage Currents and Voltages

Input guarding for stray leakage currents and voltages can be an important design consideration, in particular for some analog but also for some digital designs (especially CMOS). Many analog design requirements are based on thermal, pressure, force, strain, and other sensor technologies that have very low levels and ranges of electrical output voltages or currents. In addition, many of the requirements are for measurement accuracy and precision of a few percent or less. In combination, these requirements can present a challenge to electronic and PBD personnel. Very few sensors are robust in terms of their electrical output parameters; most of them have what is termed in the analog world “low-level” signal output for voltage and/or current. Therefore, many of these sensors require signal conditioning and amplifier circuits to improve the integrity of the electrical signal(s). Many of these signal conditioning and amplifier circuits have high-input-resistance characteristics which cause them to be more susceptible to erroneous signals. As a result, “guarding,” as described later, becomes necessary to control stray voltages and currents.

Small, undesired, and unintended leakage currents and voltages can have a significant impact on the electrical signal integrity of some analog, as well as digital, applications. Leakage currents of a few nA or less, and leakage voltages of a few  $\mu\text{V}$  or less, can affect the designed functional performance of an electronic assembly. It is nearly impossible, from a practical point-of-view, for a high-input-resistance circuit to distinguish between a desired and undesired electrical signal. Thus, extreme care must be used in the design, manufacturing, and assembly processes of high-input-resistance products. Therefore, suitable PBD concepts must be included in the design to reduce and control the leakage currents and voltages. The following list identifies some of the common causes for leakage currents and voltages in PBAs.

- Insufficient (surface or volume) insulation resistance of base laminate
- Environmental contamination, fingerprints and skin oils, human breath, residual manufacturing and processing chemicals, improperly cured materials, solder fluxes, and surface moisture, such as humidity.
- Surface and subsurface contamination, such as can be found:
  - On or in the assembled component
  - Between conformal coatings and the surfaces they are protecting
  - On, in, or under the solder resist
  - Between conductive patterns on or in the electrical interconnection substrate

**15.5.2.1 Design Concepts to Control Leakage Currents and Voltages.** The primary concept for input guarding is to limit and control undesirable leakage currents and voltages or to prevent their formation in the first place. In theory, the principal is very simple: There are no leakage currents or voltages if there are no differences in electrical potential. In practice this is difficult to achieve and may not be a viable solution. However, by minimizing (the goal being to eliminate) the differences of potential between the critical electrical interconnection networks and components (leads and/or bodies) and all other materials, the formation of

undesired leakage currents and voltages can be controlled (minimum effect) or eliminated (maximum effect).

- Form a *Faraday cage* around the critical conductive patterns and components using a combination of conductive patterns (frequently called *input guarding* and *guard rings*) and shielding enclosures.
- Keep all unguarded voltages out of the Faraday cage or protected area.
- Electrically connect the Faraday cage to a low-impedance voltage source that follows the critical (protected) voltage.

#### 15.5.2.2 *Guard Rings—A Design Method to Control Leakage Currents and Voltages.*

The control of electrical leakage to the more critical signal terminals/leads can be optimized through the selection of components, various levels of implementing input guarding into the design, and the selection of the materials for the electrical interconnection substrate.

Some components provide unconnected, unused, or guard terminals/leads adjacent to the input terminals. Care must be exercised for the balance or trim terminals/leads, as in most cases these terminals are connected (internally) in the component directly into the input differential amplifier circuitry of the component; thus, any undesirable leakage currents or voltages to these terminals/leads may result in undesired operation. Some linear operational amplifiers (op-amps) and other linear components are more suitable for input guarding than others; some have two (or more) unused terminals/leads that are used to improve electrical isolation between the protected terminals/leads in the component itself, as well as the component land pattern and electrical interconnection substrate.

The simplest method for providing input guarding to control input leakage currents and voltages is through the use of guard rings of conductive patterns *on all layers of PB conductive patterns* that surround the terminals/leads and associated circuitry. The guard ring is attached to a low-impedance voltage source that best follows the input signal or, as recommended by some analog IC manufacturers in their application notes, to the metal case of the component. As a result, the input terminals of high-input-resistance, low-bias-current, low-offset-voltage Op-amps can be guarded from stray electrical leakage currents and voltages.

### 15.5.3 Voltage and Ground Distribution Concepts

There are a few main concepts for the distribution of voltage(s) and ground in PBs, their assemblies, and other electronic assemblies. In general, most serious PCDs use one or more ground planes for the common electrical connection(s), for the source(s) of electrical power, and for the reference or return electrical signal path. The keys to good voltage and ground distribution systems are:

- Providing a low-impedance voltage and ground distribution system
- Meeting functional performance product definition design requirements
- Optimizing EMC

Depending on the design, the ground system may also be used for the grounding conductor interconnection(s) for the electrical safety and similar compliance requirements. For electrical signal integrity considerations, it is generally desirable to have separate but parallel electrical interconnection networks for the grounded (signal and power) and grounding (electrical safety) conductors. Like ground, voltage distribution for serious PCDs generally consists of one or more voltage planes (or portions thereof), although for some designs routed conductive patterns or buses may be a functionally acceptable option. A bused voltage and ground system may be acceptable for some designs, but they are generally limited to the PCD

with lower operating frequencies and slower rise and fall times. The voltage and ground distribution and the location and type of bypass capacitors can have a significant impact on EMC and electrical signal integrity.

**15.5.3.1 Grounding Concepts.** Electrical grounding is one of the most important concepts and probably the least understood aspect of electrical signal integrity and EMC. All electrical conductors, including ground, form very subtle, but active, electrical interconnection network that can significantly compromise the product definition's requirements for electrical signal integrity and EMC. In particular, the grounding system is critical to ensure compliance to functional performance and regulatory requirements. Grounding (and voltage distribution) concepts are a matrix of requirements, concepts, concerns, considerations, and practices. In general, there is no universal solution suitable for all applications. Grounding is considered by some to be an art, which can be supported in that some grounding systems are completely unstructured and the reasons that some systems work, while others do not, are not clear. As a result, there has been an ongoing search to find a set of rules that can be used for the design of grounding systems and, unfortunately, many of the rules are conflicting. For example, a modular modem PCMCIA electronic assembly may have a suitable grounding system for normal telecom line operation. Yet, this may be totally inadequate if a 100-1kA electrical current, coupled through the PCMCIA assembly into the personal computer's electrical grounding system, is induced in the telecom line due to a nearby lightning strike or fallen power line. Similarly, a suitable electrical safety grounding system for power line frequencies may not be suitable near a high-power, high-frequency radio, television, or telecommunications transmitter. The following are some of the major concerns and considerations that are involved in good grounding practices:

- Integration of analog and digital signal converters, especially with more than 12 bits of resolution—ground loops and noise
- High-speed and high-frequency operation—ground pull-up and EMC
- High-speed and high-frequency bus line drivers and receivers—major ground pull-up and EMC concerns
- Low-signal-level analog sensors (transducers)
- Length of the conductors in the voltage/grounding system as a considerable portion of the electrical wavelength of one of the frequencies of the signal range of EMC
- When designing a grounding system, consideration of developing a grounding map that identifies all grounding requirements and voltage/current/frequency requirements

**15.5.3.2 Grounding Systems.** The following is an introduction to several grounding and voltage distribution systems and their electrical characteristics.

*Single-Point and Point-Source Grounding Concepts.* Single-point grounding is a method whereby the grounding electrical interconnection network is connected to ground at a single point at either the source or load end of the electrical interconnection network. The voltage drops between the various grounding nodes is a function of the interconnection network impedances, operating frequency, and current. Point-source or *star* grounding systems have a single-point grounding location for all electrical loads. The point-source grounding point is connected to another grounding point using a low-impedance bus or grounding conductor.

*Multiple-Point Grounding Concepts.* A multiple-point grounding system may be in the form of a loop or tree-like structure. In a loop grounding system the voltage drops around the loop may vary, depending on the electrical characteristics of each of the loads attached to the grounding loop. In a tree, the grounding system has good voltage regulation and allows leads to be independently attached or removed from the tree without a significant impact on the remaining loads.

*Ground Planes.* Ground planes are the grounding system of choice for most serious PCD requirements. Ground planes can improve the electrical signal integrity of the grounding system

and EMC, provided all critical conductors are buried (lands only) on outer layer(s) of the printed board assembly.

*Separation of Grounds.* The identification and separation of natural groupings of grounds into similar requirements increases the assurance of conformance to product definition requirements. Some of the natural groupings are as follows:

- Electrical safety ground
- Power supply ground
- Low-level analog ground
- High-level analog ground
- Digital ground
- I/O ground
- Pulsed power/energy ground

When defining the printed circuit design requirements for a particular assembly, results of an analysis of the grounding elements necessary for proper functional performance must be included.

**15.5.3.3 Bypass Capacitors.** The selection, location, number, and value of the bypass capacitor(s) for PCDs can affect functional circuit performance. The purpose of the bypass capacitor is to provide the necessary electrical energy to minimize the effect of a component's normal transient switching and load currents during functional operation. The selection, location, and placement of the bypass capacitor can have a significant impact on EMC and a lesser impact on functional performance. One of the keys to EMC management is to prevent or minimize the generation and subsequent radiation of electromagnetic fields in the first place.

**15.5.3.4 Voltage and Ground Buses.** As operating frequencies and speeds increase, voltage and ground bus distribution systems may function as lump constant shock-excited oscillators. The frequency of oscillation is dependent on the series inductances of the voltage and ground bus system and shunt capacitors. One of the worst cases is when the voltage and ground buses are placed as railroad rails with the bypass capacitors, and digital integrated circuits are alternated in position like railroad ties bridging between the rails.

**15.5.3.5 Voltage and Ground Planes.** Voltage and ground planes can be an effective means to provide a relatively low resistance and impedance<sup>1</sup> to distribute voltage and ground within a PBD. However, maximum effectiveness—solid metal, with no holes or cutouts for plated through-holes or other necessary features—is an unobtainable condition. Therefore, voltage and ground planes are a compromise in design and requirements due to the necessary holes in the planes for electrical interconnections and component mounting.

*Voltage and Ground Plane Resistance.* The sheet resistance of solid copper voltage and ground planes is relatively low for most copper foil thicknesses. For 35- $\mu\text{m}$ -thick copper foil, the dc (solid) sheet resistance is less than 1 m $\Omega$ /sq. The dc resistance of copper foil is shown in Eq. (15.2). The (solid) sheet resistance for selected copper foils is shown in Table 15.3. Due to the almost infinite number of possible variations in the size, placement, and shape of perforated mesh planes, the following data are presented for informational and comparative purposes only.

$$R_{\text{DC}} = \frac{17.2}{t_{\mu\text{m}}} \text{ m}\Omega/\text{sq} \quad (15.2)$$

$t_{\text{mm}}$  is in  $\mu\text{m}$

**TABLE 15.3** Solid Area Copper Foil Sheet Resistance

Copper thickness, $\mu\text{m}$	Sheet resistance, $\text{m}\Omega/\text{sq}$
5	3.44
9	1.911
12	1.433
17	1.012
26	0.662
35	0.491
70	0.246

Resistance models for periodic mesh grid planes<sup>2</sup> is of interest for *uniform* grids, but is of limited use for grid planes that are not periodic and for ac electrical network analysis.

*Voltage and Ground Plane Impedance.* The impedance of perforated mesh voltage and ground planes is difficult to perform due to the number of variations in the size, placement, and shape of perforated mesh planes.

## 15.6 MECHANICAL DESIGN REQUIREMENTS

The design intent of PBs and their assemblies is primarily to mount and lend mechanical support to components as well as to provide all of the necessary electrical interconnections. However, PBAs should not be used as a (major) structural member.

There are three general forms of PBAs:

1. *Functional module*—A plug-in and a mechanically mounted PBA. The functional module is in the form of a component, whereby leads or other types of electrical terminals provide both electrical interconnections and mechanical mounting of the module to the next higher level of electronic packaging.
2. *Plug-in module*—This provides all of the necessary electrical interconnections at one or more edge-board connectors. A plug-in module typically plugs into a mother board, or sometimes electrical cables are used. The plug-in module is mechanically supported on one edge by the edge-board connector and on one or more edges by card guides, rails, or a mounting frame.
3. *Mechanically mounted PBA*—This is mounted and/or supported in a mechanical assembly or housing with a number of mechanical fasteners around its periphery (and internally to the PBA for additional support, if required). The most common mechanically mounted PBA is the mother board, such as is frequently used in personal computers. Mechanically mounted PBAs are one of the members of an electrical/electronic assembly and are physically mounted in the assembly using one or more mechanical fasteners, such as screws, clips, and standoffs. A common example of a mechanically mounted PBA is a modular power supply.

All forms of PBAs have many common requirements necessary to meet their product definition requirements, although there will be significant variations in the product definition requirements for PBAs due to their specific form and application requirements. For example, the requirement for PBA flatness due to bow and twist may be different for a plug-in than for a mechanically mounted PBA. The requirements for the number and location of mounting fasteners for a mechanically mounted PBA will be different for a relatively thick MLB with low-mass components than for a simpler PB with high-mass components.

The following list of factors, based primarily on Ginsberg,<sup>3</sup> must be considered and evaluated in the design of a PB and its assembly:

- Configuration of the PB, size, and form factor(s)
- Need for mechanical attachment, mountings, and component types
- Compatibility with EMC and other environmental
- PBA mounting (horizontal or vertical) as a consequence of other factors such as dust and environment
- Environmental factors requiring special attention, such as thermal management, shock and vibration, humidity, salt spray, dust, altitude, and radiation
- Degree of support
- Retention and fastening
- Ease of removal

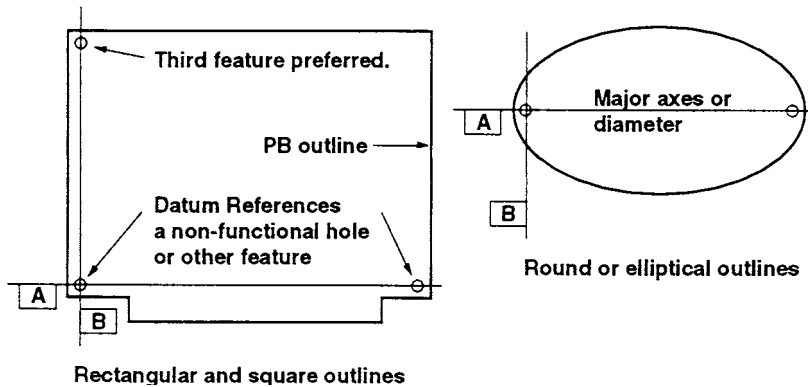

### 15.6.1 General Mechanical Design Requirements

The general mechanical design requirements for PBs and PBAs include the methods of dimensioning, mounting, guiding during insertion and removal of plug-in components or assemblies, retention, and extraction. Frequently, the PBA mounting method is predetermined as a design requirement to an established compatibility with existing hardware. In other cases, the printed board designer has a choice in determining which PB mounting method is more suitable after considering such design factors as the following:

- PB size and shape based on form, fit, and function requirements
- Input/output terminations and locations
- Area and volume restrictions
- Accessibility requirements
- Ease of repair/maintenance
- Modularity requirements
- Type of mounting hardware
- Thermal management
- EMC
- Type of circuit in its relationship to other circuits

**15.6.1.1 Dimensioning and Tolerancing.** The dimensioning and tolerancing system for PBs and PBAs must ensure that the product is appropriately defined for all of the product form, fit, and function requirements for the complete product life cycle, from definition through manufacturing to end use. Dimensioning and tolerancing are critical at least for the design, manufacturing, assembly, inspection, test, and acceptance phases.

Regardless of the dimension and tolerance standards that are used to establish and document the product definition's mechanical design and acceptance requirements,<sup>4</sup> there should be at least two (primary) data reference features in every PBD (see Fig. 15.1). The purpose is to ensure the integrity of a PB's and PBA's datum reference throughout the production and acceptance process. In general, it should be a nonfunctional hole (in the case of PBs) or a surface feature that is used as the primary datum reference for final dimensional measurements and acceptance of the product. The datum reference should not be a machined edge that is formed in the last phases of the manufacturing, fabrication, or assembly process in a secondary machining operation.

**FIGURE 15.1** All printed boards and their assemblies should have their datum references included into the design to ensure the integrity of the mechanical datum references throughout a product's production and acceptance cycles.

**15.6.1.2 Mechanically Mounted Printed Board Assemblies (PBAs).** PBAs should be mounted to ensure their mechanical (and sometimes electrical grounding) integrity throughout their product life cycle. The following are some of the generally accepted requirements and practices for mechanically mounted PBAs:

- PBAs should be supported within 25 mm of the edge of the PBA on at least three sides.
- As good practice, fabricated printed boards (PBs) having a thickness of about 0.7 to 1.6 mm should be mechanically supported on 100-mm or lower intervals, and PBs thicker than 2.3 mm on less than 1.3-mm intervals.
- Fasteners should not be located on less than the PBs thickness or the fastener's head diameter (whichever is lower) from the edge of the PB.

**15.6.1.3 Guides for Printed Board Assemblies.** A major advantage of using plug-in printed board assemblies rather than other electronic packaging techniques is the suitability of PBAs for use with mechanical PBA card guides for ease of maintenance, changing configuration, and up-grading function or performance. There are many PBA guide hardware systems that are available either commercially, as industry standard, or proprietarily. The PBA may be predetermined as a design requirement or may be developed based on the size and shape of the PBA, the degree of dimensional accuracy needed to ensure proper mating alignment with the mating connector system, and the desired degree of sophistication. Some PBA guide systems contain a built-in locking system that provides mechanical retention and thermal management (conductive).

**Caution:** Some PBA card guide systems have become somewhat of industry standards and can be obtained or assembled to fit most PBAs. However, not all of the industry-standard-like PBA guide systems are compatible or interchangeable for retaining or extracting PBAs.

**15.6.1.4 Retaining Printed Board Assemblies.** Quite often, shock, vibration, and normal handling requirements necessitate that the PBA be retained in the equipment by mechanical devices. Some PBA retaining systems are attached as hardware to the PB during assembly; other retaining systems are built into the PBA mounting hardware frequently called a cage. The selection of a proper PBA retaining system is important, since the retaining devices may reduce the amount of PB area available for component mounting and interconnections, and can add significantly to the cost of the electronic equipment.

**15.6.1.5 Extracting Printed Board Assemblies.** A number of unique principles have been developed and applied to solve the various problems of extracting PBAs from their plug-in enclosures. The result has been a proliferation of proprietary and a few industry-standard-like extraction systems. The most common industry-standard extractor is injection-molded plastic hardware that is free to partially rotate when attached to the PBA with a pressed-in pin. Many of these PBA extraction tools use a minimum of PB space, thereby maximizing available PB area for components and conductor routing. They also protect both the PBA and the associated mating connector(s) from damage during the extraction process.

The following should be considered when selecting among the many different types of PBA extraction tools:

- The area of the PBA available for attachment
- The extractor's effect on the PBA-to-PBA mounting pitch
- The need for special provisions in the PBD, such as mounting holes, mounting clearance holes, and notches
- The size of the extractor, especially if the extractor is to be stored in the equipment with which it is used
- The need for an extraction device that is permanently attached to the PBA, usually by riveting
- The need for specially designed considerations, such as load-bearing flanges, in the PBA mounting chassis or cage hardware
- The suitability of the extractor to be used with a variety of PB sizes, shapes, and thicknesses
- The cost of using the extractor, both in piece price and added design costs
- The degree of access required inside the equipment to engage and use the extraction tool

## 15.6.2 Shock and Vibration

Shock, vibration, flexing, and bowing can be functional performance and reliability concerns for PBAs—more so for larger PBAs. For many PBAs, the worst-case exposure to shock and vibration occurs in nonfunctional or operational usage, during shipping and other forms of transportation from one location to another, or possibly in functional use when the functionally operating product containing PBAs is inadvertently dropped on the floor. Other PBAs are designed to withstand specified levels of shock and vibration in transportation and in use. The design requirements for shock and vibration vary, depending on each family of general requirements. For example, there are nonoperating shock and vibration withstand requirements for Level 1, 2, or 3 products, which include various procedures and requirements for packaging. The shock and vibration functional design requirements are many and varied, and are very dependent on the application. Some sources of shock and vibration are very obvious, while others are very subtle. The levels and duration of shock and vibration vary significantly in each application: An electronic sensor mounted on a vehicle's axle is different from the radio mounted on the dashboard. There are the differences among ground-based, rack-mounted, industrial control equipment, aircraft, aerospace, and munitions applications. Some vibrations are subtle, low-level continuous, and are frequently caused by electric or gas motor-driven rotating machinery and equipment. Continuous low-level vibrations can induce *mechanical fatigue* in some electrical/electronic equipment.

**15.6.2.1 Shock.** *Mechanical shock* can be defined as a pulse, step, or transient vibration, wherein the excitation is nonperiodic.<sup>5</sup> Shock is a suddenly applied force or increment of force, by a sudden change in the direction or magnitude of a velocity vector. With few exceptions, shocks are not easily transmitted to electronic equipment by relatively light mounting

frames and structures. Most shocks to electronic equipment in the consumer, commercial, and industrial markets are due to dropping during handling or transportation, the exceptions being electronic sensors or equipment mounted to heavier mounting frames, such as vehicle axles and punch-press-like equipment, or military equipment subjected to air dropping or to explosive forces, such as munitions. Most shock impact forces result in a transient type of dampened vibration which is influenced by the natural frequencies of the mounting frame. Generally, shock either results in instantaneous failure or functions as a stress concentrator by reducing the effective strength of the connection or lead for subsequent failure due to additional shock(s) and vibration.

**15.6.2.2 *Vibration.*** *Vibration* is a term that describes oscillation in a mechanical system, and is defined by the frequency (or frequencies) of oscillation and amplitude. PBAs that are subjected to extended periods of vibration will often suffer from fatigue failure, which can occur in the form of broken wires or component leads, fractured solder joints, cracked conductive patterns, or broken contacts on electrical connectors. The frequency(s) of vibration, resonances, and amplitude(s) all influence the rate to failure.

Flexing and bowing in PBAs is the result of induced shock and vibration into the PBA. Different PBA mounting methods have differing susceptibilities to shock and vibration. In general, most small PBA functional modules are manufactured as components and are frequently encapsulated with a polymeric potting material into a solid mass, and they therefore have minimal shock and vibration requirements within the module. The plug-in PBA is restrained on one edge by the edge-board connector(s), and to some extent along the two sides of the PBA by mechanical guides. This leaves only one edge of the PBA free to flex from shock and vibration or to bow from residual manufacturing or assembly stress in the PBA. However, a handle along the free edge of the PBA or a restraining bar can be located across the center of the free edge of the PBA and mechanically attached for support at the ends of the restraining bar to the PBA mounting hardware (card cage). Generally, the mating edge-board connector has a molded-plastic body that provides mechanical support to the mated edge-board connector and has sufficient compliance in the electrical contacts to maintain good electrical connections within the connector's performance specifications. Mechanically mounted PBAs can be more of a shock and vibration concern for three main reasons:

1. The PBA can be very large, sometimes as large as 600 mm<sup>2</sup>. More frequently, the maximum width is 430 mm (the width of a standard electronic chassis) and less than 600 mm long. Although most are less than 300 mm<sup>2</sup>, this still creates a large area and can be a problem if unsupported.
2. The PBA is misused as a mechanical support structure for high-mass components, such as magnetic components (iron-cored transformers and inductors), power supplies, and large (in physical size) function modules.
3. The PBA is not included in the mechanical design definition.

**15.6.2.3 *Major Shock and Vibration Concerns.*** These include the following:

- Flexing between PBAs may cause shorts between adjacent PBAs or to the enclosure.
- The fundamental mode is the primary mode of concern because it has the large displacements that cause fatigue damage to solder joints, component leads, and connector contacts.
- Continuous flexing of a PBA will fracture component leads and, more important, surface-mounted component solder joints, due to mechanical fatigue failure. (Mechanically induced flexing or vibration in assembled PBAs is used under controlled conditions to induce failures in solder joints for quality and reliability studies.)
- Movement of a PBA within its mechanical guides will be amplified due to shock and vibration resonance or harmonic resonance.

- Fatigue life modeling for PBA mounted components has become significantly more complex due to in-use simultaneous application of both vibration and thermal cycles. Vibration strains and thermal strains should be superposed for more representative modeling.

**15.6.2.4 Types of Edge Mounting.** The problems, methods of analysis, and minimization of the effects of shock and vibration on PBAs are the same as in other engineering applications, and similar solutions can be used. PBAs are designed and manufactured in a wide range of shapes and sizes, with rectangular being the most common because of the shape of most electrical/electronic equipment, especially for plug-in PBAs. Though PBAs are a multi-degree-of-freedom system, the fundamental mode is of primary importance because it has the large displacements that are the primary cause of fatigue failure in solder joints, component leads, wires, and connector contacts.<sup>6</sup> Most vibrational fatigue damage occurs at the fundamental or natural frequency because displacement is highest and stress is maximized. Edge or boundary conditions are terms that are used to define the method of attachment of the PBA (or, more generically, a panel) to its mounting frame. The term *free edge* is used to define those edges that are not restrained and are free to move and/or rotate along the edge of the PBA out of their normal mounting plane. The terms *supported edge* or *simple support* used to define an edge that is restrained in out-of-plane movements but is allowed rotational movement around the PBA's edge. The terms *fixed edge* or *clamped edge* are used to define an edge that is restrained in both out-of-plane and rotational movements. Illustrations of the definitions for fixed edge, supported edge, and free edge, and their applications to plug-in mounted PBAs, are shown in Fig. 15.2.

**FIGURE 15.2** The method of mounting PBAs contributes to shock and vibration concerns, but can be reduced by good design practices.

**15.6.2.5 Board Deflection.** The amount of strain on a PBA component is a function of the maximum deflection of the PBA when subjected to shock and vibration. Those components mounted closest to the center of the assembly are subjected to the greatest strain, as illustrated in Fig. 15.3.

A set of empirical maximum deflection ( $\delta$ ) calculations has been developed by Steinberg, and his latest equation<sup>7</sup> has more parameters than previous equations, reflecting the sophistication and requirements for modern PBDs (units adjusted from inches to mm).

$$\delta = \frac{k \cdot 0.00022 \cdot B}{ct\sqrt{L}} \quad (15.3)$$

**FIGURE 15.3** The PB bends in a PBA during shock and vibration, with the most severe stresses applied to the components mounted centermost on the assembly.

- where  $k$  = units conversion coefficient; for inches  $k = 1$ , for mm,  $k = \sqrt{25.4}$   
 $B$  = length of PB edge parallel to component located at center of board (worst case), mm  
 $L$  = length of component, mm  
 $t$  = thickness of PB, mm  
 $c$  = 1.0 for standard DIP  
       = 1.26 for DIP with side brazed leads  
       = 1.0 for PGA with four rows of pins (one row extending along the perimeter of each edge)  
       = 2.25 for CLCC

Analysis of the maximum deflection calculation formula reveals (as expected) that components with some compliance built into their component mounting and electrical terminations (such as the DIP and PGA) can be subjected to about twice the vibrational deflection as an SMT CLCC, provided component size, PB size, and PB thickness are equivalent. The latest equation for maximum deflection calculations is rated for 10 million stress reversals when subjected to harmonic (sinusoidal) vibration, and 20 million stress reversals when subjected to random vibration. It must be understood that this equation is a first approximation for predicting solder joint life. There are many factors that must be included for a more rigorous analysis and prediction. A more thorough discussion is found in Barker.<sup>6</sup>

**15.6.2.6 Natural (Fundamental) Resonance of Printed Board Assemblies.** The mechanical mounting of PBAs and their components is a key design consideration in the ability of the PBA to withstand shock and vibration. The overall size of the PBA is not a major factor, provided a suitable mechanical support structure is included as a part of the PBA's product definition requirements. There is a large matrix of ways to mount panels (PBAs) using various combinations of free edges, supported edges, fixed edges, and point supports and by calculating fundamental resonance. The following four examples compare the fundamental natural resonances of the same rectangularly shaped PBA using different edge-mounting techniques. Additional formulas for calculating other natural resonances are found in Barker,<sup>6</sup> Steinberg,<sup>7</sup> and others.

In the following examples—demonstrations of the sensitivity of PBAs to their methods of mounting—the same PBA is used for direct comparative purposes (see Fig. 15.4). The following are the design requirements and material parameters that were used for the calculations:

**FIGURE 15.4** The same PBA can have a wide range of natural resonances depending on the mounting method, which is why shock and vibration concerns are a critical design consideration.

<i>E</i>	Modulus of elasticity (type GF epoxy-glass)	$1.378 \times 10^4$ MPa
$\mu$	Poisson's ratio	0.12 (dimensionless)
<i>a</i>	Longer dimension of the PBA	200 mm
<i>b</i>	Narrower dimension of the PBA	150 mm
<i>t</i>	Thickness of the PBA	1.6 mm
<i>W</i>	Weight of the PBA including components	0.25 kg

$$D = \frac{Et^3}{12(1 - \mu^2)} \tag{15.4}$$

where *D* is the plate bending stiffness.

$$M = \frac{W}{g} \tag{15.5}$$

$$f_n = C_0 P_0 \sqrt{\frac{Dab}{M}} \text{ Hz} \tag{15.6}$$

where *f<sub>n</sub>* is the natural resonant frequency.

### 15.6.3 Methods of Reinforcement and Snubbers

Printed board assemblies are stiffened using one or more methods to raise the natural resonant frequency sufficiently above the shock and vibration threat. The most obvious is to change the method of retaining or mounting the PBA in the next higher level of assembly. Frequently, though, this may not be an acceptable option due to the resources and schedule changes that may be necessary for extensive redesign. However, some simpler modification in the design may meet requirements. Sometimes changing the plug-in PBA guide from a loose supportive guide to a tighter spring-loaded or clamping-type guide may be sufficient. Other methods are to add ribs or stiffeners, additional single-point mounting locations, or *snubbers* across the surfaces of the PBAs.

## CHAPTER 16

---

# CURRENT CARRYING CAPACITY IN PRINTED CIRCUITS

---

**Mike Jouppi**

*Thermal Management Inc., Centennial, Colorado*

---

### 16.1 INTRODUCTION

---

One important consideration when designing electronics is to ensure that the electrical components operate at temperatures that will maintain long life and be reliable. Current carrying capacity of the printed circuit board traces is a part of managing the board temperature, which directly impacts the components. (A *trace* is a copper conductor in a printed circuit board. The terms *conductor* and *trace* are used interchangeably for a printed circuit throughout this chapter. *Track* is another common term for trace or conductor.) Properly sizing the traces for current is necessary to achieve the desired temperature rise at the board level.

It is a difficult task to generalize current carrying capacity for all printed circuits and all applications. The only safe way to simplify this task is to overdesign. As technology requires pushing the limits on current levels, as well as using small trace widths and trace spacing, overdesigning is not a solution.

Several sets of charts for sizing traces are presented in this chapter. These charts are explained and additional charts are presented. Thermal management of printed circuits often requires an accurate estimate of trace heating. This chapter presents information about conductor sizing charts and trace heating information as an aid to printed circuit design.

---

### 16.2 CONDUCTOR (TRACE) SIZING CHARTS

---

Charts are used to define the size of a trace for a given current level and temperature rise. The temperature rise of a trace is defined as the increase in temperature, above the local board temperature, that the trace reaches when current is flowing through it. The board temperature is similar to the ambient temperature when component power dissipations are low, although when the component power is several watts or more, the board temperature is significantly higher than the ambient temperature, especially in a still air or vacuum environment.

### 16.2.1 Conductor Sizing Chart Development

Charts have been in existence for many years. They have been adequate for most applications, although they have their limitations. The external and internal conductor-sizing charts in IPC 2221, “Generic Standard on Printed Board Design,” are the standard for sizing traces and are included as Figs. 16.1 and 16.2, respectively.

The original external conductor chart was developed in 1956. It was assembled from trace heating test data taken from boards of different materials, different thicknesses, and different copper weights, as well as from boards with and without copper planes. The external charts are nonconservative for thin double-sided boards without copper (power, ground, or thermal) planes. “Nonconservative” in this context means that the traces are higher in temperature for a given current level than the charts suggest. The temperature differences are discussed later in the chapter.

The internal conductor chart is conservative for traces with cross-sectional area up to 700 sq. mil. It becomes less conservative at high current levels or with larger cross-sectional areas. The internal conductor-sizing chart represents half the current from the external conductor chart. It does not represent internal conductor test data. The internal trace chart has significant margin and should be used for sizing both internal and external conductors when possible. When that is not possible, a more detailed approach can be taken. The first step is to use new charts that focus on the baseline set of charts.

### 16.2.2 New Conductor (Trace) Sizing Charts

IPC-2152, “Standard for Determining Current Carrying Capacity in Printed Board Design,” is written specifically for the carrying capacity of conductor current. Additional charts are provided that separate the variables that impact the temperature rise of a trace when current is applied.

There is a baseline set of charts for internal and external conductors. The baseline is conservative for most designs, although generally less conservative than the IPC 2221 internal conductor-sizing chart. The difference between the new and old is that attention is given to parameters that affect the temperature rise of a trace; some of these parameters include the board thickness, presence of copper planes, and the environment surrounding the circuit board. This chapter is presented as additional information on the existing charts in IPC 2221, as well as an aid to bridge the gap between the old and new charts that are presented.

## 16.3 CURRENT CARRYING CAPACITY

---

Current carrying capacity is commonly defined in terms of the temperature rise in a trace as a result of applying a specific amount of current to a specific size trace. The temperature rise is dependent on:

- The current level
- The board thickness
- The cross-sectional area of the trace
- The thickness of the trace for a given cross-sectional area
- The distance from a trace to copper planes
- The board material
- The environment (still air, forced air, vacuum, etc.)
- Skin effect at high speed (GHz)

### 16.3.1 Circuit Board Designs

Circuit boards can be extremely different from one design to another. They can vary from a double-sided board the size of a postage stamp to a 40-layer board that is 2 ft. wide and 4 ft. long. The environment in which they operate is also a consideration—for example, whether they are used on earth, in space, or on some other planet.

Because there is such a broad range of printed circuit board (PCB) construction and materials, a single trace-sizing chart cannot be expected to describe the temperature rise of a trace as a function of current for all boards. Fine-line and space, heavy copper, single-layer boards, and multilayer boards all constitute different configurations in which traces with the same cross-sectional area could vary from 10 to 70°C, or more for the same amount of applied current.

### 16.3.2 Conductor (Trace) Sizing Charts

Five different charts are presented in this chapter. The first has been around since the beginning of the printed circuit industry and is intended for external traces. The second is for sizing internal traces. The third and fourth are for internal and external traces. These are from more recent studies and are referred to as baseline charts. The fifth is used with the baseline charts to account for the heat spreading and cooling effect when copper planes exist in the board. Even with these charts, there are times when charts alone do not offer enough information and analysis tools must be used to solve current carrying capacity problems.

The charts included in this chapter are presented as a guide for sizing copper traces. There are limitations to their use and those limitations are discussed in the trace-sizing guidelines. The trace-sizing charts are used to manage trace heating, which includes sizing parallel conductors and vias. Finally, design problem areas such as “swiss-cheese” effect and environments are discussed at the end of this chapter.

For each set of charts, a discussion of what each chart represents and where it best applies for circuit board design applications is included. The charts included are as follows:

- External and internal charts from IPC 2221, the industry standard for printed circuit board design:
  - The external chart, Fig. 16.1, does not include design margin unless there is at least one internal copper plane in the board, such as a power or ground plane.
  - The internal chart, Fig. 16.2, is conservative, has significant margin, and keeps internal board heating to a minimum; more discussion is included in the design guidelines.
- Baseline charts. These are additional charts for sizing conductors and show an example of the effect of variables that impact trace temperature rise when current is applied. (Additional baseline charts can be obtained from Thermal Man, Inc., that take into account FR-4, BT, copper planes, and board thicknesses of 0.038 to 0.059 in.) Further discussion follows regarding the significance of the copper weight or thickness, board material, board thickness, and copper planes:
  - Internal conductor sizing charts for 1 oz. copper in a 1.78 mm (0.07 in.) thick polyimide board. (It is common to refer to the thickness of copper by weight, e.g.,  $\frac{1}{4}$  oz.,  $\frac{1}{2}$  oz., 1 oz., 2 oz., etc. The weight refers to the weight of a 1 sq. ft. piece of copper at a specific thickness. For example, 1oz. copper is 1 sq. ft. of 0.00135 in. copper. The weight can be calculated using the density of copper, 0.323 lb./in.)<sup>3</sup>
  - External conductor sizing charts for 2 oz. external conductors in a 1.78 mm (0.07 in.) thick polyimide board.
  - Plane chart for a 1.78 mm thick polyimide PWB. This is a chart that describes the reduction in trace temperature rise as a function of the distance from a single copper plane. This chart is used with the internal and external baseline charts.

(For use in determining current carrying capacity and sizes of etched copper conductors for various temperature rises above ambient.)

FIGURE 16.2 IPC-2221 internal conductor sizing chart.

## 16.4 CHARTS

---

### 16.4.1 External and Internal Conductor Charts

Figure 16.1 is for sizing external conductors, whereas Fig. 16.2 is for internal conductors; both are from the IPC standard 2221. External refers to the outermost layers of the printed circuit board. Until recent years, internal trace heating data were not broadly published. Figure 16.2 represents a conservative approach to internal trace heating; it does not represent internal trace heating data, although it does represent half the current from the external trace-sizing chart.

### 16.4.2 Trace Temperature Rise

The trace temperature rise derived from a conductor-sizing chart represents the increase in the trace temperature above the local board temperature surrounding the trace. For example, if the board temperature is 85°C as a result of component heating, and the trace is designed for a 10°C rise, then the trace will be 95°C. The temperature rise is the increase in temperature that the trace experiences when current is applied.

### 16.4.3 How to Use the Charts

Conductor sizing charts require knowing two of three variables: current, trace temperature rise, or trace size. If you know any two of these variables, you can calculate the other. When a more accurate estimate of the trace temperature rise is needed, board thickness, copper thickness, and board material are also used.

**16.4.3.1 Chart Basics:Known Current.** When the current and the desired temperature rise are known, then the trace width can be calculated for various trace thicknesses. A 10°C rise is a common temperature rise for a design. The temperature rise should always be minimized. If the designer can manage a 1°C rise or less, then the contribution to board heating will be minimized. Increasing the size of a trace lowers the temperature rise, lowers the voltage drop, decreases component temperatures, and improves the reliability of the product.

The following is an example of using Fig. 16.1:

What is the required size trace that will have a 10°C rise if 6 amps is applied to it? Starting with the top chart, follow the line going across from 6 amps to the curve labeled 10°C. The 10°C curve represents the temperature rise that occurs for a specific size trace at that current level. Next, follow the line going down from the 10°C curve and look at where it intersects the axis labeled “CROSS SECTION IN SQ MILS.” The cross section is the cross-sectional area of the trace. The final step is to determine the trace width.

The lower chart in Fig. 16.1 is used to determine the trace width for various copper thicknesses. For the same cross-sectional area, the width will be smaller for thick copper and wider for thin copper. Continuing with the example, follow the vertical line down from 200 sq. mil. into the lower chart to the line labeled “(1 oz/ft<sup>2</sup>) 0.0014””; see the discussion of copper thickness in Section 16.4.5. Following the line across to the axis labeled “CONDUCTOR WIDTH IN INCHES” shows that the trace should be 0.15 in. wide for a copper trace that is 0.0014 in. thick. If 3 oz. copper were selected, the trace width would be approximately 0.05 in. wide rather than 0.15 in. wide for 1 oz. copper.

**16.4.3.2 Chart Basics:Known Cross-Sectional Area.** If a trace size is known, the temperature rise or the current can be determined. The temperature rise can be estimated only in the range between the curves of constant temperature rise. The current can be estimated if the temperature rise is given. Each of these calculations is performed using the method presented in Fig. 16.1.

**FIGURE 16.3** National Bureau of Standards 10°C chart.<sup>1</sup>

#### 16.4.4 Chart Data

Data collection, to develop conductor-sizing charts, is performed following test procedures defined in IPC-TM-650 2.5.4.1a, "Conductor Temperature Rise Due to Current Changes in Conductors." Understanding these data, test vehicle, and test conditions used to derive conductor charts is important for understanding the limitations of these charts.

The chart shown in Fig. 16.1 was created from external trace heating data from double-sided boards. The internal trace chart, Fig. 16.2, was not developed from internal trace data; it represents half the current defined in the external chart. Further discussion on the internal trace chart is included in Sec. 16.4.5, "Trace-Sizing Design Guidelines."

The external trace chart represents a best-fit line through trace temperature data points from boards with different materials (epoxy and phenolic, different board thicknesses (3.175 mm [0.125 in.], 1.587 mm [0.0625 in.], and 0.794 mm [0.0312 in.]), and different copper thicknesses ( $\frac{1}{2}$  oz., 1 oz., 2 oz., and 3 oz.), and, most important, from boards with copper planes. Board material, board thickness, copper thickness, and especially the copper planes all have an impact on the temperature rise of the trace. Averaging these variables together skews the results.

The top curve in Fig. 16.3 shows the original 10°C line used to create the 10°C curve in Fig. 16.1. All of the curves in Fig. 16.3 represent a 10°C rise, but each curve represents a different set of conditions. Going from the top down, the next curve is supposed to represent coatings, although it is a mix of traces with coatings, thin boards, and boards that were dip-soldered. The next curve represents test boards that were dip-soldered. The last curve represents traces that were removed from the board and tested in free air. The boxed area in Fig. 16.3 is increased in size and shown in Fig. 16.4.

**FIGURE 16.4** Influence of copper planes.

The top curve in Fig. 16.3 includes a variety of data points as described previously. In Fig. 16.4, several things can be observed with data points O and L, specifically the influence of board thickness and the influence of a copper plane. O and L are the same size trace in boards that are identical, with one exception: The board with trace O has a copper plane on the back of the board. A difference of 3 amps is observed between the two cases for a 10°C rise.

Data point L represents an external, 1 oz. copper trace on a 0.03 in. thick PWB. A trace on a thin board runs hotter than a thicker board. The trace in the thin board reaches a 10°C rise at a lower current level than the other boards. Data point O also represents an external, 1 oz. copper trace on a 0.794 mm (0.0312 in.) thick PWB, although it has a 1 oz. copper plane on the backside of the board. The trace on the board with the copper plane can have significantly more current before reaching a 10°C rise than the trace on the board without the plane due to the heat-spreading capability of the plane.

As a result of the way the curves in Figs. 16.1 and 16.2 were developed, there are areas where they are conservative and areas where they are not.

Guidelines have been prepared to help further define these areas of the curves.

#### 16.4.5 Trace-Sizing Design Guidelines

This section summarizes and expands the design notes from IPC-2221:

- Design charts have been prepared as an aid in *estimating* the temperature rise of a trace above the local board temperature versus current for various cross-sectional areas of etched copper conductors. It is assumed that for normal design, conditions prevail where the conductor surface area is relatively small compared to the adjacent free panel area and that the panel area is approximately 3 in. × 3 in. or greater.
- The curves as presented are not derated. Consideration should be given to allow for variations in etching techniques, conductor width estimates, and copper thickness.
- A standardized process is not used to determine the amount of undercut resulting from the etching process that creates the traces from the layers of copper of a printed circuit board. Circuit board manufacturers have their own techniques for adjusting artwork to provide the desired trace size in a design. Variations exist from one manufacturer to another. The IPC Process Capability, Quality, and Relative Reliability (PCQR<sup>2</sup>) database is a source for determining the capability of a circuit board manufacturer. Two of the pieces of data collected are trace width and thickness source. This database is a source for finding the cross-sectional area of a trace of a final product compared to the initial artwork. Etch back is primarily a concern for small traces where the aspect ratio (the ratio of width to thickness) is small.
- The final width of a trace should take into account the undercut that occurs during manufacturing. Consult a board manufacturer for undercut estimates.
- The IPC PCQR<sup>2</sup> database is a source for copper thickness in a final product. The thickness of copper has a minimum allowable value that is less than the assumed thicknesses found in literature (see Sec. 16.7). A random selection of a half-dozen trace sizes from board coupons was collected for four different copper weights and is presented in Table 16.1.
- The temperature rise of a trace should always be kept to a minimum. The trace temperature rise otherwise referred to as the delta T ( $\Delta T$ ) is the temperature rise above the local board temperature surrounding the trace. Components and other conditions drive the board to temperatures above those of the surrounding environment. The temperature rise ( $\Delta T$ ) from the charts describes the temperature rise above the board temperature. For example, if the circuit board is at 75°C and the trace is sized for a 10°C rise, the trace temperature will be 85°C.

**TABLE 16.1** Sample Internal Copper Thickness

	1/2 oz. (in.)	1 oz. (in.)	2 oz. (in.)	3 oz. (in.)
Maximum	0.0006	0.0015	0.00260	0.00400
Minimum	0.0006	0.0010	0.00230	0.00380
Median	0.0006	0.0011	0.00245	0.00385
Average	0.0006	0.00117	0.00247	0.00387

- The IPC internal trace-sizing chart is suggested under the following conditions if:
  - The board does not have internal or external copper planes
  - The panel thickness is 0.8 mm (0.315 in.) or less
  - The conductor thickness is 0.108 mm (0.00425 in.) or thicker
- For single conductor applications, a chart may be used directly for determining conductor widths, conductor thickness, cross-sectional area, and current carrying capacity for various temperature rises.
- For groups of similar parallel conductors, if closely spaced, the temperature rise may be found by using an equivalent cross-section and an equivalent current. The equivalent cross-section is equal to the sum of the cross-sections of the parallel conductors, and the equivalent current is the sum of the currents in the conductors. Parallel conductors refer to conductors on all layers of a PWB. Closely spaced is as much as 25.4 mm (1 in.) spacing and less.
- Closely related to parallel conductors are coils. “For applications where etched coils are to be used, the maximum temperature rise may be obtained by using an equivalent cross-section equal to  $2n$  times the cross-section of the conductor, and an equivalent current equal to  $2n$  times the current in the coil, where  $n$  is equal to the number of turns.”<sup>2</sup>
- The effect of heating due to attachment of power-dissipating parts is not included. Component heating will impact the board temperature rise. The increase in electrical resistance of the trace due to an elevated temperature is a secondary effect on trace temperature rise. The final trace temperature is estimated as the PWB temperature plus the delta T selected for the trace.
- All design guidelines presented are for a still air environment.
- The IPC internal conductor chart is recommended for the following:
  - Flex circuits
  - All trace sizing, which includes external traces when possible
  - Space (vacuum) and high-altitude environments
- The IPC external conductor-sizing chart should be used only when at least one copper plane (power or ground) exists in the PWB.
- For trace sizes outside the range of the chart (over 700 sq. mil), consider the following:
  - Extrapolating the external IPC charts is not recommended.
  - If extrapolation is to be performed, use a baseline chart; however, extrapolating the IPC charts is not recommended.
  - Use a thermal analysis software tool for determining the temperature rise.
- For space (vacuum) environments, consider the following:
  - The internal conductor chart is best for sizing both internal and external traces that must operate in space or vacuum environments.

- When sizing traces and taking into account the copper planes in the board (still air), consider the following:
  1. Using charts developed from trace heating data in PWBs with no internal copper and following IPC-TM-650 guidelines is the recommended method for sizing traces. Charts that include the influence of copper planes should be used for determining design margin. A copper plane that is 0.127 mm (0.005 in.) or less from a trace can reduce the trace temperature rise by as much as 70 percent.
  2. The presence of copper planes in the printed circuit board provide heat spreading and lower the temperature rise of a trace. When sizing traces using data that takes into account copper planes, the design guidelines change. The heat spreading is significant and heating from all conductors in the area of a plane are mutually influential. Therefore, all traces within the area of the plane must be considered when summing the current following the parallel conductor rule. (The trace must be under or over the plane, not adjacent to the plane, to use charts that consider planes, and the plane must be larger than 3 in.  $\times$  3 in. in area.)
  3. The distance from a trace to the plane has a significant effect on the temperature rise of the trace. Multiple factors are involved when sizing traces using charts that take into account the heat spreading due to the presence of copper planes:
    - a. The trace temperature rise is a function of the size of the plane:
    - b. Below 9 sq. in. (3 in.  $\times$  3 in.), the impact has not been completely characterized, although the cooling effect is not enough to take the heat spreading into account over the baseline prediction.
    - c. From 9 sq. in. to 40 sq. in., the cooling effect from the increased area is improved by approximately 10 percent.
    - d. Above 40 sq. in., the effect on trace temperature remains the same.
    - e. The trace temperature rise is a function of the total power dissipated by all the traces. There is a diminishing return when the power dissipated by the traces exceeds the capability of the board to spread and dissipate the power.
    - f. The thickness of the copper plane has a direct effect on the trace temperature rise.

The next section shows a very specific set of trace heating data. The data set is presented so that the variables that impact the temperature rise of a powered trace are separated. A discussion is included with each data set.

## 16.5 BASELINE CHARTS

---

The charts in Figs. 16.5 through 16.8, called *baseline charts*, were developed from current carrying capacity testing using polyimide PWBs with no internal copper planes. Test vehicles were developed and current carrying capacity testing was performed following IPC-TM-650-2.5.4.1a, “Conductor Temperature Rise Due to Current Changes in Conductors.”

One internal data set, 1 oz. internal traces, and one external data set, 2 oz. external traces, on a 0.07 in. thick polyimide PWB, are presented. These two data sets are a subset of data collected for 1/2 oz., 1 oz., 2 oz., and 3 oz. copper weights, FR-4, and polyimide boards, and PWBs with board thicknesses of 0.965 mm (0.038 in.), 1.498 mm (0.059 in.), and 1.78 mm (0.07 in.). The other data sets are used to discuss the effect of the other variables with respect to the charts in Figs. 16.5 through 16.8.

- **Board thickness** Traces in the 0.965 mm (0.038 in.) thick boards are approximately 30 to 35 percent higher in temperature than the 1.78 mm (0.07 in.) thick PWB data, and the 1.498 mm (0.059-in.) thick boards are 20 percent higher.

Note: This chart is for a 0.07" thick (or greater) PCB.

**One-oz. Internal Conductor

**FIGURE 16.5** Baseline (Jouppi) 1 oz. internal conductor chart. [The baseline (Jouppi) charts represent the author's personal data collection.]

Note: This chart is for a 0.07" thick (or greater) PCB.

**One-oz. Internal Conductor  
Current Carrying Capacity  
in Air for Polyimide PCB Material**

**FIGURE 16.6** One-ounce internal conductor chart (fine line). [The baseline (Jouppi) charts represent the author's personal data collection.]

**FIGURE 16.7** Two-ounce external conductor chart. (The baseline (Jouppi) charts represent the author's personal data collection.)

**FIGURE 16.8** Two-ounce external conductor chart (fine line). (The baseline (Jouppi) charts represent the author's personal data collection.)

- **Copper weights** Half-ounce copper traces are similar in temperature rise for the same size cross-sectional area as the 1 oz. traces. An increase in temperature rise of 10 to 15 percent over the 1 oz. traces is observed for 2 oz. traces, and 15 to 20 percent increase for 3 oz. traces for the same cross-sectional area. The higher percentage is for a 45°C rise and the lower percentage is for a 10°C rise.
- **Board material** The FR-4 versus polyimide board material properties did not have a significant impact on trace temperature, which is determined primarily by the thermal conductivity of the dielectric laminate material construction. Table 16.2 lists measured thermal conductivity values for each of the test boards. The column labeled  $k_z$  presents values through the thickness of the board and represents the resin thermal conductivity. The values in columns  $k_x$  and  $k_y$  are “in-plane” and the difference is attributed to the influence of the glass fiber.

**TABLE 16.2** Dielectric Thermal Conductivity

Material	$k_x$ (w/in.-C)	$k_y$ (w/in.-C)	$k_z$ (w/in.-C)
FR-4	0.0124	0.0124	0.0076
Polyimide	0.0138	0.0138	0.0085

### 16.5.1 Copper Planes

One factor that has significant impact on the temperature rise of a trace for a given current level and trace size is the influence of copper planes. Whether they are power, ground, or simply thermal planes, the copper planes help spread the heat and lower the temperature rise of what would otherwise be a hot spot.

When designing with baseline charts, the copper planes add margin to the design. Multiple planes have more of an impact on lowering the temperature rise of a trace, although a single plane of 1 oz. copper is the starting point from the baseline configuration.

### 16.5.2 Single Plane

Trace heating data was collected from testing 1.78-mm (0.07 in.) thick polyimide PWBs and 0.965-mm (0.038 in.) and 1.49-mm (0.059 in.) thick FR-4 PWBs. The testing was performed in air and vacuum. Computer (thermal) models were developed that simulate the steady state and transient (time-dependent) temperature response for trace heating in each test board. The models were correlated to the test data. After correlating the models, copper planes were added to the models and used to develop charts that represent trace temperature rise as a function of current for traces in boards with copper planes. (The finite element models were developed using the thermal analysis software package ANSYS Thermal Analysis System [TAS]. The thermal models were correlated to the trace heating data collected in still air environments.) Figure 16.9 represents some of the results from that work.

Figure 16.9 shows the temperature rise of an internal, 0.010 wide, 1 oz. (0.00135 in.) copper trace (13.5 sq. mil), in a 127 mm (5 in.) wide  $\times$  127 mm long  $\times$  1.78 mm thick polyimide board, with 1.85 amps. The baseline column represents a trace in a board with no copper planes. The other two columns represent the same trace and current, although now there is a 1 oz. copper plane in the board. The trace is centered in the board and can be above or below the plane. The center column illustrates the temperature rise if the copper plane is 0.508 mm (0.02 in.)

**FIGURE 16.9** Copper plane influence on trace temperature.

from the trace. The column on the right shows the temperature rise of the trace when it is 0.127 mm (0.005 in.) from the plane.

Several key points can be observed when looking at this chart and comparing against the IPC-2221 internal conductor-sizing chart.

- The predicted temperature rise of the same trace using the internal conductor-sizing chart in IPC-2221 is 266°C.
- The internal IPC chart is conservative for sizing conductors in printed circuit board applications.
- Significant margin exists in trace sizing if copper planes exist.
- Design guidelines require a full description of their origin.
- When multiple variables impact the temperature rise of a trace, the impact of each variable requires definition to improve the level of design optimization.
- The presence of a single plane has a significant impact on the temperature rise of a trace.

Trace temperature rise has been characterized with respect to board thickness, copper weight, board material, internal versus external, air versus vacuum, as well as the distance from copper planes. A single copper plane has the most significant impact of all the variables described in this chapter. Guidelines for estimating trace temperature rise when a copper plane is present are as follows:

- Use a baseline chart to calculate the trace temperature for a given current and trace size:
  - The baseline represents the trace temperature rise in a PWB with dielectric only (no internal copper planes).
  - The baseline represents a specific board (dielectric) material and board thickness. (A 1.78 mm thick polyimide PWB, baseline conductor chart is provided in this chapter.)
  - The influence of a copper plane on the baseline trace temperature rise is more significant for thinner boards and boards with lower dielectric thermal conductivity values.
- The distance from a trace to a copper plane must be known. The closer the trace is to the plane, the lower the temperature rise of the trace.
- The thickness of the copper plane must be known. As the amount of copper increases, the temperature rise of the trace decreases.

**FIGURE 16.10** Distance from trace to copper plane.(The copper planes do not take into account the swiss-cheese effect from vias. The planes are assumed to be continuous solid planes.)

- The number of copper planes is not as significant, although the planes should be continuous with very few etched away areas:
  - The most significant decrease in trace temperature occurs with the introduction of a single plane.
  - As the number of planes increase, the trace temperature rise decreases, but not as much as the influence from the first plane.
- The area that the copper plane covers on a specific layer is important. The plane must completely cover the trace in order for it to impact the temperature of the trace. The size of the internal copper plane impacts the amount of heat spreading that can occur:
  - Below 58 cm<sup>2</sup> (9 sq. in.), the impact has not been completely characterized, although the effect is reduced and is observed on the left hand side of the curves in Fig. 16.10.
  - From 58 cm<sup>2</sup> (9 sq. in.) to 258.1 cm<sup>2</sup> (40 sq. in.), the effect is increased by approximately 10 percent.
  - Above 40 sq. in., the effect remains the same.
- The chart shown in Fig. 16.10 is used to determine the reduction in a trace temperature rise as a function of the distance from the trace to a copper plane.

Figure 16.10 represents estimates of temperature rise as a function of copper plane size and distance from trace to plane in a 0.07-in. (1.78 mm) thick polyimide board. The set of curves in Fig. 16.10 is used with the baseline charts, shown in Figs. 16.5 through 16.8. The first step is to calculate a delta T using the appropriate chart from Figs. 16.5 through 16.8.

The second step is to determine the size of a copper plane in the board and the distance from the trace to the plane. For example, start with a 1 oz. solid copper ground plane in a 127 mm (5 in.) long and 203.2 mm (8 in.) wide board 258.1 mm (40 in.<sup>2</sup>). Assume that the trace is several dielectric layers from the ground plane. If the distance from the trace to the plane is 0.02-in., then Fig. 16.10 can be used to find the coefficient to be used with the baseline trace temperature rise.

The size of the copper plane, 40 sq. in., is selected on the x-axis of Fig. 16.10. The distance from trace to the plane, 0.02 in., is the second curve from the top in Fig. 16.10. The coefficient is found on the y-axis directly across from the intersection of the curve and copper plane area. The trace temperature rise will be approximately 0.42 times the temperature rise calculated from Fig. 16.5 or Fig. 16.6.

If the trace were located 0.127 mm (0.005 in.) from a 2 oz. copper plane, the third curve from the top in Fig. 16.10, the temperature rise would be 0.29 times the temperature rise. So, if a 10°C rise were calculated from the baseline chart, the temperature rise would be 4.2°C in the first example and 2.9°C in the second example.

### 16.5.3 Parallel Conductors

Parallel conductors refer to traces that are parallel to each other as shown in Fig. 16.11. Parallel conductors also refer to traces on adjacent layers that are parallel to each other. The design rule for sizing parallel traces from the design guidelines is stated in this section.

1.1/1.1 1/s. 1/4oz

**FIGURE 16.11** Parallel traces. (Photograph used by permission from Richard Snogren.)

For groups of similar parallel conductors, if they are closely spaced (that is, as much as 25.4 mm [1.0 in.] spacing and less when using a baseline chart), the temperature rise may be found by using an equivalent cross-section and an equivalent current. The equivalent cross-section is equal to the sum of the cross-sections of the parallel conductors, and the equivalent current is the sum of the currents in the conductors.

Example: Determine the maximum current that can be applied to 16 parallel traces that are 0.028 mm (0.0011-in.) wide  $\frac{1}{4}$  oz. copper (0.00035 in. thick):

- Cross-sectional area of one trace = 0.00035 in.  $\times$  0.0011 in. = 3.85E-07 in.<sup>2</sup> = 0.385 sq. mil.
  - Cross-sectional area of 16 traces = 3.85  $\times$  E-07 in.<sup>2</sup>  $\times$  16 = 6.2 sq. mil.
  - Find the current for the total cross-sectional area, 6.2 sq.-mil., and a 10°C rise, using Fig. 16.6 results in 0.7 amps.
  - Divide the current by 16 traces, 0.7/16 = 0.0438 amps.
  - Round down = 0.04 amps per trace.
- For boards that are less than 0.07 in. thick, the temperature rise will be higher.
  - If copper planes are present in the board, then the temperature rise will be lower.
  - Trace data for  $\frac{1}{4}$  oz. copper is not available, so there are assumptions regarding the temperature rise. It is assumed that  $\frac{1}{4}$  oz. copper will exhibit a similar temperature rise for a defined cross-sectional area as 1 oz. copper.

Closely related to parallel conductors are coils. "For applications where etched coils are to be used, the maximum temperature rises may be obtained by using an equivalent cross-section equal to 2n times the cross-section of the conductor, and an equivalent current equal to 2n times the current in the coil, where n is equal to the number of turns."<sup>2</sup>

Example: Determine the maximum current for a coil with 10 turns and the same size trace as the previous example:

- Trace cross-sectional area = 0.385 sq.-mil. or 3.85E-07 sq. in.
- The number of turns,  $n$ , is = 10.
- $2 \times n \times$  cross-sectional area =  $2 \times 10 \times 0.385$  sq.-mil. = 7.7 sq. mil.
- Equivalent current =  $2 \times n \times$  current = 0.8 amp.
- Coil current for a 10°C rise = 0.8 amp/2n = 0.04 amp.

#### 16.5.4 Board Thickness

The board thickness is a part of defining a baseline for creating a trace-sizing chart and has a direct impact on conductor heating. The thickness of the board affects the heat transfer path, causing energy to flow away from the trace. As the board thickness increases, the heat transfer path away from the trace increases. When the heat transfer path is increased, the thermal resistance is lower and the temperature rise is lower.

The dielectric material is the first material that begins to transfer heat from the trace. The board material—although poor in terms of thermal conductivity—is better than just air itself. Figure 12 illustrates the impact of board thickness on trace temperature rise. Each category represents the same trace and current level. The x-axis represents the board thickness in in. A 9 percent increase is seen in the trace temperature rise, going from a 0.07 in. thick to 0.059 in. thick board. A 43 percent increase is seen in the trace temperature rise, going from 0.07 in. thick to 0.038 in. thick. And a 260 percent increase is seen in the trace temperature rise going from 0.07 in. thick to a trace in free air. The free air case is equivalent to the IPC internal conductor-sizing chart.

FIGURE 16.12 Temperature rise versus board thickness.

#### 16.5.5 Board Material

The PWB material, or more precisely the PWB material thermal conductivity, has a direct impact on the temperature rise of a trace. The differences between the FR-4 material and

polyimide material thermal conductivity, shown in Table 16.3, have approximately a 2 percent impact on trace temperature rise.

The thermal conductivity reported in most data sheets is the z-axis thermal conductivity, which represents the resin in the material. The x- and y-axes are higher due to the woven fibers in the laminate. There is not much information provided on the thermal conductivity of

**TABLE 16.3** Material Thermal Conductivity

Material	Kx w/in.-C (w/m-K)	Ky w/in.-C (w/m-K)	Kz w/in.-C (w/m-K)
FR-4	0.0124 (0.488)	0.0124(0.488)	0.0076 (0.299)
Polyimide	0.0138 (0.543)	0.0138 (0.543)	0.0085 (0.335)
Copper OFHC	9.935 (391.2)	9.935 (391.2)	9.935 (391.2)
Air	0.000879 (0.0346)	0.000879 (0.0346)	0.000879 (0.0346)

laminate materials, and the values listed in Table 16.3 for FR-4 and polyimide are measured values from current carrying capacity test board coupons.

The thermal conductivity of copper is almost 1,000 times greater than the dielectric material and is the reason that internal copper planes have such a significant effect on trace temperature rise. The thermal conductivity of air, which is 10 times less than the dielectric, helps explain why external traces generally run hotter than internal traces.

**16.5.6 Environments**

The term *environment* refers to the surroundings to which the circuit board is exposed and in which it operates. The circuit board may be mounted in an electronics box in a vacuum or surrounded by still air. The board and electronics may be exposed to forced air or it could be immersed in an inert fluid.

It may be necessary to estimate the impact of one environmental condition over another; therefore, it is important to know that the baseline configuration is for a still air environment.

One environment that is not more conservative than still air is an environment in vacuum or in space (see Fig. 16.13). In a vacuum, the internal and external traces run approximately at the same temperature. The internal IPC chart is recommended for sizing traces

**FIGURE 16.13** Vacuum versus baseline environments.

for both internal and external traces in vacuum environments. If the baseline chart is used, the temperature rise should be derated by 55 percent for internal traces and 35 percent for external traces.

### 16.5.7 Vias

The cross-sectional area of a via should maintain the same cross-sectional area as the trace or be larger than the trace coming into it. If the via has less cross-sectional area than the trace, then multiple vias are required to maintain the cross-sectional area. The cross-sectional area can be calculated based on the barrel diameter and the plating thickness. Consult with the printed circuit board manufacturer to determine the plating thickness. Figure 16.14 illustrates the cross-sectional area of a via.

$(D - d)$  = barrel plating thickness

**FIGURE 16.14** Via cross-sectional area.

### 16.5.8 Trace to Via to Plane

If a trace is connected to a via and the via is connected to a plane, the plane will conduct heat away from the via and the via will run cooler than the trace.

### 16.5.9 Microvias

Microvias respond to current the same as a through-hole via. The cross-sectional area is the parameter to match to a current level and temperature rise.

## 16.6 ODD-SHAPED GEOMETRIES AND THE "SWISS CHEESE" EFFECT

High current is often applied to copper planes that deliver the current to various locations in the printed circuit. It is not uncommon for these copper planes to be odd-shaped geometries, or "swiss-cheese" (referring to the holes in copper planes resulting from vias, holes, and sections of copper that are etched away from the copper plane). The simple conductor sizing charts become limited in their use for these applications.

A technique for evaluating the temperature distribution in copper planes of odd-shaped geometries, as well as the result of many vias and cutouts, is by using a voltage drop analysis.

### 16.6.1 Voltage Drop Analysis

Voltage drop in an odd-shaped geometry can be calculated accurately only with numerical techniques. The easiest way is to use software tools (such as ANSYS Thermal Analysis System (TAS) Thermal Modeling Software) that are designed for this type of problem.

There is a direct analogy between thermal resistance and electrical resistance. Because of this, thermal analysis tools can be used to calculate voltage drop rather than temperature drop. The following summarizes the analogy between thermal and voltage drop analysis:

(*Mho* is a unit of conductance equal to the reciprocal of an ohm; mho is more properly referred to as siemens = amperes/volts.)

Temperature (degrees)	is analogous to	voltage (volts)
Heat flux (watts)	is analogous to	current (amps)
Thermal conductivity (Watts/(in-C))	is analogous to	electrical conductivity (Mhos/in.) <sup>1</sup>
Resistance (degrees/watt)	is analogous to	resistance (ohms or 1/Mhos)

The voltage drop is calculated based on actual dimension for the problem. If plate elements are used to represent a copper plane in a printed circuit board, the actual PCB dimensions are needed and the actual copper thickness is required.

### 16.6.2 Voltage Sources

A voltage source is defined as a point where voltage is applied in a circuit. This would typically be a power supply. In a thermal analysis tool, this is analogous to defining a boundary temperature.

### 16.6.3 Current Source (or Sink)

A point where a defined amount of current is added or removed is a *heat load* in a thermal analysis tool. If a component draws a specified current at a point in the PCB model, the current would be represented as a negative heat load at that point. If a voltage source acts as a constant current source as opposed to a constant voltage source, it would be represented as a positive heat load.

### 16.6.4 Electrical Conductivity

For geometric elements such as plates, bricks, and tetrahedrons, thermal conductivity should be in units of Mhos/length, where Mhos equals 1 ohm. Units of length must be consistent with those used in the rest of the model.

## 16.7 COPPER THICKNESS

Copper thickness is assumed 35.6  $\mu\text{m}$  (0.0014 in.) thick for 1 oz. copper or possibly 34.3  $\mu\text{m}$  (0.00135 in.). Two-ounce copper is considered twice those values and half the thickness for 1/2 oz. copper. IPC 2221 specifies the minimum acceptable copper thickness for an internal layer as shown in Table 16.4. The minimums are significantly less than what designers may think and should be considered when pushing current limits on small trace widths. For example, 1 oz. is

**TABLE 16.4** Minimum Internal Copper Foil Thickness<sup>3</sup>

Internal conductor thickness after processing		
Copper foil	Minimum thickness	
	( $\mu\text{m}$ )	(in.)
1/8 oz.	3.5	0.000138
1/4 oz.	6	0.000236
3/8 oz.	8	0.000315
1/2 oz.	12	0.000472
1 oz.	25	0.000984
2 oz.	56	0.002205
3 oz.	91	0.003583
4 oz.	122	0.004803

**TABLE 16.5** Minimum External Conductor Thickness<sup>4</sup>

Base copper foil	External conductor thickness after plating	
	Minimum	
	( $\mu\text{m}$ )	(in.)
1/8 oz.	20	0.000787
1/4 oz.	20	0.000787
3/8 oz.	25	0.000984
1/2 oz.	33	0.001299
1 oz.	46	0.001811
2 oz.	76	0.002992
3 oz.	107	0.004213
4 oz.	137	0.005394

allowed to be a minimum of 0.00098 in. thick rather than 0.0014 in. This significant difference can cause a 50 percent difference in trace temperature rise. Fortunately, copper thickness tends to run more toward a nominal, although attention should be given to the fact that minimum thicknesses do exist and have the potential of being a problem if the limits are being pushed on temperature rise and current level.

External conductors have a thicker minimum (see Table 16.5) due to plating during the final processing steps at the manufacturer. It is always recommended to discuss the details of the board with the circuit board manufacturer. The board manufacturer will know what the typical thickness of the final product will be, which will vary from one board design to another. The final thickness can also be defined on drawings that are sent to the manufacturer.

## 17.1 INTRODUCTION

---

The reliability and electrical functionality of electronic components is partially determined by the temperature at which they operate. As such, control of the component temperatures in the system is an important design consideration. Factors that impact device temperatures include the power at which they operate, the air flow surrounding them, heat generation upstream to them, the environment in which the system operates (either indoors or outdoors), the system orientation (either vertical or horizontal), and a variety of printed circuit board (PCB) layout and design properties. These PCB design factors include the design of the copper (Cu) traces contacting the components, the number and area of Cu planes that are connected to them, any thermal vias that might be designed between them and the spreading planes, the proximity of other devices that dissipate power, and any cuts in the thermally conducting layers. Additional PCB features that impact the thermal performance of components include chassis screws, connectors, edge guides, and shields.

To control component temperatures, PCB factors that impact thermal energy flow must be considered in the design phase of the PCB layout. These factors include many complex interactions that make application of simple equations to calculate system temperatures impossible. For example, the historical equation used to calculate component temperatures from a thermal resistance parameter called Theta-ja ( $\theta_{ja}$ ) as shown in Eq. 17.1 is not applicable in modern systems. This is stated clearly in the Joint Electron Device Engineering Council (JEDEC) standard for  $\theta_{ja}$ .<sup>1</sup>  $\theta_{ja}$  is not a constant. It is a function of the PCB onto which the component is placed and can vary by a factor of two or more as a function of the PCB design layout. Therefore, if component temperatures are calculated using Eq. 17.1, wildly erroneous estimates may be accepted, which might lead to a system design that fails thermally.

$$T_{\text{junction}} = T_{\text{ambient}} + (\theta_{ja} * \text{Power}) \quad (17.1)$$

where  $T_{\text{junction}}$  = the temperature of the active portion of the component  
 $T_{\text{ambient}}$  = the temperature of the air at a specified location  
 $\theta_{ja}$  = the thermal resistance of the component as defined by JEDEC  
 $\text{Power}$  = the power of the component

This chapter describes best-design practices that enable the PCB designer to achieve the best possible thermal performance for a given design. As there is no method to calculate analytically the combined impact of the methods described, the designer is encouraged to use sophisticated tools to model the final component temperatures.

## 17.2 THE PCB AS A HEAT SINK SOLDERED TO THE COMPONENT

The PCB can be considered to be a heat sink that has been soldered to the leads or solder joints of the electronic component. The physical design of the PCB dramatically impacts its efficiency as a heat sink and the temperatures at which the components operate. Figure 17.1 helps to illustrate this point. Here, a packaged component (shown in cross section) is attached to the PCB. Heat is generated by current flowing through electrical resistances on the active surface of the die. This raises the temperature of the surface, resulting in a thermal gradient. Thermal energy (heat) flows from regions of high temperatures to regions of lower temperatures. For the component illustrated in Fig. 17.1, heat flows from the die through the die attach, then through any Cu metallization in the package substrate, then through the solder joints into the PCB. If there are good thermal conduction paths in the PCB, the heat spreads out over a large area of the PCB, allowing the potential for efficient convection and radiation into the environment. If there are few heat transfer paths in the PCB, the component is insulated and the temperature increases.

**FIGURE 17.1** Cross section of an electronic component on a PCB. The arrows indicate heat conduction paths.

How important is the PCB to the thermal performance of components? Depending on the PCB design, up to 60 to 95 percent of the thermal energy can be dissipated by the PCB. This type of performance can be achieved by PCBs that meet the following criteria:

- Large spreading planes to conduct heat away from the components
- Sparsely populated PCBs with large areas for convection and radiation
- Long traces interconnecting the components, again to conduct heat away from the components
- Sufficient spacing of PCBs in a system rack to enable adequate convection

Failure to meet these conditions will result in reduced thermal dissipation from the PCB, higher component operating temperatures, degraded device reliability, and perhaps even lack of electrical functionality.

## 17.3 OPTIMIZING THE PCB FOR THERMAL PERFORMANCE

To optimize the PCB's thermal performance, it is important to consider the trace layout, the thermal planes, and the thermal vias. Component spacing on the PCB and the maximum PCB power dissipation (thermal saturation) are also critical.

### 17.3.1 The Impact of the Trace Layout

The thermal conductivity of a material is a measure of the thermal energy that can flow through the material under an applied temperature gradient. Figure 17.2 shows a plate of material where two sides are held at different temperatures,  $T_1$  and  $T_2$ . Experimentally, the one-dimensional thermal energy transferred through this material is found to be governed by Eq. 17.2.

$$q = \frac{kA}{l}(T_1 - T_2) \quad (17.2)$$

where

- $q$  = the heat energy
- $A$  = the area of the plate
- $l$  = the thickness of the plate
- $k$  = the thermal conductivity of the material
- $T_1, T_2$  = the applied temperatures on the plate's opposing faces

Table 17.1 lists typical thermal conductivity values important to PCB and electronic components. Where a range of material properties is given, multiple factors determine the exact thermal conductivity value. These factors can include the filler percentage and composition in a polymer, or in the case of silicon (Si), the doping type and level. Material property measurement or vendor data should be used to determine the thermal conductivity of the specific material of interest. One alloy of Cu is shown to demonstrate that the Cu alloy

**FIGURE 17.2** Typical thermal conductivity test schematic showing a block of material with area  $A$  constrained by two different temperatures,  $T_1$  and  $T_2$ , on opposing faces.  $Q$  indicates the heat flow direction when  $T_2$  is greater than  $T_1$ .

**TABLE 17.1** Typical Thermal Conductivity Values<sup>2,3</sup>

Material	$k$ (w/m-°C) at 25°C
Air	0.0026
Copper (pure)	386
Copper EFTEC-64T	301
FR-4 (in-plane)	0.6–0.85
FR-4 (out-of-plane)	0.25–0.3
Solder mask material	0.15–0.5
IC encapsulant	0.6–1.0
Silicon	110–149

**FIGURE 17.3** Modeled temperature rise above ambient thermal performance of an 8-pin SOIC powered at 1 watt as a function of the trace length.

composition can play a role in the thermal conductivity of metals. These material properties are valid at room temperature ( $\sim 23^{\circ}\text{C}$ ). Due to the temperature-dependent nature of thermal conductivity, further references for these properties should be pursued when operation is expected at temperatures above  $85^{\circ}\text{C}$  or below  $-25^{\circ}\text{C}$ .

It is critical to note that the thermal conductivity of Cu is three orders of magnitude greater than the conductivity of most polymers such as PCBs and solder mask materials. This means the majority of the thermal energy will be conducted through the Cu, which implies that the layout of the Cu traces and power planes will be critical to the thermal performance of the PCB as a heat sink. Figure 17.3 shows this graphically. In this model, an eight-pin small-outline integrated circuit (SOIC) package dissipating 1 watt was soldered to a single-layer FR4 PCB of 1.57 mm thickness. The temperature rise above ambient is plotted as a function of the trace length connected to the device pins. As shown, the device temperature changes by  $\sim 40$  percent for this variation in trace length. The data show that to get the lowest possible temperatures, the longest possible traces should be used to spread heat away from components. Equally important, the widest possible traces should be used. These thermal design optimizations need to be made within the constraints of the electrical performance requirements such as the system time delay budget.

An important feature of thermal management is evident from this chart. After a trace length of about 15 mm, there was little additional improvement as the trace lengthened further—seeking thermal optimization by increasing the trace length had reached a point of diminishing return. Often, once a specific parameter has been optimized, further changes in that parameter lead to little additional efficiency gain. Intuitively, heat flow can be thought of by analogy to fluid flow through pipes of different diameters. The pipe with the smallest diameter limits the fluid flow rate for a given fluid pressure. If the diameter of this constriction is made larger, the next smallest pipe diameter becomes the next constriction. Thermal resistance is analogous to the resistance to fluid flow in this pipe illustration. Once a thermal resistance restriction has been minimized, the thermal conduction “bottle neck” moves to a different portion of the problem.

The PCB trace thickness is another important parameter that interacts with the trace length and width. If the traces are thick, they offer less thermal resistance to heat transfer. If the traces are thin, their thermal resistance is increased and the heat will not spread as far. For best thermal performance, use the thickest possible Cu foil material with the thickest possible electroplating. Unfortunately, the trace thickness is often specified to achieve the best possible etch performance for tight pitch routing, which in turn gives the smallest PCB with the fewest signal layers and lowest cost. Within these limits, ensure that Cu traces are as thick as possible. Use them to provide direct thermal conduction paths to thermal features such as thermal vias, thermal side rails, or thermal conduction screw holes.

**FIGURE 17.4** A typical four-layer PCB cross section showing a package with an exposed pad soldered to a thermal landing that is in turn connected to the PCB ground plane through thermal vias. The vias are isolated from the power plane for electrical reasons. In this figure, the ground plane would become the thermal spreading plane assuming it was continuous over a large area.

### 17.3.2 Thermal Planes

Cu planes in the PCB can provide very effective heat spreading for the electronic components. The intent is to conduct the heat over as large an area as possible in order to optimize convection and radiation heat loss from the PCB. Figure 17.4 shows a cross-sectional view of a PCB highlighting features that make good thermal planes. These include:

- A thermal landing (sometimes called a thermal collection plate) or solder land to gather the heat that the device is shedding
- Thermal vias to conduct heat from the thermal landing into a buried plane (most often either the power or ground plane)
- Continuous Cu to spread the heat
- A possible thermal landing on the bottom side of the PCB where an indirect heat sink might be attached
- Isolation areas to ensure that the thermal vias don't short all planes in the PCB

Many integrated circuit (IC) packages are optimized to “dump” power into such thermal planes in the PCB. Figure 17.5 shows images of packages with exposed pads that are intended

**FIGURE 17.5** Two package types with exposed thermal “slugs” on the bottom of the package intended to be soldered to thermal spreading elements on the PCB.

to be soldered to thermal collection plates on the PCB. The die of these packages are glued directly to these exposed pads, giving a very low thermal resistance into the PCB. This thermal resistance can be found from vendor data sheets and might be listed as Theta-jc ( $\theta_{jc}$ ), for junction to case, or as Theta-jp ( $\theta_{jp}$ ), indicating junction to pad resistance. Ball grid array (BGA) packages often include thermal balls that are designed with optimized thermal conduction paths to the die inside the package. These balls should be soldered to thermal collection lands for spreading heat throughout the PCB. Often, thermal ball arrays include both power and ground balls, allowing at least two PCB planes to be used for spreading, thereby increasing the spreading efficiency of the PCB.

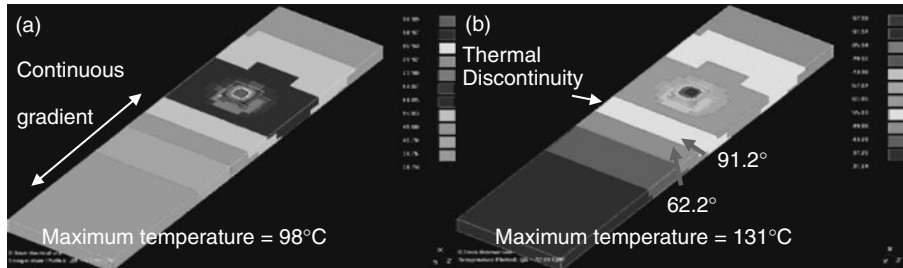

Large thermal spreading elements that must be soldered to the PCB can sometimes present manufacturing problems. Improper control of solder paste leading to too much paste under these large thermal pads can result in “floating” the components on a pool of molten solder during reflow. When this happens, continuity yield suffers as the package tends to tilt one way or the other, lifting high side leads off their solder lands. Some users faced with this problem eliminated the solder between the exposed thermal pad and PCB, which led to high operating temperatures and severely degraded reliability in the field. The solution to the floating package problem is to optimize the solder paste volume, not to eliminate the thermal conduction path to the PCB. Always connect thermal management features of electronic components to the appropriate thermal collection pattern, which should then be connected through thermal vias into a thermal plane. Failure to do so will result in devices not running at the expected thermal efficiencies.

Figure 17.6 shows the impact of thermal spreading plane area on the thermal performance of a  $12 \times 12$  mm chip scale package (CSP) BGA-type package with 49 thermal balls. When the thermal plane size is small, the thermal performance is poor, whereas when the thermal plane size is large, the thermal performance improves by a factor of two or more. Often, suppliers of components with exposed thermal attach pads will also provide guidance as to the recommended size and shape of the thermal planes. It is best to ensure that the maximum plane area be close to the component; there shouldn't be a large thermal resistance getting from the component into the plane. Maximize the area of the thermal spreading planes to maximize thermal dissipation.

It is important to point out that the plane must be continuous, that is, with few or no isolation breaks in the Cu area. Since the thermal conductivity of Cu is about 1,000 times higher than that of the FR-4, a 1 mm F-R4 break in a plane offers about the same thermal resistance

**FIGURE 17.6** The effective  $\theta_{ja}$  of a  $12 \times 12$  mm Chip scale package (CSP) with 49 thermal balls as a function of the (x,y) length of a continuous thermal plane under the package. Two trace lengths were assumed, showing different amounts of coupling of heat from the traces into the plane.

**FIGURE 17.7** Thermal contours of a component on an isolated section of PCB in two configurations: (a) with a solid thermal plane over the section of PCB, (b) with a 0.25 mm electrical isolation zone in the thermal plane. The isolation zone increased the component temperature by 33°C.

as a 1,000 mm span of Cu. A model result showing the impact of an electrical path break in a thermal plane is shown in Fig. 17.7. Here, a small  $7 \times 7$  mm device with an exposed solder pad was intended to be cooled by a specific size of PCB area. However, due to electrical constraints, a 0.25 mm electrical noise isolation break was placed halfway down the plane to produce a quiet island. The PCB designer didn't think this would have much impact, but thermally, it cut the plane size by half. As shown in the figure, there was a 29°C temperature drop across this single 0.25 mm break in the thermal plane and the component temperature increased by 33°C. For best thermal performance, don't hamper thermal spreading in a thermal plane with continuous electrical isolation cuts.

Sometimes, the overall thermal performance of a PCB can be enhanced by carefully utilizing isolation cuts in the PCB to thermally segregate components that can afford to run at higher operating temperatures. For example, if a series of power regulator components can operate at junction temperatures of 150°C but are dumping so much heat into the PCB that the digital components' maximum junction temperatures are exceeded, it might be effective to cut the thermal plane between the power regulator components and digital portion of the PCB. This design technique will cause the temperatures of the power components to rise, but will lower the temperatures of the digital components. Of course, care must be taken to ensure the Cu connecting to the power regulation devices can carry the required current, so judicious application of this design technique is advised.

For the best spreading performance, the thickest possible Cu should be used in the construction of the thermal planes. If a thermal plane is to be 0.5 oz. Cu thickness ( $17.8 \mu\text{m}$ ), it is wise to double this plane with another thermal plane, giving an effective 1 oz. layer of Cu to spread the heat over the PCB surface. Little additional advantage is gained when the thickness of all planes for spreading thermal energy is greater than 2.8 oz. Cu.

### 17.3.3 Thermal Vias

Thermal vias are simply those that connect the thermal lands or thermal collection plates to the thermal planes. They are formed using the same processing techniques that are used for the PCB's electrical vias. However, unlike electrical vias, the primary intent of a thermal via is that it conducts thermal energy efficiently into the thermal planes. As such, a number of conditions should be met:

- There should be at least one thermal via associated with each thermal ball of a BGA package.
- The density of thermal vias under a thermal landing should be maximized within the limits of what can be allowed without degrading the PCB mechanical integrity.
- If the PCB uses through hole vias, the plating thickness should be maximized to optimize thermal conduction.

**FIGURE 17.8** An illustration of two possible thermal via connections to the thermal spreading plane. The first via is a solid connection, which is recommended. The second via connection is made with a spoke or web connection to the thermal plane. This is not recommended for a thermal via.

- If the PCB uses build up technology and nested vias are possible, nested vias should be used to connect to the thermal plane.
- If the PCB uses build-up technology but nested vias are not allowed, the shortest possible path between vias should be used to route the thermal energy into the spreading planes.

Figure 17.8 shows the proper way to connect thermal vias to power or ground planes. A web or spoke via connection is not recommended, as either constricts heat flow into the thermal plane. The exit side of the thermal via should have a Cu ring to anchor it to the PCB. Common thermal via dimensions for exposed pad packages are 1.0 to 1.2 mm center-to-center spacing, 0.3 mm drill diameter, with 0.025 mm Cu plating thickness or higher. Through hole thermal vias should be filled with solder, epoxy, or solder mask to avoid wicking solder from the thermal joints or thermal balls that might otherwise create an open or a reliability hazard.

The thermal resistance of an individual thermal via can be easily calculated from the via diameter, the via plating thickness, and the via length between the thermal land and thermal plane using Eq. 17.3.

$$\theta_{via} = \frac{l_{via}}{k * \pi * \left( \left( \frac{diameter_{via}}{2} \right) - \left( \frac{diameter_{via} - (2 * T_{plating})}{2} \right)^2 \right)} \tag{17.3}$$

where

- $\theta_{via}$  = the via’s thermal resistance (°C/W)
- $k$  = the thermal conductivity of Cu (W/mm-°C)
- $diameter_{via}$  = the via’s drill diameter (mm)
- $T_{plating}$  = the Cu plating thickness in the via (mm)
- $l_{via}$  = the via’s length between the thermal land and thermal spreading plane

Substituting some typical values such as a drill diameter of 0.3 mm, a plating thickness of 0.025 mm, a via length of 0.38 mm, and a thermal conductivity of 0.389 W/mm-°C, the typical thermal resistance of a thermal via is found to be 45°C/W. Since a thermal resistance is analogous to an electrical resistance, equations for calculating parallel resistance can be used to calculate the effective

thermal resistance of a thermal via array. Using Eq. 17.4 below, a  $4 \times 4$  array of vias is found to give a thermal resistance of  $2.8^\circ\text{C}/\text{W}$ . It is evident that the thermal performance of a component can be optimized with a relatively small number of thermal vias (see Eq. 17.4).

$$\frac{1}{R_{total}} = \sum_{i=1}^n \frac{1}{R_i} \quad (17.4)$$

where  $R_{total}$  = the total resistance of the via group  
 $R_i$  = the resistance of each individual via

Evaluating the thermal via resistance as a function of trace plating variability, a 0.015 mm thick plated via with the same dimensions as the preceding will have a thermal resistance of  $73^\circ\text{C}/\text{W}$ . Thus, the thermal performance of a PCB is sensitive to variations in the plating thickness of its thermal vias. To ensure thermal via performance, the plating thickness in the via should be checked. This is usually performed by parallel polishing down from the surface of the PCB rather than through a cross-sectional polishing of the via. When cross-sectioning a via, if sectioning plane does not intersect the exact center of the via, an incorrect plating thickness will be measured; this problem does not occur when parallel polishing into the depth of the PCB.

### 17.3.4 Component Spacing on the PCB

There is a finite spreading thermal resistance to any PCB as a function of its thickness and the number of planes in the PCB. Eq. 17.5 is a simple equation to calculate the in-plane thermal conductivity of a PCB as a function of the spreading plane thicknesses versus the FR-4 material layers. For example, if a 1.57 mm thick FR-4 board has a single solid thermal spreading plane that is 0.036 mm thick, the effective in-plane thermal conductivity of the plane is  $8.9 \text{ W}/\text{m}\cdot^\circ\text{C}$ . This is substantially lower than the thermal conductivity of pure Cu, which is  $386 \text{ W}/\text{m}\cdot^\circ\text{C}$ . Therefore, thermal spreading through the PCB with a single plane will be worse than thermal spreading through a plate of Cu with the same thickness as the PCB.

$$k_{effective} = \frac{\sum_i k_i t_i}{\sum_i t_i} \quad (17.5)$$

where  $k_{effective}$  = the PCB's effective in-plane thermal conductivity  
 $k_i$  = the thermal conductivity of the  $i$ th layer  
 $t_i$  = the thickness of the  $i$ th layer

The net effect of the limited spreading resistance of a PCB is that component temperatures will rise as they are clustered more tightly on a PCB of a given size and construction. For example, Table 17.2 shows the maximum component temperature of four small devices on a

**TABLE 17.2** Case Example of Component Temperature versus PCB Spacing

Component spacing (mm)	Maximum temperature ( $^\circ\text{C}$ )
50	81.6
25	84.4
12.5	92.9
8	98.4

100 × 100 mm PCB containing two buried planes. As the components were moved closer to each other, the device temperatures increased from 81.6°C to 98.4°C, representing an increase of 30 percent compared to the ambient temperature of 25°C. To make the best use of a PCB as a heat sink spreader, the power of individual components should be distributed as evenly as possible on the PCB to minimize hot spots.

The location of a component with respect to the air flow is also important. As air flows across power sources on a PCB, it picks up heat and increases in temperature. Components in the air flow downstream from high-power devices are heated by the warmer air. Air temperatures can easily rise 10 to 30°C just past a high-powered component such as a micro-processor, power amplifier, or power regulator block. If a component is running too hot, one possible solution is to move it as far upstream in the air flow as possible such that it receives the coolest air.

### 17.3.5 Thermal Saturation of the PCB

When the power of individual components has been evenly distributed over the PCB surface such that further geometrical rearrangement of the components or further optimization of the trace and thermal plane design is ineffective in cooling the components, thermal saturation of the PCB is said to have occurred. At this point, the power dissipation capability of the PCB becomes the factor limiting the component temperatures. The maximum power dissipation of a PCB with good thermal planes and evenly distributed power sources is in turn limited by a number of geometrical and system-level factors. These include:

- The air stream velocity
- Any air ducting or shrouding around the PCB
- The configuration of heated surfaces around the PCB
- The altitude at which the PCB is operating
- The orientation of the PCB with respect to gravity

Each of these parameters impacts either the convection or radiation from the PCB. Convection is the heat transfer mechanism whereby heat is removed from the PCB through conduction of thermal energy into the gas or fluid that surrounds the PCB. In a natural convection environment, the heating of the air around the PCB causes its density to decrease. In the presence of a gravitational field, the less dense air will rise, carrying away heat with it—fresh, cool air moves in to replace the heated air. In a forced-air environment, the heated air is “blown” away from the surface by cooler air, which in turn becomes heated through the conduction of thermal energy from the PCB. The heat removed from a surface of area  $A$  due to convection, either natural or forced, can be represented by the simplified one-dimensional Eq. 17.6.

$$q = hA(T_{surface} - T_{ambient}) \quad (17.6)$$

where

- $q$  = heat
- $h$  = convection coefficient
- $A$  = surface area
- $T_{surface}$  = the average temperature of the surface
- $T_{ambient}$  = the temperature of the ambient air

Equations to calculate the convection coefficient  $h$  are beyond the scope of this chapter. Convection is a function of (1) the PCB size, with smaller PCBs having higher convection efficiencies; (2) the PCB orientation, with vertical PCBs being more efficient; (3) altitude, with lower altitudes being more efficient than higher altitudes; and (4) air ducting, with ducting tending to make the PCB more efficient in forced air environments.<sup>4</sup>

Radiation is the removal of heat from a surface by the emission, or “radiation,” of photons. These photons are generated when thermally excited atoms collide with each other, resulting in overlapping electron energy states. Since electrons are fermions, meaning no two electrons can occupy the same energy band, when the energy states of two electrons overlap during the collision, one electron is forced into a higher, empty energy state. This reduces the momentum of the colliding atoms, ensuring that energy is conserved. After collision, the displaced electron decays back to its initial energy state, giving up a photon of energy in the process. At the surface of the object, this photon is emitted, carrying away some of the thermal energy, while in the bulk of the material, this photon is reabsorbed by neighboring atoms. The simplified one-dimensional equation that describes the total energy loss from a surface due to radiation is shown in Eq. 17.7. This equation for radiation neglects heat that the PCB might reabsorb from heated objects such as power supplies around it, but does include an ambient temperature radiation reabsorption.

$$q = \epsilon \sigma A (T_{\text{surface}}^4 - T_{\text{ambient}}^4) \quad (17.7)$$

where  $q$  = heat  
 $\epsilon$  = the emissivity of the surface  
 $\sigma$  = the Stefan-Boltzmann constant ( $5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4$ )  
 $T_{\text{surface}}$  = the PCB surface temperature  
 $T_{\text{ambient}}$  = the ambient temperature

The emissivity of the object is a unitless number that describes how efficiently a surface radiates. It varies from 0, which is a surface with no radiation that is perfectly reflective, to 1, which is a perfectly radiative and absorptive black surface. The emissivity of the surface is a function of both the type of material that composes the surface as well as the roughness of the surface. Typical solder mask material has an emissivity ranging from 0.85 to 0.95. Typical exposed Cu trace has an emissivity ranging from 0.1 to 0.3 depending on the roughness and oxidation condition of the Cu.

It is important to note that the area of the PCB plays a major role in both of these equations. This is intuitive; the larger the PCB, the more heat it can dissipate. In combination, the preceding equations can be used to estimate the power that a given PCB at a given temperature can dissipate. For example, Fig. 17.9 shows the best-case power that can be dissipated by a series of PCBs ranging in size from  $10 \times 10$  cm to  $20 \times 20$  cm. The PCBs were assumed to be oriented horizontally in an unobstructed natural convection environment of  $25^\circ\text{C}$  with no significant neighboring radiating surfaces. Convection was allowed to vary as a function of temperature. Most importantly, the power was assumed to be uniformly distributed over the PCB such that there were no thermal gradients on the PCB. This is a major assumption, meaning that the power dissipation figures in the chart are best-case, a condition that no practical PCB will attain. The chart indicates that 50 W can't realistically be dissipated in natural convection from a PCB that is  $10 \times 10$  cm, but it can be dissipated by the  $15 \times 15$  and  $20 \times 20$  cm PCB. The  $15 \times 15$  cm PCB will rise  $80^\circ\text{C}$  above the ambient to dissipate 50 W, while the  $20 \times 20$  cm PCB will rise only  $50^\circ\text{C}$  to dissipate the same power. This graph has been formatted to look the same as typical heat sink curves that are available from many vendors.

**FIGURE 17.9** Temperature rise above  $25^\circ\text{C}$  of a horizontal PCB in natural convection as a function of PCB size and power dissipation. Both convection and radiation are dissipating the power.

## 17.4 CONDUCTING HEAT TO THE CHASSIS

When the PCB is thermally saturated and the component temperatures are still too high to be tolerated at the maximum obtainable system air velocity, other means of conducting heat from the PCB to even larger area system structures are required. The chassis of the system is often the largest surface area structure in the system, is exposed to the ambient air, and often makes a good sink for heat that cannot be dissipated by the PCB alone. Mechanisms to conduct heat into the chassis include chassis screws, gap fillers, connectors, and side rails. Sometimes, radio frequency (RF) shields that are appropriately connected to components can provide additional heat sinking.

### 17.4.1 Chassis Screws

A properly designed chassis screw thermal sink connection in a PCB includes connection to the thermal spreading plane of the PCB, through hole plating, and a thermal contact area for the screw and stand-off sleeve to clamp onto. This configuration is shown in Fig. 17.10. The thermal screw should be as close to the hot electronic component as possible to minimize thermal resistance into the chassis. As well, the chassis where the thermal screw attaches should have a high thermal conductivity to spread the heat away from the screw. Preferably, the chassis should be made of metal. If a plastic chassis is used, molding a plate of aluminum (Al) into the plastic will improve its thermal heat spreading capability. A plastic chassis alone is usually a poor thermal spreader and may not provide substantial thermal performance enhancement.

**FIGURE 17.10** Schematic of a chassis screw implementation for sinking heat to the chassis. The thermal screw mounts through a plated through via that is shorted to the thermal plane as shown. The thermal plane conducts heat from the thermal balls of the PBGA package.

How much improvement might be expected from using the chassis of an enclosure for cooling? This depends substantially on the enclosure construction and the location of the chassis screw with respect to the hot component. In one example, a device was cooled with a thermal screw that connected between a hard drive PCB and the hard drive enclosure. Connecting the device thermally to the hard disk drive resulted in a 10 percent thermal enhancement.

### 17.4.2 Gap Fillers

It is sometimes not possible to use screws for conducting heat to the chassis. In other cases, large areas of high-power density might need to be sunk into the chassis. In these instances, another type of thermal conduction path is available that lends itself to conducting heat to the chassis: gap fillers. Gap fillers are thermal compounds that fill the gap between the PCB and chassis whose sole purpose is to conduct heat to the chassis. There are many different types of

gap fillers. The most common is a soft, flexible silicone rubber material that has been filled with thermally conducting particles to enhance its bulk thermal conductivity. Sometimes, thermally filled foams are used. When the soft, compliant material is compressed between the PCB and chassis, it conforms to the protruding components on the PCB, making a good thermal connection. Important criteria to consider in selecting elastomeric gap fill materials are the thickness needed, the thermal conductivity required, and the pliancy of the material. A variety of materials with varying compositions are readily available on the market. There is normally a trade-off between the pliancy of the material and the thermal conductivity, with higher thermal conductivity materials exhibiting less pliancy.

Plastic sacks filled with a thermal fluid are sometimes used as gap filler materials. The fluid is usually optimized to produce convection in the gap of interest. The convection in the fluid can give an effective thermal conductivity that is substantially higher than the conductivity of the fluid alone.

### 17.4.3 Connectors

Connectors can either provide a direct or indirect means of conducting heat from the PCB. Direct conduction occurs in those system configurations where the PCB is plugged into an edge connector or back plane socket, or is held in place with an edge guide. To take advantage of these direct connect thermal features, it is necessary to extend thermal planes into the areas where the connection or clamping occurs. The connector, clamping, or edge guide should have as large a contact area as possible to optimize thermal conduction of heat from the low thermal conductivity PCB material. In some military applications, the PCB is built around a thick Cu core that is clamped by the edge rail of the card cage. The thick Cu core provides very effective thermal conduction from the PCB into the edge rail, which is then cooled by a system of channels containing either moving air or moving water.

Indirect conduction of heat from the PCB can occur when cables are plugged into connectors on the PCB. These indirect conduction paths are much harder to include accurately in system-level thermal analyses, but can provide some margin in a PCB thermal design. Care must be taken, however, to ensure that these plug-in cables don't block critical airflow paths that would lead to overheating.

### 17.4.4 RF Shields

RF shields are used over sensitive RF and analog circuits to minimize electrical interference with the circuit function or to minimize electrical radiation from the circuit into the surrounding environment. RF shields are usually made of a thin metal which is soldered to ground on the PCB. In most instances, the RF shield is a continuous plate or box that encloses the circuits. Unfortunately, this continuous box creates a dead zone in the air flow directly above the components within the box, degrading natural convection for those components. To enhance the thermal performance of components within RF shields, perforations or meshing of the RF shield cage is recommended. If these perforations are kept less than 1/10 the wavelength of the shielded electromagnetic radiation, the RF shield will function adequately to quiet the circuit and block out extraneous signals while allowing air flow through the shield to cool the interior components.

If additional steps are taken, the shield can be used to spread heat from hot components inside the shield over a larger section of the PCB, thereby maximizing convection and radiation cooling for the heated components. Figure 17.11 shows a schematic of a shield over a stacked package component. It is normally difficult to conduct heat from the top device in such a stack to the PCB, but when the RF shield is brought into contact with the top device, heat can conduct into the shield and down to the PCB. It is suggested that the thermal connection between the shield and the electrical components be made with a thermal epoxy or thermal grease after the shield is soldered in place to avoid issues with mechanical tolerances

**FIGURE 17.11** A stacked package configuration on a PCB with a perforated RF shield that is being used to spread heat from the top package. Thermal gap filler material such as thermal grease is used to conduct the heat from the top package into the RF shield.

or interference between the shield and the components. If the high-powered components to be cooled reside immediately outside the shield, it is possible to conduct heat from them into the shield such that the shield behaves as a heat sink.

### 17.5 PCB REQUIREMENTS FOR HIGH-POWER HEAT SINK ATTACH

Most IC components with power dissipations of 2.5 W or higher require attached heat sinks to dissipate the power. These heat sinks are often glued or clamped to the components with few special constraints placed on the PCB. If a large number of components requiring heat sinks are placed on the PCB, it is important that the PCB be thick enough to handle the weight of the attached heat sinks, especially if the system environment subjects it to vibration or mechanical shock. High-powered components in the 50–300 W range require special PCB design features to handle the high-loading force of the heat sink against the electronic component. Clamping forces of 20–200 lb. are possible for these high-power heat sinks in order to get the best possible thermal contact between the heat sinks and components. One such high-power heat sink configuration is shown in Fig. 17.12.<sup>5</sup> Here, the heat sink is spring loaded

**FIGURE 17.12** Cross section of a mechanical design for a high-power heat sink clamped on a microprocessor. The bolster plate on the bottom of the PCB minimizes PCB warpage and breakage.

against the package with tensioned screws which tighten into a bolster plate. The bolster plate provides the rigidity needed to avoid bending and damaging the PCB under the spring loading. A mylar film between the bolster plate and PCB minimizes electrical shorting of the fixture to the PCB. For such heat sink constructions to work, no components can be placed between the PCB and bolster plate.

## 17.6 MODELING THE THERMAL PERFORMANCE OF THE PCB

Each of the many PCB thermal optimization techniques described in this chapter will have some amount of impact on the thermal performance of the system. Determining the relative impact of a single optimization is difficult to perform analytically. When an entire ensemble of optimization techniques is employed across multiple devices operating at a variety of powers, analytical solutions of the thermal problem become impossible. The simplicity of system-level temperature calculations implied by Eq. 17.1 is misleading unless the effective  $\theta_{ja}$  of each component in the specific system is known *a priori*. Since the impact of the PCB design on the thermal performance of the system must be determined before design completion and tooling, the question becomes how to quantify the impact of the PCB thermal features. Relay and redesign of the PCB to fix thermal issues once tooling is generated is prohibitively expensive and leads to noncompetitive design cycle times. The only predictive method currently available that addresses this need is computer simulation, which can incorporate all relevant PCB design features, perform a thermal analysis, and report back the component temperatures to identify problem locations.

Many commercial computer simulation tools exist, ranging in complexity, accuracy, and cost. Computational fluid dynamics (CFD) programs incorporate equations that solve the problems of air flow around the PCB, thermal conduction from the PCB into the air, and thermal conduction within the PCB. Solutions using CFD don't require special knowledge of convection coefficient equations, thereby making the modeling process easier and less prone to convection coefficient calculation errors. Accuracy of CFD analysis can be as high as  $\pm 5$  percent. CFD codes tend to be slow, however, taking substantial computer resources to run a reasonably complex model. A step down from CFD are codes that employ user supplied convection coefficients that are applied to the PCB and component surfaces. These solutions can be quite accurate, though no more than  $\pm 10$  percent precision can be projected without substantial correlation to experimental data.

Whichever analysis code is selected, it should be capable of reading in data from the user's PCB layout tool and should be capable of incorporating the specific thermal conduction paths that were optimized for component performance. It should be able to handle relatively complex system-level structures and should be capable of inputting a variety of thermal characteristics of the components. Postprocessing identification of PCB regions and components above limit temperatures is a plus. The code should run fast enough to enable multiple design iterations to optimize the PCB layout without slowing down the design cycle.

### 17.6.1 System-Level Thermal Modeling Phases

System-level thermal analysis normally includes three phases due to the complexity of the task and the difficulty of inputting a fully detailed system design into a tool. The first phase concentrates on airflow optimization through the system to minimize any dead zones in the cabinet. The PCBs, cables, fans, and other air blockages are included in the analysis during this phase. The second phase includes dissipation of power on the PCB by applying power areas to the PCB. During this phase, it is fairly easy to change locations of power sources to optimize the air cooling paths. The final phase is the fully detailed phase, which includes the PCB layout geometries and details of the electrical components. By the time phase three is reached, there should be few remaining major iterations for thermal optimization.

During each phase of thermal modeling, the solids of the components, PCB, and system enclosure must be defined to the code. These solids are meshed by the code, a process through which the objects are broken into tens of thousands of discrete nodal points. The computer calculates thermal parameters such as temperature and heat flow at each of these nodal points as a function of neighboring nodal points rather than trying to solve analytical equations for the thermal fields. If the meshing is fine enough, the calculated solution will be very accurate. If the meshing is too coarse, errors will creep into the model. There is a trade-off between accuracy and run time in computer simulations; models with coarser meshes usually run much faster than models with fine meshes. It is best for users to become familiar with the mesh sensitivity of their chosen modeling tool to optimize run time versus accuracy before running critical analyses.

When performing a CFD system-level analysis to determine temperatures on a PCB, it is important to include all airflow obstructions that might change the convection on the PCB and its components. Common airflow obstructions include cables, RF shields, daughter cards, brackets, air filters, capacitors, transformers, memory single in-line modules (SIMs), power regulators, and hard drives. Failure to include these air blockages in the modeling process can result in systems that run too hot or that suffer from thermal shutdown. External blockages should be accounted for as well. Cabinet vents should not be located where a user might carelessly toss a magazine or CD cover. The impact of accumulated dust over the lifetime of the system should also be considered, as the dust can substantially reduce convection.

From a PCB layout standpoint, the highest velocity air stream on the board may well occur between two tall components if they block the airflow path. The blockage causes the air to be channeled through the gap, resulting in higher air velocities. High-power electronic components can sometimes be more effectively cooled by placing them in this channeled air stream. Locations to avoid for high-power components are the leeward side of air blockages, immediately downstream of high-power components, or on the bottom center of a natural convection-cooled PCB.

### 17.6.2 Required Component Thermal Parameters

Thermal models of a PCB loaded with detailed models of components in a system can become very complex with many nodes. Such analyses can run for days and weeks, making them impractical. As well, it is often impossible to get detailed models of each component to be used in a system. To address these issues, the industry has developed two levels of component thermal abstraction. The first method reduces the electrical component's thermal behavior to two thermal resistances,  $\theta_{jc}$ , which represents the thermal resistance from the active portion of the component to the top component surface, and  $\theta_{jb}$ , which represents the thermal resistance between the active portion of the component to a point on the PCB at the edge of the component. The component is then represented to the system as shown in Fig. 17.13. The thermal resistance from the top of the component to the ambient,  $R_a$ , is calculated either through CFD or from the convection coefficients. It also includes radiation heat losses. Thermal conduction through the PCB to other components and to the air is calculated by the simulation tool. Accuracy of a two-resistor component thermal model temperature delta with respect to the ambient is in the

**FIGURE 17.13** Thermal conduction representation of an electrical component by two thermal resistances,  $\theta_{jc}$  and  $\theta_{jb}$ . The resistance to ambient ( $R_a$ ) is the result of convective and radiative heat loss.

+/-20 percent range, even when using CFD. The parameters  $\theta_{jc}$  and  $\theta_{jb}$  are usually available in the component supplier's data sheets. If not, the supplier should be contacted for the information.

A more complex modeling configuration has been developed to improve thermal estimations from +/-20 percent to +/-5 percent. Called a *compact model*, these resistor network topologies better represent heat flow within the package and from one side of the package to another. Compact models should therefore be used whenever they are available. Often, the system design engineer must ask the component supplier for them since they are not commonly printed in data sheets. Many tools allow the user to mix compact component models with the simpler two-resistor models.<sup>6</sup>

### 17.6.3 Handling Cu Traces and Power Planes

Due to the complexity of meshing the fine geometries of a PCB trace layout, many if not most modeling tools include the ability to “smear” Cu layers into solid sheets. A smeared layer is a single sheet whose average thermal conductivity is equivalent to the thermal conductivity of the detailed trace layer. Unfortunately, most tools use an incorrect averaging technique to determine the effective thermal conductivity of a layer. The tool asks for the percent Cu coverage in the trace layer. Based on this input, the tool then calculates the thermal conductivity of the trace layer as the weighted average between the Cu conductivity and the insulator conductivity. For example, if a 100 percent coverage of Cu layer has a thermal conductivity of 380 W/m-°C, a 95 percent coverage of Cu would have an effective conductivity of 360 W/m-°C, and a 0 percent Cu coverage layer would have a conductivity of 0.8 W/m-°C. Smearing in this fashion neglects critically important details such as isolation regions that might cut through thermal spreading planes. Therefore, trace smearing using a conductivity averaging scheme should be avoided.

If the modeling tool can't represent the PCB in full complexity, some attempt should be made to perform a better estimation of the thermal conductivity in Cu spreading layers connected to critical components. The overall smeared thermal conductivity of the plate should be replaced with patches of thermal conductivity that account for heat flowing either parallel or perpendicular to the Cu conductors. Eqs. 17.8 and 17.9 can be used to estimate parallel and series thermal conductivities in Cu layers respectively. Figure 17.14 shows graphically what is meant by a parallel thermal conductivity. Here, multiple stripes of thermally conductive materials pass thermal energy from the top to bottom. Each material channel can be considered as a thermal resistor. The thermal resistance of each resistor can be calculated as a function of its

**FIGURE 17.14** A diagram to illustrate how heat flowing along parallel conductors can be represented through electrical analogy to electrical resistors in parallel. The parallel resistance representation is used in the derivation of Eq. 17.8.

cross-sectional area (thickness  $\times$  width) and thermal conductivity, and the effective parallel resistance can be backed out (Eq. 17.8).

$$k_{parallel} = \frac{\sum_i k_i \cdot Area_i}{\sum_i Area_i} \quad (17.8)$$

where  $k_{parallel}$  = the effective thermal conductivity of a plate where the heat flows parallel to the conductors  
 $k_i$  = the thermal conductivity of the  $i$ th material  
 $Area_i$  = the area of the  $i$ th material (thickness of stripe  $\times$  width of strip)

In the case of series thermal resistances, the dimension of interest is the length of each section of material in the direction of the heat flow (see Eq. 17.9 and Fig. 17.14).

$$k_{series} = \frac{\sum_i Length_i}{\sum_i \frac{Length_i}{k_i}} \quad (17.9)$$

where  $k_{series}$  = the effective thermal conductivity of a plate where the heat flows perpendicular to the conductors  
 $k_i$  = the thermal conductivity of the  $i$ th material  
 $Length_i$  = the length of the  $i$ th stripe parallel to the heat flow path

## 18.1 INTRODUCTION TO DATA EXCHANGE

---

This chapter presents the elements of data exchange, the data exchange process, its pitfalls and best practices, the most widely used data exchange formats and their main characteristics, and evolution drivers in data exchange.

The electronics manufacturing marketplace is a dynamic domain where supply chains of trading partners compete in a global economy in which time to market and efficiency are key factors for success. Outsourcing is becoming more common; printed circuit board (PCB) fabrication has been outsourced in the 1980s and early 1990s, whereas assembly is following very quickly. Data communication is a vital key to supply chain management. Efficient and accurate data exchange is an extremely important factor in customer supply networks.

The challenge of more efficient and accurate data exchange has only recently begun to be addressed and the future for data exchange improvements holds much potential.

### 18.1.1 Data Exchange Format Defined

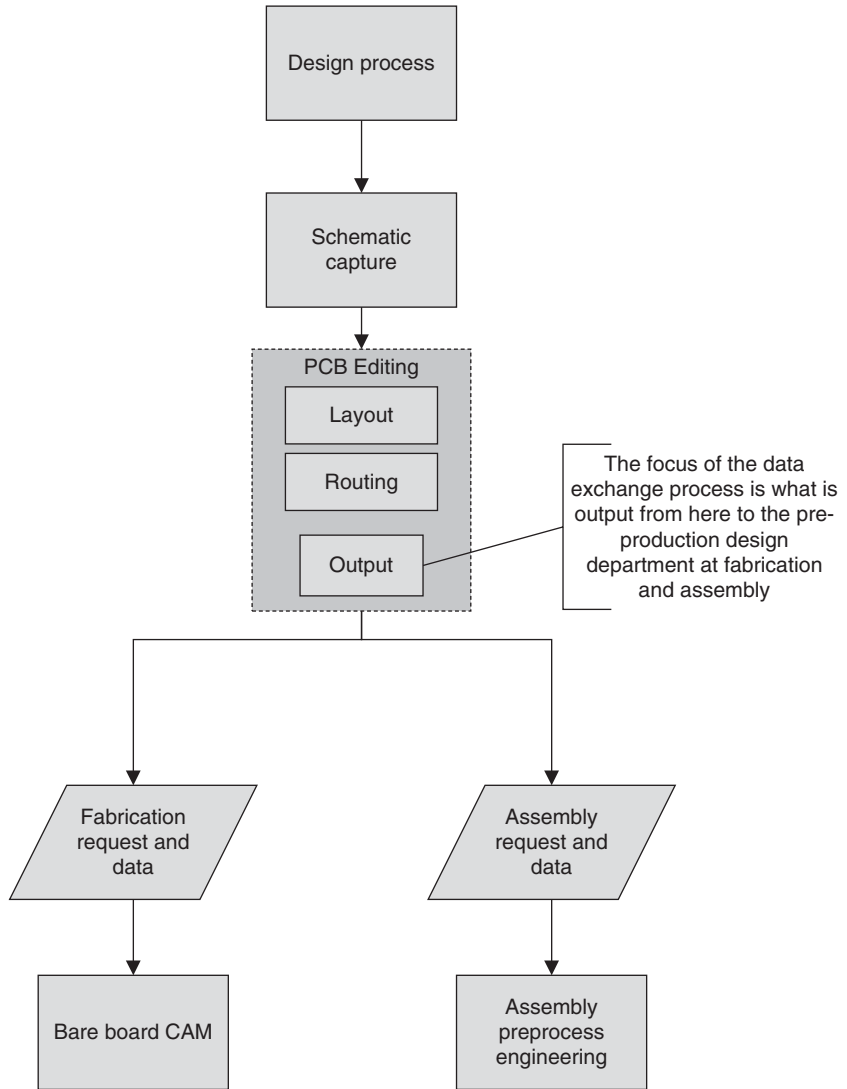

Once the design of a printed wiring board (PWB) is complete, it is necessary to pass the design intent to internal or external suppliers for manufacture and assembly. This is mostly done using electronic data file transfer. A short dictionary entry for a data exchange format would read:

Virtual format that one computer program outputs and another one reads and creates an internal representation thereof that can be manipulated and output. The main criteria for data exchange format quality are its clarity and the accuracy with which it passes the design intent between trading partners.

### 18.1.2 PCB Design Process Overview

PCB design and manufacturing process (see Fig. 18.1) proceeds as follows:

1. In the *schematic stage*, components and their interconnection pattern (netlist) are defined, simulated, and verified for functionality using schematic capture tools such as Mentor's Design Architect and Cadence's Concept. (The schematic interconnection list is usually called *schematic netlist*. It is an electrical network-based grouping of connection points of

**FIGURE 18.1** A flow chart representing the design through manufacturing data exchange process.

the form component ID + pin ID. A physical or PCB-level netlist is the same grouping, whereas the points are described by their physical [geometric] location on the board and the board side[s] from which they can be tested.)

2. The *editing stage* begins with the layout phase. The component shapes (still virtual and within design tools) and the interconnection list are transferred to the target PCB design tool (such as Mentor’s Boardstation or Cadence’s Allegro) and are manually or (semi-) automatically placed on the PCB as determined by the system’s mechanical engineering and manufacturing rules.

3. Still within the PCB editing stage, the layout phase is followed by the routing phase. This routing (manual and automatic) implements the interconnection list in a PCB conductive pattern composed of traces, planes, and vias (vertical conductors).
4. After PCB routing and layout have been completed, the output phase begins, where the design is output from the PCB editing system and sent to bare board manufacturing to produce the actual bare board layers and then laminate, drill, and finish them.
5. When PCB boards are ready, the design data together with the boards are sent to assembly houses, where the components from the bill of materials (BOM) are assembled onto the finished bare board at the locations specified by the design.

### 18.1.3 Board Manufacturing Data

In addition to PCB design data, copious information pertinent to board manufacture is exchanged between partners in the manufacturing and assembly process. Such information can include standard compliance requirements (e.g., UL), statements of workmanship (SOW), and delivery and packaging instructions. Modern data exchange formats address some of these comprehensive data exchange issues. The design-to-manufacturing data exchange process should ideally progress to become online collaboration. The drivers of this progression are globalization, the supply chain, and time-to-market pressure.

Historically, the PCB design-to-manufacturing flow began with manually laid-out artworks whose images were printed on copper-clad laminates and developed, etched, and stripped within the same vertically integrated organization. Advances in miniaturization and multilayer board technology led to the need for specialization, and outsourcing of bare board fabrication became the norm. Together with advances in PCB fabrication tools and digital communication, the outsourcing supplier communication advanced from courier-delivered artwork to data tapes and disks and later to electronic transfer over modems and finally over the Internet. Globalization and outsourcing continue to push the envelope of electronic business communication in the PCB industry as well as everywhere around us.

The PCB fabrication tools driving the history of data exchange are mostly imaging tools and placement machines. PCB lithography began with hand-routed artworks and continued with photo plotters, aperture wheels, and computerized numerical control (CNC). Gerber Scientific was the most successful of the early photo-plotter vendors, and hence the Gerber 274D format caught on.<sup>1</sup> Later these were replaced with laser plotters without aperture wheels, but the Gerber data format remained the “lowest common denominator” format. In the PCB assembly arena, robotic assembly machines of varying complexities succeeded hand assembly. This trend led to the need for electronic assembly data, just as the artwork-to-laser-plotter development in board fabrication led to the need for electronic fabrication data.

Bare board fabrication and board assembly share some common data elements but also have distinct data needs. Examples of common elements are the outer circuit and mask layers and through-drill information. Unique data elements are, for example, inner layers for board fabricators and component placement locations and functional component descriptions for assembly houses. All these data elements are described in the next section.

## 18.2 THE DATA EXCHANGE PROCESS

---

When a printed circuit assembly (PCA) design (layout, routing, and verification) is complete, the board data must be sent to the PCB manufacturer. An output format is chosen to export the data from the computer-aided design (CAD) system. Historically, the output to bare board manufacturing was in Gerber data format and Excellon drill information and was accompanied by some textual “readme” files. (These files did not contain precise definition of layer stack-up, drill span, or component outlines). These files would be sent—or rather, “thrown over the wall” to the fabricator,

sometimes without even being checked. When the board reached the assembly stage, the board assembler would receive Gerber images of the outer layers, x, y locations of the components and a BOM file. These methods were recognized as troublesome because errors and lack of communication necessitated many clarification calls, faxes, and e-mails, and slowed down the process.

### 18.2.1 Assessing Quality of Data Exchange Formats

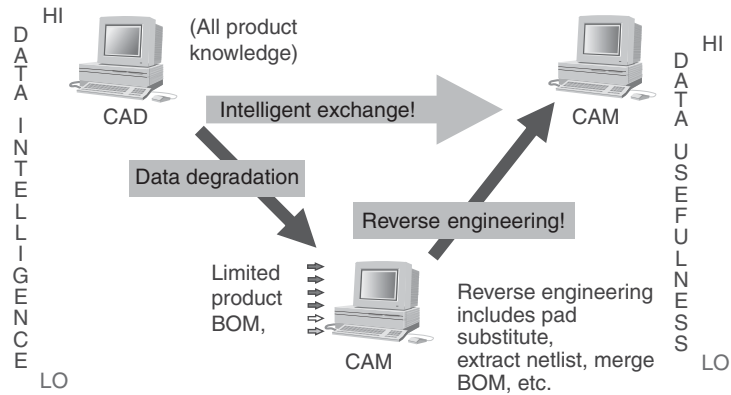

Designers and editors, forced to verify the data after output for correctness and manufacturability, began to work with CAD and computer-aided manufacturing (CAM) tool vendors and industry consortia to develop better formats and methods for data exchange. They sought a data exchange format that was explicit, intelligent, optimized, and bidirectional:

- **Explicit** There should be no need for guesswork or reverse engineering of design and no need for external files (see Fig. 18.2).

**FIGURE 18.2** A CAM system view of a typical six-layer PCA after input from an “intelligent” format that defines the layers’ order and characteristics explicitly and unambiguously. If Gerber files were used it would take some time to arrange the layers’ order and characteristics manually. The example includes the following:

- Silk screen legend files: **sst** (for top) and **ssb** (for bottom)
- Solder paste stencil aperture layers: **spt** and **spb**
- Solder mask images: **smt** and **smb**
- Outer copper layers: **sigt** and **sigb**
- Second layer: **pg2** (power layer, which is negative)
- Fifth layer: **gnd5** (ground layer, which is also negative)
- Inner circuit layers: **sig3** and **sig4**
- Drill layers: **drill** (through drill layer) and **dr3-4** (buried via connecting **sig3** and **sig4**)

**FIGURE 18.3** OEM, CEM, and Fab communication levels. In this figure the y-axis denotes the level of intelligence and the x-axis denotes the data exchange process progression over time. When the formats used carry less design intelligence, it is lost (data degradation). Non-value-added reverse engineering (such as manually rebuilding the board stack-up) is required to rebuild intelligence that is required for manufacturing. If an intelligent exchange format is used, no design data are lost and no reverse engineering is required, resulting in a faster, more accurate, and more efficient process.

- **Intelligent** The format retains CAD information that may help the manufacturer (see Fig. 18.3).
- **Optimized** A surface should be represented by a clear outline and not drawn with overlapping vectors (see Fig. 18.4).
- **Bidirectional** The format should be inherently capable of passing data back and forth, not just passing them one way. This can be achieved through free viewers, annotations tools, and so on.

Other important issues to consider in the context of data exchange are the following:

- **Accountability** Who is responsible if something is misunderstood? If the exchange always succeeds, it is easier to differentiate between design and manufacturing errors.

**FIGURE 18.4** Optimizing surfaces: (a) a polygon filled by different vector widths; (b) the same polygon as drawn by a pen plotter; (c) the polygon as defined by its external outline. Option c is clearly much more efficient and economical. The outline in (c) is the actual outline of the polygon, whereas (a) and (b) represent approximations.

- **Data ownership** Who can authorize changes? If reverse engineering is performed, subtle design changes may be introduced without OEM authorization.
- **Trust** Is the supplier an ally to whom all available data are provided, or are some design details withheld to protect intellectual property rights?

The next section details all the data elements that designers and manufacturers need to pass among each other.

### 18.2.2 Elements of Data Exchange: Intelligent Design Data

The goal of a supply chain is short time to market, high quality, and lowest cost, and achieving this goal requires high clarity, efficient communication, and not just a bare-bones data hand-over.

Although a PCB can be manufactured from supplied artworks and drill tapes alone, it is much more efficient to send accurate and verifiable electronic data. The data can include information elements beyond the graphic image and component location information that form the minimum “pure” design data required for improved manufacturing. Among these elements are:

- Mechanical specifications
- Component geometry
- Component tolerances and vendor information
- Standards that the product has to meet

Some of the information belongs in an SOW and need not be repeated in the case of an established partnership. Included may be marking instructions, packaging instructions, and information needed to ensure conformance to standards.

### 18.2.3 Elements of Data Exchange for Fabrication

This section lists the information required for data exchange for fabrication.

**18.2.3.1 Minimum Requirements.** These are the minimum required elements of data needed for fabrication:

**FIGURE 18.5** A layer graphic representing the features of a circuit (or a document) layer represented by computer-readable geometric entities involving x and y coordinates and geometric objects—lines, arcs, circles, and so on.

- Layer graphics (see Fig. 18.5)
- Drill data: locations, spans (for blind and buried vias), tolerances, and plating thickness
- Board outline and rout information
- Stack-up requirements (layer order)

**18.2.3.2 Important Additional Information.** These elements are important but not absolutely required for fabrication:

- Netlist information is required to verify that the graphic and drill data truly represent the design. It is highly advisable always to include netlist data so that the graphics can be verified.
- Assembly panelization definition is required to deliver multiple PCBs in a ready-to-assemble array form (four or more cell-phone boards can be assembled together due to their small dimensions).

**18.2.3.3 Extra Information.** This extra information is not covered by computerized formats, but is useful in fabrication:

- Electrical (impedance) and material requirements (solder mask, legend, etc.). (Impedance requirements refer not only to line width and tight tolerances thereof but also the actual impedance value, in ohms, and the frequency and impedance model to use.)
- Fabrication drawing (extra instructions, dimensions).
- Type of finish and quality requirements (hot air solder leveling [HASL] versus organic solderability preservative [OSP], solder mask).
- Packaging and delivery instructions.
- Testing coupon requirements.

These additional information elements can be provided as well:

- Design for manufacturing (DFM) analysis results and criteria (for example, spacing criteria and violations thereof)
- Component placement information, which can help the manufacturer create solder mask clearances that provide a good fit for soldering

## 18.2.4 Elements of Data Exchange for Assembly

This section lists the data elements to consider for assembly processes.

**18.2.4.1 Common to Fabrication and Assembly.** These elements are common to fabrication and assembly:

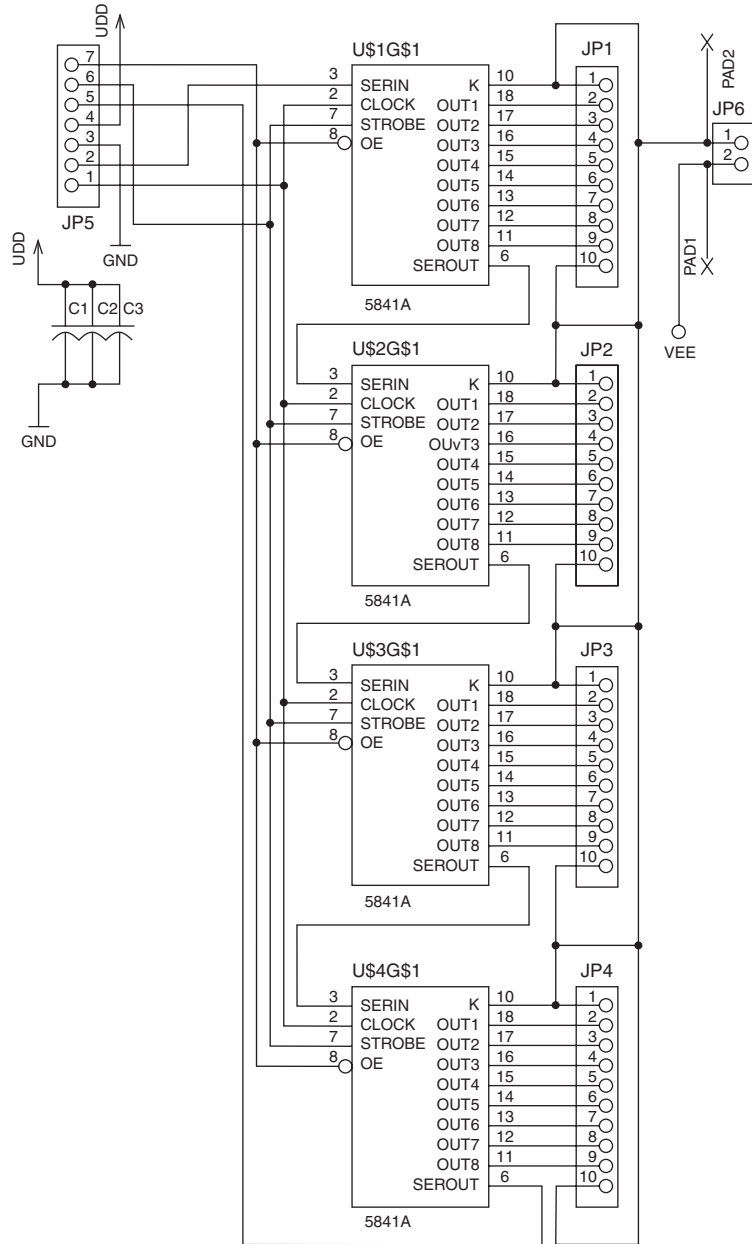

- Outer layer graphics (for circuit, solder mask, and legend images)
- Drill information (especially through drills and mechanical drills)
- Board dimensions and outline

**18.2.4.2 Required for Assembly.** These elements are required specifically for assembly:

- Component placement information, including rotations.
- BOM and approved vendor list (AVL) information (AVL is not required if parts are supplied by consignment).
- Mechanical assemblies and their locations (screws, shields and heat sinks, etc.).
- Board electrical schematics for testing (see Fig. 18.6). This information is usually transferred either as an element of a CAD database or as a human- and machine-readable drawing format (usually as a Hewlett Packard Pen Plotter [HPGL] or Data eXchange Format [DXF] file). (Machine-readable in this context means identification of textual labels for nets (signals) and pin and component names. The computer programs cannot understand the connectivity symbolism of the line drawings within schematic drawings.)

**18.2.4.3 Extra information.** This extra information, not currently covered by electronic formats, must be read and understood:

- Test requirements
- Material instructions
- Delivery and packaging instructions

**FIGURE 18.6** Product schematic drawing (for components, signals, and interconnections) as sent by the product electrical designer to the PCB editor. There are four 18-pin logical components having SERIN (serial in) and eight output (out1-out8) pins each connected to output connectors (JP1-JP4) and to an input connector JP5 and a ground connection with three capacitors.

**18.3 DATA EXCHANGE FORMATS**

This section describes the most widely used data exchange formats in the electronics industry according to a common list of characteristics. Advantages and disadvantages of each format are discussed.

**18.3.1 Format Types and Their Characteristics**

There are several format families differentiated by their origins, properties, and usage. They fall into four categories:

- Historical file collections
- Full-design databases
- Component information (BOM and AVL)
- Formats that support full design to manufacturing

**18.3.1.1 Historical File Collections.** The historical file collection that is used to transfer design data is composed of three file types:

- **Graphic image formats** Gerber 274D and 274X<sup>2</sup> belong to this group (see Section 18.3.2.1). (There are other formats in this group, most of which are used internally within CAM systems and as archive formats within bare-board fabrication facilities. Pentax format, DaiNippon Screen, and MDA Autoplot belong to this group.) Most of these formats originated as a photo-plotter machine language; they describe single, graphic (drill, drawing), two-dimensional layers. They are usually accompanied by drill files indicating drill locations and diameters. The main drawbacks to graphic image formats are that they represent single layers rather than whole PCBs and that they cannot be verified unless accompanied by a netlist file.
- **Netlist** A netlist presents a list of net numbers, and for each net a list of points by their x and y coordinates, and the surface upon which they can be found (see Fig. 18.7). This is the basic information representing PCB connectivity against which PCB graphics can be verified

```

327LDIN_47      IC52  -U5      A01X+110078Y+030997X0200Y      R180
317LDIN_47      VIA   -      MD0100PA00X+110274Y+031194X0230Y      R180
327LDIN_47      IC10  -J2      A01X+134371Y+039414X0200Y
317LDIN_47      VIA   -      MD0100PA00X+134174Y+039217X0230Y

```

(a)

```

IC52 U5
IC10 J2

```

(b)

**FIGURE 18.7** Example of a netlist: (a) this part represents a physical netlist with x and y coordinates (the first line translates as “Pin U5 of component IC52 is connected to net LDIN\_47 and is at location [11.0078, 3.0997]”); (b) this part represents the same netlist but at schematic stage with only component and pin names; the electric signal identified as LDIN\_47 connects IC52 pin V5 to IC10 pin J2 through two vias.

and from which a test program for an electrical test machine can be constructed. One type of netlist identifies the locations of the nets that the PCB is designed to implement. Another type of netlist is a CAD software design package schematic netlist that identifies connectivity between components (by component and pin number as an input/output [I/O] pin identifier), but does not identify their physical location.

- **Component information** In addition to being part of the historical file collection, BOM and AVL files are also part of an independent file class that is required even when the more advanced formats are used (see Section 18.3.5).

**18.3.1.2 Full-Design Database: CAD Formats.** Full-design databases, which are formatted using either the CAD system database format or American Standard Code for Information Interchange (ASCII)\* extracts thereof, represent information for the component and their connectivity through the board as hierarchical arrangements of nets and subnets broken into traces, vias, and planes. They are transferred for board assembly and test but not for board fabrication. Because OEMs consider these formats to present a proprietary information security risk, they often prefer to convey inferior quality information using other formats in order to preserve privacy.

**18.3.1.3 Explicit Design for Manufacturing Formats.** Formats for full design for manufacturing were explicitly built for design-to-manufacturing data exchange and contain nearly all of the required computer-readable data elements in a well-designed, explicit, intelligent layout. Some of these formats originated as DFM/CAM vendor formats whereas others were designed by an industry association committee.

**18.3.1.4 Component Information: BOM and AVL.** A PCA may be designed for more than one product variant and to support future functionality. Therefore, for almost all designs, some of the reference designators (or actual bare board footprints on which components can be placed) will not be populated for all assembled board orders. BOM files are used to tell the assembler which reference designators should actually be placed on a given board for a specific order.

The separation between electrical functionality of components and their actual procurement leads to the need for an AVL file. CAD databases usually contain part numbers that represent functionality and are internal to the design organization rather than part numbers (including the vendor and catalog number) that customers can order. Component engineers are charged with finding true part numbers to implement the internal ones, and this information is usually organized in spreadsheets or text files called AVLS or approved component lists (ACLs).

## 18.3.2 Historical File Formats Descriptions

Each format description that follows includes its domain (the elements that are covered), its history and expected future path, distinctive characteristics, and a short example. Format description references can be found at the end of the chapter.

**18.3.2.1 Gerber (274D and 274X), Drill and “Readme.”** Gerber formats are the “lowest common denominator” for passing bare-board fabrication information. They are composed of one file per graphic layer, one file for each drill layer, text files that list the PCB stack-up, and optional drawing files that list critical dimensions and requirements. Inclusion of a netlist file with each Gerber transfer is imperative to ensure correct board fabrication.

---

\* See <http://www.lookupables.com/>.

**FIGURE 18.8** A photo plotter uses a stationary light source to deliver light through a rotating variable size aperture wheel (which determines the size of the light spot on the table) onto a table that can move in the x and y directions. A shutter shuts or allows light passage as required. Precision optics control the focus of the light spot.

A common problem with both Gerber 274D and drill formats (usually Excellon I and II) is the lack of definition of both units and scale factor of numbers (Excellon is a precision drill machines manufacturer). Each coordinate is given as a collection of digits, and the translator, or user, must define the units (in in. or mm) and the location of the decimal points in the format. Another problem stems from the use of arbitrary numbers (“Dcodes” for aperture numbers on an aperture wheel) to describe the width of lines and size of pads. Accurate translation of these files depends on the correct definition of an aperture wheel, which is described separately. Figure 18.8 shows a photo-plotter schematic that explains the source of the terminology.

The commands that drive this mechanism are x and y coordinate movement commands to position the table, those that turn the shutter on and off, and Dcode commands that rotate the aperture wheel to the required position.

Gerber 274X was designed in the early 1990s (by a team of two engineers—one from Gerber Scientific and another from what used to be the biggest PCB factory in the United States, the AT&T plant in Richmond, Virginia) to overcome some Gerber 274D problems. Gerber 274X permeated slowly at first, but its adoption accelerated and Gerber 274D is now used less frequently.

Both 274D and 274X are used to transfer graphic images of circuit and mask layers and images of documentation layers used for instructions. Other graphic drawing formats are occasionally used to transfer board and drawing data. The most common formats are HPGL (the format of HP pen plotters) and DXF (the AutoCAD exchange format).

Several drill formats originating from drill machine makers other than Excellon (Sieb and Mayer, Posalux, etc.) are sometimes used to transfer drill data or to archive old drill data. They suffer from the same problems of Dcode (explained in Fig. 18.9) and unit definition.

**18.3.2.1.1 Gerber 274D.** Gerber RS-274-D has been the most common format for describing PCB plot data. This format was originally intended to drive vector photo plotters (see Fig. 18.8), produced by Gerber Systems Corporation (see Fig. 18.9 for an annotated snapshot section of a Gerber file).

*Example*

<b>G90*</b>	G90 indicates absolute coordinates. This means that each set of coordinates is referenced to the table's origin (0,0). The converse to absolute is incremental; each coordinate is measured relative the previous coordinate value and is set by issuing the G91 command.
<b>G70*</b>	G70 indicates inch units.
<b>G54D10*</b>	G54, tool select (line 3), is the most commonly encountered Gcode and instructs the plotter to rotate the aperture wheel to the position described by Dxx immediately following the G54 command. If this code is omitted, the the photo plotter then identifies the next Dxx command as telling it to select a tool.
<b>G01X0Y0D02*</b>	Dcodes are instructions to the photo plotter that, naturally, include the letter <i>D</i> . The first three Dcodes control the movement of the x,y table. D02 (D2) tells the plotter to move to the x,y location specified with the shutter closed.
<b>X450Y330D01*</b>	D01 (D1): This command tells the plotter to move with the shutter open to the x,y location specified.
<b>.X455Y300D03*</b>	D03 (D3): This command tells the plotter to move with the shutter closed to the x,y location specified, then open and close the shutter—known as flashing the exposure.
<b>G54D11*</b>	
<b>Y250D03*</b>	
<b>Y200D03*</b>	
<b>Y150D03*</b>	
<b>X0Y0D02*</b>	
<b>M02*</b>	The <i>M</i> in Mcommands stands for miscellaneous; in this case, M02 means stop or end of file.

**FIGURE 18.9** An annotated section of a Gerber file.

The basic commands of this format include:

- Selecting the aperture
- Opening and closing the aperture shutter
- Moving the head to a given x, y coordinate

Typically, commands are separated by the asterisk character (\*).<sup>3</sup>

*18.3.2.1.2 Gerber 274X.* Gerber RS-274-X is a common format in use today for describing PCB plot data. The format can be divided into two parts:

- The Gerber part
- The extended part, which includes commands for the following:
  - Standard aperture definition
  - Aperture Macro definition (special symbols)
  - Layer polarity selection

Typically, extended commands begin with % and end with \*%.

Unlike Gerber 274D format, Gerber 274X includes definition of coordinates using the FS command (see Fig. 18.10). Reading software uses this information when reading Gerber parts.

The most serious limitation of Gerber 274X is polygon representation. No solution was provided for describing internal cutouts or clearances. Each implementation of Gerber 274X-based CAD output deals with these in its own way. The most problematic way is to use self-intersecting polygons (SIPs) where the “pen” does not leave the board while drawing the internal cutouts, but “swerves” to the inside of the external outline to draw the internal cutout and then returns (see Fig. 18.11).

*Example*

```
%FSLAX23Y23*%
%MOIN*%
%SFA1.000B1.000*%

%ADD13C,0.00800*%
%ADD14C,0.01000*%
%ADD70C,0.02000*%
%ADD71C,0.02500*%
G54D11*
%LPD*%
G11*G70*G01*D02*G54D10*X-0020000Y-0250000D02*X-0020000Y-0265200D01*
X0010000Y-0255000D02*X0010000Y-0250000D01*X0025200Y-0344800D02*
X0025200Y-0285000D01*X0022800Y-0265200D02*X0022800Y-0270000D01*
```

This command indicates (L)leading zero suppression,(A)bsolute, 2,3, or xx.xxx and yy.yyy decimal point location

This command specifies inches

These are aperture definition commands defining various diameter circles (5, 8, 10, 20, and 25 mil, respectively)

Here the Gerber part begins.

This command indicates that digitized data is dark. However, when the entire film is reversed, the digitized data will be clear.

This is straight Gerber code with multiple commands on a line.

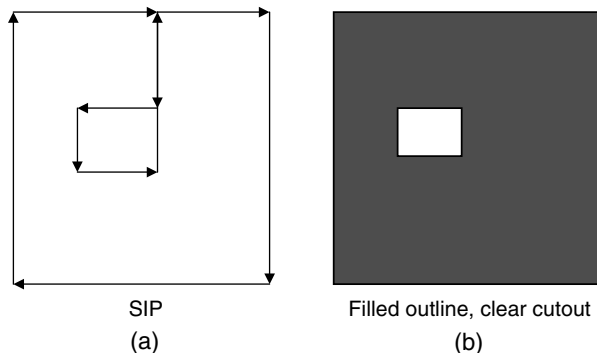

**FIGURE 18.10** An annotated Gerber 274X section.

An SIP is a polygon with two nonconsecutive edges (segments or curves) touching each other. SIPs are illegal in CAM systems that define legal polygons as those whose edges intersect only at endpoints of consecutive edges.

Translation of 274X data into a CAM system might fail with a “Self Intersecting Polygon” error because some CAD systems create surfaces using self-intersecting polygons.

SIPs are not mathematically robust, and the following SIP operations are problematic:

- Resizing (enlarge, shrink, scale—especially with differing x and y values)
- Accurate copper calculations (these require unambiguous definition of the copper location)

**FIGURE 18.11** SIP and non-SIP ways of drawing the same polygon: (a) An SIP: as drawn by self-intersection, with a single path and the pen not removed from the paper; (b) not an SIP with a filled rectangle as an outline and a clear rectangle as the cutout.

**FIGURE 18.12** This surface is composed of one rectangular island, with a circular cutout in the top-right corner representing copper and eight round holes representing clearances.

In most CAM systems, a surface is a mathematical entity that describes planes. It can contain islands (positive polygons) and holes (negative polygons). If the layer is positive, islands represent copper, whereas holes represent non-copper (see Fig. 18.12). Copper planes usually implement power or ground connections, where the clearances provide spacing for data signal vias that pass through the plane but must be electrically disconnected from it.

There are two non-ambiguous ways of drawing planes with cutouts in 274X. The first is to use positive polarity for the islands and negative polarity for the holes. The second is to decompose the plane into positive surfaces that, when combined, yield the outline with the holes.

**18.3.2.2 Netlist Formats.** A netlist is a set of connection points joined together to form networks. Each point represents a contact point on the surface of a bare board. A connection point can be either a drilled hole or a surface mount pad. All points belonging to one network should be connected to each other through PCB layer circuitry and/or power and ground planes.

**18.3.2.2.1 IPC-D-356.\*** IPC-D-356 is an ANSI-accepted standard that has become the most widely used standard for transferring netlist information. The IPC-D-356 format is used to transfer netlist information within the PCB design and fabrication community. This information can be used to verify the integrity of the design by netlist extraction from the Gerber graphics and comparison with the IPC-D-356 CAD reference. The information is also used within both the bare board and the assembled board test domains.

Most data in the IPC-D-356 file (see Fig. 18.13) consist of electrical test records of two types:

- Drill records (starting with “317”)
- Surface mount pad records (starting with “327”)

There are also other general parameter records.

\*References ANSI/IPC-D-356 published by the Institute for Interconnecting and Packaging Electronic Circuits (IPC).

**FIGURE 18.13** A section of an IPC-D-356 file. It contains two drill records (“317”) and six surface mount records (“327”). The four bottom solder mask (SMT) points should not be connected, hence their “net name” fields contain “N/C,” indicating “Not connected.”

Each IPC-D-356 record consists of one line and (for historic reasons) is of a fixed length with a maximum of 80 characters.

The information extracted from translation of IPC-D-356 files to an internal netlist might include solder mask coverage and midpoint flags, along with the dimensions and location of connection points and their groupings into networks. Information in component and pin identification fields is not necessarily extracted for comparison purposes.

There are two amendments to IPC-D-356: IPC-D-356A and IPC-D-356B. Most of the extra information included in these formats is important for bare-board electrical testing and, unless buried passives are used, the information is generally not needed for CAD-to-CAM data consistency verification. If buried passives are used, it is better to transfer IPC-D-356A after verifying readability by the supplier.

*18.3.2.2.2 Mentor Graphics Neutral File.* Several nonstandard netlist formats can be output by various CAD software suites. All such formats contain connection point records and their grouping into nets. American designers and fabricators occasionally used a stripped-down version of the Mentor CAD format Neutral File to transfer netlist information, and thus it is described here.

The Mentor Graphics Board Station Fablink application produced the Mentor Graphics Neutral File format. It has several sections, each describing one aspect of a board (components, netlist, holes, etc.).

A full neutral file contains these information sections:

- BOARD: board attributes
- NET: net points
- GEOM: packages and pins
- COMP: components and “toeprints”—another name for a pad pattern outline
- HOLE: drilled holes
- PAD: approximate shape of pads

The BOARD and NET sections contain sufficient information to derive a netlist. If the file includes all sections, it is possible to derive components and drills but not full routing (trace) information.

The Fablink user can control which sections are included in the file (see Fig. 18.14).

**18.3.2.3 Component Placement List.** Component placement lists (CPL) are ASCII or spreadsheet files used to transfer component x, y locations if CAD data files are not sent. CPL files are usually minimally formatted into columns. Required columns are the reference designator, x, y locations, and component rotation. In Fig. 18.15, the example CPL file also includes CAD package information.

FIGURE 18.15 An example of a typical simple text tabulated CPL file. The first line translates as “Place resistor R101 at x= 5.065 y=0.88 at 90°. Use part number 10467C. For information, see CAD package R0805. The mounting process is SMT.” This example is just a text file listing.

### 18.3.3 CAD Formats

The leading CAD system vendors have created several formats. When there is a high level of cooperation between customer and supplier, the design customer can send the whole design database from the CAD system on which it was created (and achieve the goal of intelligent exchange as depicted in Fig. 18.3). CAD formats are excellent for testing assembled boards because they include the schematic information. In addition, they include component locations and packages, as well as enough data to derive the graphics of any board layer. They must be accompanied by BOM information and also AVL information (unless parts are consigned) to define which components to place for each board variant and which components to procure.

CAD formats are less suitable for board fabrication, because they lack a flattened WYSIWYG (“what you see is what you get”) representation of the circuit layers. Examples of CAD formats include Mentor’s Board Station Neutral and Geoms files, as well as Cadence or ORCAD layout files.

When CAD formats are used for data exchange, their format is, by definition, the format of the specific CAD system that was used for layout and routing. The designer must therefore verify that the supplier can read it or use some translation tool to convert the data to a format readable by the supplier, risking conversion errors.

### 18.3.4 Modern Data Exchange Formats

ODB++ and IPC-2581 are examples of formats that were explicitly designed for the purpose of CAD to CAM data exchange. ODB++ is the internal format for Valor’s\* tools and was developed early as an exchange format. IPC-2581 is a vendor-independent format developed as a joint effort by Valor and an IPC-sponsored committee to correct the historical problems associated with data exchange.

ODB++ and IPC-2581 are the only formats that can include all the data needed for manufacturing, including BOM and AVL information. They come closest to the idea of intelligent exchange depicted in Fig 18.3.

**18.3.4.1 ODB++.** The ODB++ data format is a common language used for DFM and CAD/CAM data exchange. It overcomes many data communication obstacles within design/manufacturing supply chains. Data in this powerful open database impart an integrated and accurate physical model of all bare-board, component, and test-related information. It is designed as a simple yet comprehensive description of all entities used in the manufacture and assembly of a PCB.

The Valor Universal Viewer (VUV) is free software that enables ODB++ design data to be viewed graphically on Windows, Sun, or HP-UX workstations.\*\*

ODB++ uses a standard file system structure.<sup>6</sup> ODB++ denotes a job using a simple directory tree that can be transferred between systems with no loss of data (see Fig. 18.16).

The advantages of a directory tree compared to one large file are apparent when a job is being read or saved. The flexible tree structure allows only selected parts of the job to be read or saved, avoiding the overhead of reading and writing a large file.

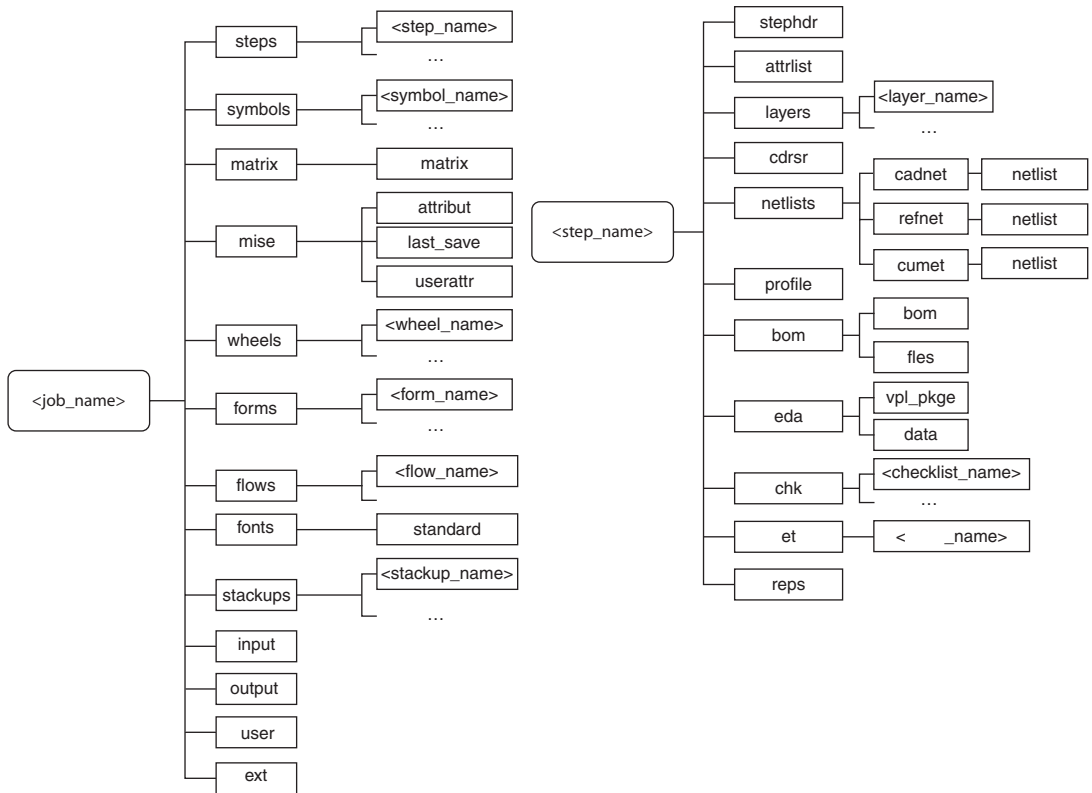

When a job must be transferred, standard compression utilities can be used to convert a directory tree into a single file.

ODB++ is widely used in the PCB industry and many vendor tools support it, including some CAD systems that offer output to ODB++ format. Description of all ODB++ format elements is beyond the scope of this chapter, but a small excerpt from a layer features file, shown in Fig. 18.17) can exemplify its explicitness and its clarity.

\* Valor Computerized Systems is a leading provider of CAD, CAM, and DFM tools for the electronics industry. See [www.valor.com](http://www.valor.com).

\*\* To obtain a free download of VUV, go to <http://www.valor.com/>, then select solutions \_> Valor Universal Viewer \_> Download and follow the simple registration procedure.

**FIGURE 18.16** ODB++ job tree—The left hand side of the figure describes the top-most elements under the Job level and the right hand side describes the top-most elements under the Step level.

**18.3.4.2 IPC-2581.** IPC-2581, on the part of the IPC and the electronics industry, is a universal vendor-independent data exchange format.\* IPC-D-350 was the first such format in the 1970s, followed by IPC-2511 GenCAM in the 1990s; in the new millennium, IPC-2581 evolved.

IPC-2581 (nicknamed “Offspring”) is based on ODB++ and is the culmination of the ODB++ and GenCAM convergence project sponsored by the National Electronics Manufacturing Initiative (NEMI). IPC-2581 has inherited some of IPC-2511 GenCAM characteristics.

IPC-2581 is actually a series of IPC-258x documents, where x represents 1–9; IPC-2581 consists of the generic requirements (or, in this case, the full format description), whereas IPC-2582 and above are sectional requirements. IPC-2584, for example, contains the sectional requirements for fabrication and explains which generic IPC-2581 elements are required for bare-board fabrication and which elements are optional.

```

**FIGURE 18.17** An ODB++ feature file with annotations. “P 5.3145669 3.215 0 P 0 0” indicates a pad at (5.314., 3.215) with a 3.937 mil diameter. (The first 0 points to symbol 0, clearly represented by “\$0 r3.937” in the symbols section. “P 0 0” indicates that the pad has “P” (positive polarity), is not rotated 0°, and has zero attribute values.

IPC-2581 is an all-inclusive, explicit, accurate, and intelligent format containing all data needed for both manufacturing and assembly. The following data elements can be described in a full-mode IPC-2581 file:

- Original schematic capture files
- Original layer/stack instance files
- Original conductor routing files

- BOM and AVL
- Component packages and logical Nets
- Outerlayer copper lands
- Solder mask, solder paste, and legend layers
- Drilling and routing layers
- Documentation layers
- Physical Nets
- Outer copper layers (non-lands)
- Innerlayers
- Nondocument miscellaneous layers
- Instructions and specifications
- Component tuning and programming instructions, program files, and/or references thereof

This format contains information not available in the earlier formats (including details about personnel and the enterprise, material requirements, and component tuning and programming). Most industry tools lack these items in their internal formats, so at this point these sections are usable primarily in human-readable form.

Future evolution and market acceptance of IPC-2581 depend on committee work and vendor implementation and could well take several more years.

### 18.3.5 Component Information

BOM and AVL files do not usually follow any global standard, but rather conform to the internal standards of each organization. Their format may be simple ASCII or a spreadsheet (see Fig. 18.18). Interpretation of BOM and AVL files requires either manual or semi-automatic parsing followed by conversion into a known supported format. This process might entail creation of templates that recognize various types of BOM and AVL files and translate them semi-automatically.

BOM and AVL files are sometimes combined in a single BOM/AVL file that lists reference designators to be placed and part-ordering information.

Figure 18.19 is a typical AVL file sample as seen in already-tabulated format.

The line numbers are not part of the file. Lines 1 through 5 are header lines and lines 6 through 15 are data lines. There are two types of data lines; line 1 contains column headers for the first line type, and line 3 contains column headers for the second line type. Lines 6 and 12 are lines of the first type, representing functional devices (usually referred to as customer part

## 18.4 DRIVERS FOR EVOLUTION

Data exchange for PCB manufacturing must evolve in two directions:

- Technology-based evolution
- Improved means of communication in a high pace, competitive global economy

With the rapid advance of technology in the PCB industry, data exchange formats must adapt to include new information. For example, none of the CAD formats mentioned here and neither ODB++\* nor IPC-2581 support buried resistors and capacitors “out of the box,” and therefore buried passive technology development is hindered by data communication errors and costs.

Other technological challenges that need to be addressed are better integrated BOM, AVL, and CAD data packaging coming out of design houses, and tool support for specifications, standards, revision information, and ECO data in an online framework.

With increasing trends toward globalization and supply chains, communication should be more than mere data exchange. The technology exists but is not yet utilized to its fullest extent. Online collaboration tools should replace file transfer. Means of maintaining issue lists and following up on their resolution would ensure that manufacturing requirements are met without compromising design integrity. Means of incrementally issuing design revisions without complete manufacturing reengineering would speed up prototype evolution.

\* ODB++ version 7 to be released in 2007 supports buried passive resistors and capacitors.

## 18.5 ACKNOWLEDGMENT

---

The author thanks Susan Kayesar for her contribution to this chapter.

# CHAPTER 19

---

# PLANNING FOR DESIGN, FABRICATION, AND ASSEMBLY

---

**Happy T. Holden**

*Mentor Graphics, Longmont, Colorado*

---

## 19.1 INTRODUCTION

---

Advances in interconnection technologies have occurred in response to the evolution of component packages, electronic technology, and increasingly complex functions. Therefore, it comes as no surprise that various forms of printed wiring remain the most popular and cost-effective method of interconnections.

Manufacturing, assembly, and test technologies have responded by improvements in their technologies. These increased capabilities have made selection of technologies, design rules, and features so complex that a new function has developed to allow for the prediction and selection of design parameters and performance versus manufacturing costs. This is the planning for design, fabrication, and assembly. This activity has also been called *design for manufacturing and assembly* or sometimes *predictive engineering*. It is essentially the selection of design features and options that promote cost-competitive manufacturing, assembly, and test practices. Later in this chapter, we will offer a process to define producibility unique to each design or manufacturing process. Section 19.3.4 describes a process to define producibility unique to each design.

The purpose of this chapter is to provide information, concepts, and processes that lead to a thoughtfully and competitively designed printed circuit, ensuring that all pertinent design and layout variables have been considered.

### 19.1.1 Design Planning and Predicting Cost

Reducing costs to remain competitive is a principle responsibility of product planning. On the average, 75 percent of the recurring manufacturing costs are determined by the design drawing and specifications.<sup>1</sup> This was one of the conclusions found by an extensive study that General Electric conducted on how competitive products were developed. Manufacturing typically determines production setup, material management, and process management costs (see Fig. 19.1), which are a minor part of the overall product cost.

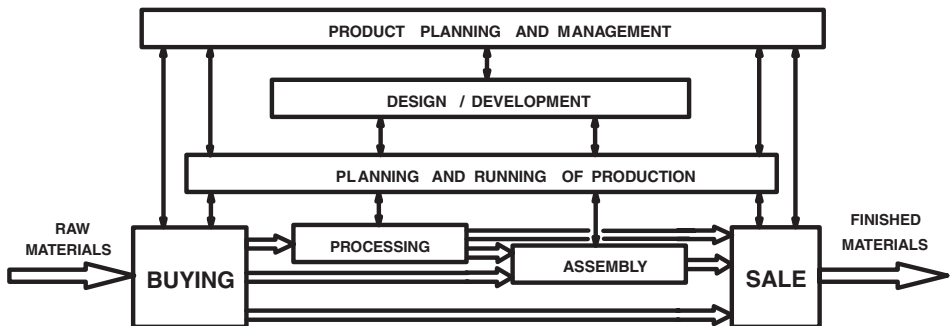

**FIGURE 19.1** Design determines the majority of the cost of a product.

Time to market along with competitive prices can determine a product’s ultimate success. Having the first of a new electronic product on the market has many advantages. By planning the printed wiring board (PWB) layout and taking into consideration aspects and costs of PWB fabrication and assembly, the entire process of design and prototyping can be done with minimum redesign (or respins).

**19.1.2 Design Planning and Manufacturing Planning**

Electronics is one of the biggest enterprises globally. It is common for design to be done in one hemisphere and manufacturing in another. It is also common for manufacturing to be done in a number of different places simultaneously. An integrated approach must be adopted when the intention is to rationalize fabrication and assembly as part of the entire production system and not as individual entities, as shown in Fig. 19.2. This dispersed manufacturing must be taken into consideration during the design planning and layout process. No finished product is ever better than the original design or the materials from which it is made.

**FIGURE 19.2** Fabrication and assembly rationalized by planning and design.

## 19.2 GENERAL CONSIDERATIONS

The planning process central focus will be the trade-offs between the loss and gain in performance for layout, fabrication, assembly, and test versus the costs in these domains. Therefore, some major considerations will be discussed in the following sections:

- New product design process (Secs. 19.3.1 and 19.3.2)
- The role of metrics (Secs. 19.3.3 and 19.3.4)
- Layout trade-off planning (Sec. 19.4)
- PWB fabrication trade-off planning (Sec. 19.5)
- Assembly trade-off planning (Sec. 19.6)
- Tools for manufacturing audits (Sec. 19.7)

### 19.2.1 Planning Concepts

Planning for design, fabrication, and assembly (PDFA) is a methodology that addresses all the factors that can impact production and customer satisfaction. Early in the design process, the central idea of PDFA is to make design decisions to optimize particular domains, such as producibility, assemblability, and testability, as well as to fit into a product family, such as custom automated manufacturing. Planning takes place continuously in the electronic design environment (see Fig. 19.3). The data and specifications flow in one direction, from product concept to

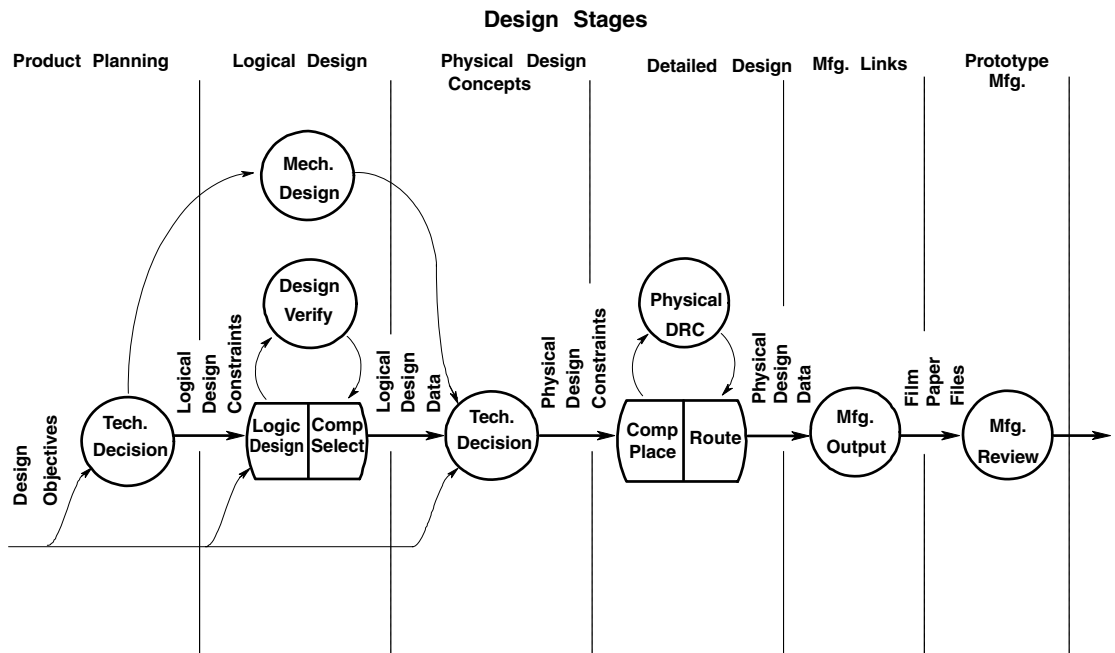

FIGURE 19.3 Electronic design environment.

FIGURE 19.4 Design cost accumulation versus intrinsic manufacturing costs.

manufacturing. During the design process, 60 percent of the manufacturing costs are determined in the first stages of design when only 35 percent of the design engineering costs have been expended. The typical response is shown in Fig. 19.4.<sup>1</sup>

### 19.2.2 Producibility

Producibility is now regarded as an intrinsic characteristic of a modern design. Like the concept of quality in manufacturing, such a characteristic must be built in, not inspected in. Producibility must be designed in; it cannot be a “checkpoint” in the design process or inspected in by tooling.

## 19.3 NEW PRODUCT DESIGN

The keys to superior producibility in new product design can be found in the expanded design process. One of those keys is the role of metrics or data-based analysis of planning trade-offs.

### 19.3.1 Expanded Design Process

The new expanded design process that incorporates planning, trade-offs, and manufacturing audits is shown in Table 19.1. The process is made up of 12 separate functions that incorporate the planning and trade-offs sections in this book:

**TABLE 19.1** The Expanded Electronics Design Process

Function	Purpose
Specification	User-supplied constraints and ideas formulate executable specifications.
Capture of system description	Technology trade-off analysis: balance of loss and gain in various domains' performance versus cost.
Synthesis	Generation of a netlist from the executable specifications.
Trade-off	Selection of layout, fabrication, and assembly features versus cost.
Physical CAD	Conversion of netlists to system and module layouts.
Simulation	Detailed analysis of design structures to support all other design (CAD) activities.
Design advisor	Continuous display of design rated by performance rules.
Manufacturability audit	Check of design to manufacturing design rules and capabilities.
Tooling	Conversion of module layouts to panel layout.
MFG	Conversion of module layouts to physical products (fabrication or assembly).
PDM database	Enterprise wide database containing all product information (product data management, or PDM) including design files, libraries, manufacturing information and revisions, etc.
Internet	Multi-team designs via access over the internet

This differs from the more conventional design process (as seen in Fig. 19.3) by the inclusion of four important functions:

- The formal technology trade-off analysis during the specification phase
- Detailed trade-off selection of features for layout, fabrication, and assembly
- Design advice during component placement and routing
- Manufacturing audits to review the finished layout for producibility, time to market, and competitiveness

### 19.3.2 Product Definition

The initial new product design stage is specification and product definition. This key step takes ideas, user requirements, opportunities, and technologies and formulates the executable specifications of a new product. During this operation, the ability of technologists who may lack any manufacturing experience to predict what will happen in manufacturing can affect both time to market and ultimate product costs. Figure 19.5 shows the technology trade-off analysis that requires the balance of loss and gain in various domains performance versus costs. Size and partitioning for integrated circuits (IC) and application-specific integrated circuit (ASIC) must be balanced with overall packaging costs and the resultant electrical performance. All of these factors affect the manufacturing and product cost.

Another definition of this process could be called a “verified design.”<sup>2</sup> A verified design is one that was predicted from models or measures that have been correlated to past designs. This is in contrast to the traditional approach, which is a “nonverified design,” or trial and error.” This is diagrammed in Fig. 19.6. The advantage of the verified design can be a significant reduction in redesigns to achieve the original product objectives.

### Specification: Capture of System Description

**Technology Tradeoff Analysis: Balance of loss and gain in various domains' performance versus cost.**

**FIGURE 19.5** Specifications determine product partitioning and producibility.

**FIGURE 19.6** A design incorporating trade-offs versus traditional design.

### 19.3.3 Metrics for Predicting and Planning Producibility

Metrics are data and statistically backed measures, such as wiring demand (Wd) (see Section 19.4.1). These measures can be density, connectivity, or, in this context, producibility. These measures are the basis for predicting and planning. When such measures are used in the design process, two categories are applied to a product. Only the metrics can be shared by all in the design team. The non-metrics provide little assistance in design.

#### Metrics

- **Metrics** Both the product and the process are measured by physical data using statistical process control (SPC) and total quality management (TQM) techniques (predictive engineering process).
- **Figure of merit** Both the product and the process are scored by linear equations developed by consensus expert opinion (expert opinion process).

**PDFA metrics are a means to an end:**

- The means: To discuss alternatives, changes, and improvements
- To reach the end: A quality, cost-competitive product

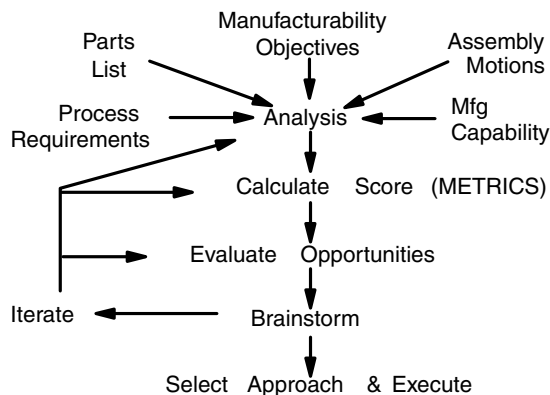

**FIGURE 19.7** The benefits of metrics as a common design language.

**Non-metrics**

- **Opinion** Opinion, albeit from an expert, is applied after or concurrent with design (manufacturing engineering inspection process).
- **No opinions** No attempt to inspect or improve the design is done during the specification, partitioning, or design stage (over the wall process).

Metrics also establish a common language that links manufacturing to design. The producibility scores form a nonopinionated basis allowing a team approach that results in a quality, cost-competitive product (Fig. 19.7).

The strategy in applying these measures is shown in Fig. 19.8. The analysis process is unique to every individual and company, but certain conditions have to be met and considered if the product is going to be successful. If the score meets producibility requirements,

**FIGURE 19.8** A process using measures and metrics to obtain a producible product.

then select this approach; if not, then evaluate other opportunities and repeat the process. In the rest of this chapter, measures and metrics are introduced that provide insight for layout, fabrication, and assembly planning.

#### 19.3.4 Non-Metrics

It is always preferable to have metrics when discussing producibility. But if metrics are not available, then the opinions of experts are better than no opinions at all. The problem with opinions is that they are difficult to defend and explain, and when used in relation to producibility, many times they vary with each person. Sometimes, the opinion process is implemented with good intentions, by having experienced production experts review a new design. This is the *expert opinion process* and although it is sometimes successful, it is difficult to replicate and often results in building barriers between manufacturing and design. That is why the figure of merit process is so popular. For a small amount of work by experts, it produces a scoring procedure that can be used and understood by all.

#### 19.3.5 Figure of Merit (FOM) Metric

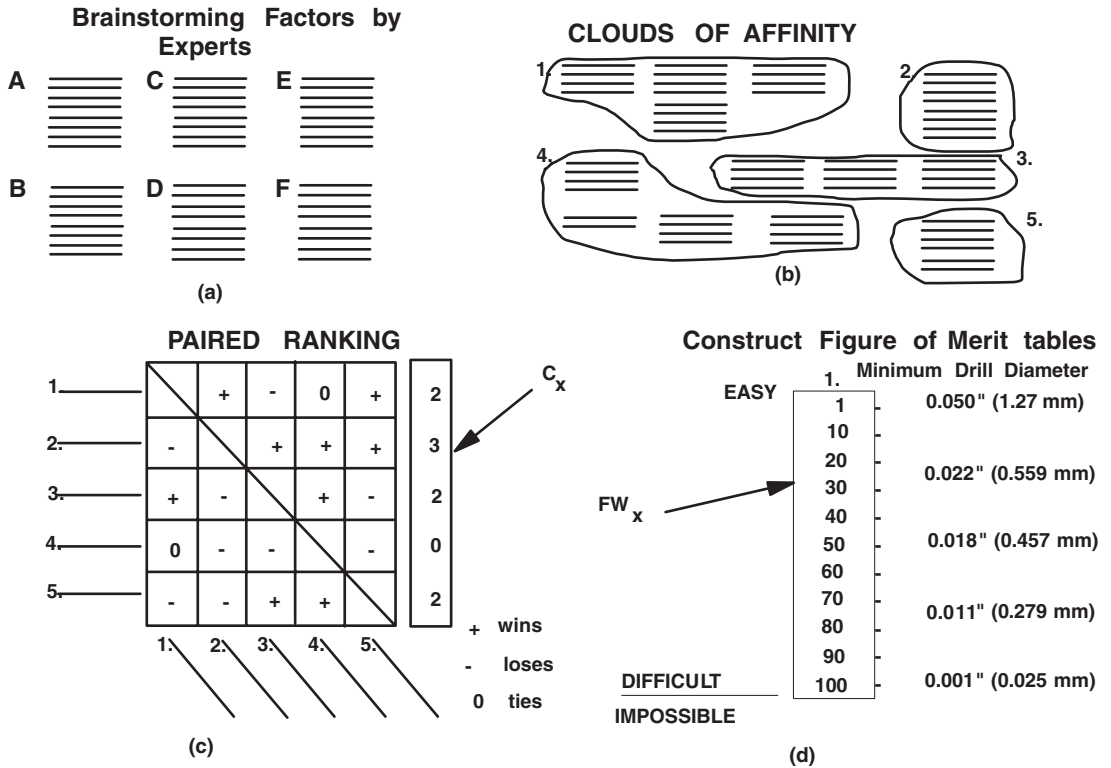

Metrics are the preferred measures for design planning, but their availability for predicting producibility is often limited. Metrics also can take many months to develop and the amount of experimentation may make them costly. The measure that is much more cost-effective and quicker to develop is the figure of merit. The FOM is the result of one or two days of work by a group of design and manufacturing experts. The process consists of eight steps:

1. Define or identify the new measure to be developed.
2. Determine why the measure was selected. Ensure the relevance of the measure to communication.
3. Survey the customers. Identify what the measure is that customers need to have communicated.
4. Identify needs and expectations and collect data.
5. Brainstorm contributing factors and variables.
6. Determine the major contributors and normalize scores. Use multivote, paired-ranking, ranking voting, or Pareto techniques to verify data if available. These are the coefficients ( $C_x$ ) of the equation.
7. Construct FOM factor weightings ( $FW_x$ ). Fill in FOM table values for 1, 25, 50, 75, and 100.
8. Construct a linear equation model (coefficient score  $\times$  FOM weightings).

#### 19.3.6 Figure of Merit Linear Equation

This FOM procedure uses classical TQM techniques to brainstorm, rank, and formulate an equation that will score producibility, assemblability, or any other measure that can be used in design planning. The two factors used in the producibility score are made up of the (1) the coefficient,  $C_x$ , and (2) the factor weighting,  $FW_x$ .

**19.3.6.1 Coefficient,  $C_x$ .** The coefficients in the producibility score are the result of brainstorming all the possible contributors to producibility that can affect the product (Fig. 19.9a). These are grouped into common ideas or factors by such techniques as clouds of affinity or Kay-Jay (Fig. 19.9b). These factors are ranked by voting or other Pareto techniques such as

**FIGURE 19.9** Elements of the figure of merit process: (a) brainstorming factors; (b) grouping similar ideas; (c) ranking factors; and (d) assigning values to factors.

paired ranking, as seen in Fig 19.9c. Whatever the method of voting, the values are normalized by dividing by the smallest nonzero value. The resulting voting scores form the coefficients,  $C_x$ . Those factors with no votes are zeros and drop out of consideration.

**19.3.6.2 Factor Weightings,  $FW_x$ .** Each factor that emerges from the ranking process is calibrated by assigning values from one (1) to one hundred (100), as seen in Fig. 19.9d. The 1 factors are easy to manufacture, and the 100 factors are impossible today but may only be very difficult in a few years.

The resulting scoring equation will look like and be used as shown in Eq. 19.1.

$$SCORE = (C_1) (FW_1) + (C_2) (FW_2) + (C_3) (FW_3) + (C_n) (FW_n) + \dots \quad (19.1)$$

where  $C_x$  = coefficients based on ranking  
 $FW_x$  = factor weightings of assigned values (1 – 100)

For example, assume that the producibility of a bare PWB may be scored with the preceding equation if the FOM process established the following factors:

- Size of the substrate:  $C_1 = 1.5$
- Number of drilled holes:  $C_2 = 3.0$
- Minimum trace width:  $C_3 = 4.0$

Now assume that the proposed PWB design specifies the following:

- Size of the substrate: FW1 = 36
- Number of drilled holes: FW2 = 18
- Minimum trace width: FW3 = 31

The producibility SCORE would equal:

$$232 = 54 + 54 + 124 = 1.5 \times 36 + 3.0 \times 18 + 4.0 \times 31$$

The SCORE can be used if it is calibrated based on the prior history of this type of product. Prior products are scored with the FOM linear equation (Eq. 19.1). Those products that went into production smoothly and presented minimum problems determine the minimum SCORE that should be sought. The SCORE from products that were a problem, had to be reengineered, or presented delays in introduction determines the SCORE that the design should exceed if problems occur and producibility is to be obtained.

## 19.4 LAYOUT TRADE-OFF PLANNING

---

Predicting density and selecting design rules are two of the primary planning activities for layout. The actual layout of a PWB is covered in Chapters 13, 14, and 15. The selection of design rules not only affects circuit routing but profoundly affects fabrication, assembly, and testing.

### 19.4.1 Balancing the Density Equation

With the need for more parts on an assembly and the trend to make things smaller for portability or faster speeds, the design process is a challenging one. The process is one of balancing the density equation with considerations for certain boundary conditions such as electrical and thermal performance. Unfortunately, many designers do not realize that there is a mathematical process to determine the routing rules of a printed circuit. Let me briefly explain. The density equation, as seen in Eq. 19.2 and Fig. 19.10, has two parts: the left side, which is the component wiring demand, and the right side, which is the substrate wiring capability.

$$\begin{array}{l} \text{Component PWB Wiring Demand} < \\ \text{PWBs Design Rules \& Construction Wiring Capabilities} \end{array} \quad (19.2)$$

where PWB Wiring Demand = total connection length required to connect all the parts in a circuit

PWB Wiring Capability = substrate wiring length available to connect all the components

Four conditions can exist between wiring demand and substrate capability:

- **Wiring Demand > Substrate Capability** If the substrate capacity is not equal to the demand, the design can never be finished. There is not enough room for either traces or vias. To correct this, either the substrate has to be bigger or components have to be removed.
- **Wiring Demand = Substrate Capability** Although theoretically optimum, this condition leaves no room for variability and it would take an unacceptable amount of time to complete the design.

FIGURE 19.10 Balancing the density equations to achieve an optimal layout.

- **Wiring Demand < Substrate Capability** This condition should be your goal. There should be enough extra capacity to complete the design on time with only a minimum of over specification and costs.
- **Wiring Demand << Substrate Capability** This is the condition that usually prevails. By PCB layout, the schedule is tight and timing is all important. Many choose tighter traces or extra layers to help shorten the layout time. This increases the manufacturing costs 15 to 50 percent higher than is necessary, which is sometimes called the sandbag approach. It is unfortunate, as the preceding models would help to create a better-planned environment.

### 19.4.2 Wiring Demand ( $W_d$ )

Wiring demand is the total connection length (in inches) required to connect all the parts in a circuit. If the design specifies an assembly size (in square inches), then a wiring density in inches per square inch or centimeter per square centimeter is created. Models early in the design planning process can estimate the wiring demand. Three cases can control the maximum wiring demand:

- The wiring required to break out from a component such as a flip chip or chip scale package
- The wiring created by two or more components tightly linked, such as a central processing unit (CPU) and its cache or a digital signal processor (DSP) and its input/output (I/O) control
- The wiring demanded by all integrated circuits and discretes collectively

Models are available to calculate the component wiring demand for all three cases; see Sec. 19.4.3. Since it is not always easy to know which case controls a particular design, it is usually to calculate all three cases to see which one is the most demanding and thus controls the layout.

Wiring demand is defined by Eq. 19.3.

$$W_d = W_c \times \epsilon \text{ (in cm/square cm or in./square in.)} \quad (19.3)^3$$

where  $W_d$  = Wiring Demand  
 $W_c$  = Wiring Capacity  
 $\epsilon$  = PWB Layout Efficiency (determined in Sec. 19.4.3)

### 19.4.3 Wiring Capacity ( $W_c$ )

Substrate wiring capacity is the wiring length available to connect all the components. It is determined by two factors:

- **Design rules** These rules specify the traces, spaces, via lands, keepouts, and such that make up the surface of the substrate.
- **Structure** This factor determines the number of signal layers and the combination of through and buried vias that permit interconnection between layers and the complex blind, stacked, and variable depth vias available in high-density interconnection (HDI) technologies.

These two factors determine the maximum wiring available on the substrate. To figure the wiring available to meet the demand, multiply the maximum wiring by the layout efficiency. The data are straightforward except for layout efficiency. Layout efficiency expresses what percentage of wiring capacity can be used in the design. Equation 19.4 shows the formula for determining wiring capacity for each signal layer. The total substrate capacity is the sum of all the signal layers.

$$W_c = T \times L/G \text{ (in cm/square cm or in./square in.)} \quad (19.4)$$

where  $T$  = number of traces per wiring channel or distance between two via pads  
 $L$  = number of signal layers  
 $G$  = wiring channel width or length between centers of the via pads

### 19.4.4 Layout Efficiency

Layout efficiency is the percentage of capacity from design rules and structure that a designer can deliver on the board. Layout efficiency is the ratio of the actual wiring density that it takes to wire up a schematic versus the maximum wiring density or  $W_d$  divided by  $W_c$ . Layout efficiencies, for ease of calculations, are typically assumed to be 50 percent. Table 19.2 provides a more detailed selection of efficiencies.

### 19.4.5 Selecting Design Rules

To calculate a potential set of design rules and signal layers, first the wiring demand ( $W_d$ ) should be calculated. Wiring models help accomplish this.

**TABLE 19.2** Typical Layout Efficiencies

Design scenario	Conditions	Efficiency* (%)
Through hole, rigid	Gridded CAD	6–12
Surface mount/mixed	W/wo back side passives, gridless CAD	8–15
Surface mount/mixed	W/back side actives, gridded CAD	9–18
Surface mount only	W/wo back side passives, gridless CAD	Up to 20
Surface mount/mixed	1-sided blind vias, gridless CAD	Up to 25%
Surface mount/mixed	2-sided blind vias, gridless CAD	Up to 30
Built-up technologies	2-sided micro-blind vias, gridless CAD	Up to 50%

\* Determined from analysis of printed circuit designs (actual wiring capacity from the CAD system divided by maximum wiring capacity (Eq. 19.4).

**19.4.5.1 Wiring Demand Models.** Seven wiring models are reported in the literature, but the first three are used commonly. The three wiring models include:

- Coors, Anderson & Seward Statistical Wiring Length<sup>4</sup>
- Toshiba Technology Map<sup>5</sup>
- Hewlett Packard (HP) Design Density Index<sup>6</sup>

The other four wiring models include:

- Equivalent ICs per square inch<sup>7</sup>
- Rent’s Rule<sup>8</sup>
- Section Crossing<sup>9</sup>
- Geometric Analysis<sup>10</sup>

**19.4.5.1.1 Coors, Anderson, & Seward Statistical Wiring Length.** This wiring demand model is based on a stochastic model of wiring involving all terminals. The probable wire length is calculated based on the distance of a second terminal and the spatial geometry of all other terminals. This is the most recently determined wiring model and represents the most practical approximation of surface mounting technology. Eq. 19.5 presents the mathematical model that results.

$$d = D * N_i/A \text{ (in. per sq. in.)} \tag{19.5}$$

where  $D$  = ave. interconnection distance (in.)  
 $D = E(x)*G$   
 $E(x)$  = expectation of occurrence  
 $G$  = pad placement grid (in.)  
 $N_i$  = total number of interconnections  
 $A$  = routing area (sq. in.)

Equation 19.6 for  $E(9x)$  is the

$$E(x) = \frac{1}{a} \frac{((S-T)(S a - 2))e^{aS} + S(2 - (S-T)a)e^{a(S-T)} - 2T}{(S-T)e^{aS} - S e^{a(S-T)} + T} \tag{19.6}$$

FIGURE 19.11 Packaging technology map.

where  $S = M + N$   
 $T = (M^2 + N^2)^{.5}$   
 $a = \ln \alpha$   
 $\alpha =$  empirically derived constant = 0.94  
 $M =$  board width of grid point = (width/G) + 1  
 $N =$  board length of grid point = (length/G) + 1  
 $N_t = 2 \cdot Nt/3$

19.4.5.1.2 *Toshiba's Technology Map.* The packaging technology map is a simple technique to predict a PWB, Chip-On-Board, or MCM-L wiring demand and its assembly complexity. By plotting components per square inch (or components per square centimeter) against average leads per component on a Log-log graph (see Fig. 19.11), you can calculate the wiring demand  $W_D$  in inches per square inch (or centimeters per square centimeters) and assembly complexity in leads per square inch (or leads per square centimeter). Eqs. 19.7 and 19.8 show the equations for these two metrics.

$$\text{Wiring Demand } W_D = \beta \times (\text{comp})^{0.5} \times (\text{leads}) \tag{19.7}$$

where  $\beta =$  wiring coefficient (typically 3.5 but can vary from 2.5–4.0 on average; notes/net is a good approximation)  
 comp = components per board area in sq. in. or sq. cm.  
 leads = average leads (connections) per component

$$\text{Assembly Complexity} = (\text{comp}) \times (\text{leads}) \tag{19.8}$$

comp = components per board area in sq. in. or sq. cm.  
 leads = average leads (connections) per component

FIGURE 19.12 Wiring and assembly density.

Using these two equations, Fig. 19.12 shows lines of constant wiring demand (in cm. per sq. cm or in. per sq. in.) and assembly complexity (in leads per sq. cm. or sq. in.) that can be plotted on this chart (see Fig. 19.11).

19.4.5.1.3 *HP's Design Density Index.* Another metric is called the Design Density Index (DDI). It is a correlation of the actual design rules for a PWB compared to the DDI metric. Equation 19.9 gives DDI, and Fig. 19.13 shows a typical calibration chart.

$$DDI = 13.6 \times (EIC/board\ area)^{1.53} \tag{19.9}$$

where  $EIC$  (equivalent integrated circuits) = total component leads/16  
board area = top surface area of a PCB (sq. inch.)

The chart shown in Fig. 9.13 gives a good visual record in PWB layout of a company's efficiency. As various PC boards are charted, their DDI's form a distribution. This distribution is a form of layout efficiency ( $\epsilon$ ) since at the bottom of the distribution, more EICs are connected than at the top of the distribution.

19.4.5.1.4 *Density of Equivalent ICs.* EIC per unit area has been a traditional measure of density since the introduction of CAD systems in the early 1970s. A simple measure of the number of electrical connections required per unit area of the board, it remains in use with

**FIGURE 19.13** Design rules and layer count for various DDIs.

surface mounting technology and is usually referred to as EIC density. An EIC is the total number of leads of the components divided by 14 or 16, the old number of pins on a dual-inline package (DIP). Many people also use 20 as a divisor. Equation 19.10 defines EIC density mathematically in EIC/sq. in.

$$\text{EIC Density} = \text{Connections}/16/\text{Board Area} \tag{19.10}$$

where Connections = total component leads  
 Board Area = top surface board area (in sq. cm. or sq. in.)

### 19.4.6 Typical Example of Wiring Demand Calculation

As an example, take a typical consumer electronic board with these characteristics:

- Design: consumer PCB, all through hole components
- Components: 86

- Leads: 1,540
- Size: 19.6 in.  $\times$  19.5 in. = 57 sq. in.
- EIC/sq. in. = 110/57 sq. in. = 1.93 (using Eq. 19.10)
- DDI =  $13.6 \times (1.93)^{1.53} = 319.7 \sim$

Figure 19.13 advises two tracks on two signal layers (using Eq. 19.9).

## 19.5 PWB FABRICATION TRADE-OFF PLANNING

---

The metrics for PWB and chip-on-board (COB) fabrication involve trade-offs between the performance objectives and the PWB price. Calculating prices requires the PCB characteristics and manufacturing yield. Manufacturing yield requires producibility estimates. Three items are required to predict PCB prices:

- Fabrication complexity matrix
- Prediction of producibility and first-pass yield
- Relative price as a function of a price index

### 19.5.1 Fabrication Complexity Matrix

The fabrication complexity matrix is supplied by a PWB fabricator. It relates the various design choices on a PWB to design points. These points are based on the actual prices that a fabricator will charge for these features. They are calculated by dividing the actual costs and the values by the smallest nonzero amount. Typical factors that fabricators can use to price a printed wiring board include the following:

- Size of the board and number that fit on a panel
- Number of layers
- Material of construction
- Trace and space widths
- Total number of holes
- Smallest hole diameter
- Solder mask and component legends
- Final metalization or finish
- Gold-plated edge connectors
- Factors specific to the design

A typical fabrication complexity matrix would look like Table 19.3. This is not a complete matrix, but does show the design factors and the design points assigned to each.

### 19.5.2 Predicting Producibility

The simple truth about printed circuit boards, multichip modules, and hybrid circuits is that the design factors such as those listed previously can have a cumulative effect on manufacturing yield. These factors all affect producibility. Specifications can be selected that individually may not adversely affect yields but cumulatively can significantly reduce yields. A simple

**TABLE 19.3** Example of Fabrication Complexity Matrix

Factors	Pts.	Highest	Pts.	High middle	Pts.	Low middle	Pts.	Lowest
No. of layers	12	8	8	6	4	4	1	2
Trace width (mils)	8	4	5	5-6	3	7-8	1	10
No. of holes	10	5000-8000	5	3000-5000	3	10000-3000	1	>10000

algorithm is available that collects these factors into a single metric, in this case called the complexity index (CI). It is given in Eq. 19.11.

$$\text{Complexity Index} = \frac{(\text{Area}) (\text{Holes/unit area})^2 (\text{no. Layers})^3}{(\text{Min. trace width}) (\text{Min.annular ring}) (\text{Min. hole dia.})} \tag{19.11}$$

where  
 Area = top area of the substrate to be designed  
 Holes = total number of drilled holes, blind, buried, and through  
 Holes/unit area = holes divided by board Area  
 Trace width = the minimum trace width on the substrate  
 Layers = the total number of layers in the substrate  
 Annular ring = 1/2 the difference between the via land and the hole dia.  
 Hole dia. = finished hole size

where Area, number of holes, minimum trace width, number of layers, and minimum tolerance (absolute number) are the factors of the board being designed

**19.5.2.1 First-Pass Yield.** The first-pass yield equation derives from the Wiebel probability failure equations.<sup>11</sup> Equation 19.12 is of a more general form of the equation typically used to predict ASIC yields by defect density.

$$\text{FPY}\% = \frac{100}{\text{Exp}[(\log \text{CI}/A)^B]} \tag{19.12}$$

where FPY= first-pass yield  
 CI = complexity index  
 A,B = constants

To determine the constants A and B in Eq. 19.12, a fabricator will need to characterize their manufacturing process. Selecting a number of printed circuits currently being produced that have various complexity indexes does this, ideally some low, medium, and high. The first-pass yield (at electrical test without repair) of these printed circuits for several production runs is recorded. Any statistical software program<sup>12</sup> that has a model-based regression analysis can now determine A and B from the model (Eq. 19.13).

$$\text{FPY} = f[x] = 100 \div \text{EXP}\{\text{LOG}(\text{complexity} \div \text{PARM}[1])^{\text{PARM}[2]}\} \tag{19.13}$$

where PARM[1] = A  
 PARM[2] = B

The first-pass yield will follow the examples in Fig. 19.14. Constant A determines the slope of the inflection of the yield curve, whereas constant B determines the x-axis point of the inflection.

**FIGURE 19.14** Estimated first-pass yield as a function of PWB design complexity.

Alternatively, any spreadsheet can be used to determine constants A and B. The [REGR] function in a spreadsheet like Excel™ or Lotus 1-2-3™ is used. The [REGR] function is defined as: (=LINEST(known\_y's,known\_x's,TRUE,TRUE)). To use this function, you must first put the FPY function into the form  $y = Ax + B$ . This is done by creating two columns: complexity index (which we will call X1) and yield. A third column is created for  $\{\log[\log(X1)]\}$ , whereas a fourth column is created for  $\{\log[\ln(-yield/100)]\}$ . Provide the regression function with column 4 as known\_ys and column 3 as known\_xs. The regression function will return 10 values; FIT (slope & int.), sig-M (slope & int.), r2, sig-B (slope & int.), F,df (slope & int.), and reg sum sq (slope & int.). The constant B is equal to the FIT (slope) and the constant A is  $10^{[-FIT(int.)/FIT(slope)]}$ . (Remember, to calculate an array, follow these steps: highlight the array on the spreadsheet; type the array formula, making sure that the cursor is in the edit bar; then press CTRL + SHIFT + ENTER.)

**19.5.2.2 Yield Calculation Steps.** To calculate the first-pass yield coefficients, there are six steps:

1. Collect design attributes of 10 to 15 currently running boards with various size and layers (see Table 19.4).
2. Collect the first-pass yield information for these selected boards, at least 10 runs (see Table 19.5).

**TABLE 19.4** Example of PCB Part Information and Calculated Complexity Index

P/N	PCS SIZE		Hole quantity	Hole density	Layers	Thickness (mil.)	Min. Trace width (mil.)	Min. Annular ring (mil.)	Min. Hole size (mil.)	Aspect ratio	Complexity x1

#13	1.250	2.660	220	66.2	4	32.0	7	8	14	2.29	2.72E+03

3. Calculate the board complexity index and average yield.
4. Prepare a spreadsheet of transformed CI (x1) and Yield (Y) (see Table 19.6)
5. Calculate regression coefficients (see Table 19.7).
6. Calculate A and B from regression fits.

**19.5.2.3 PCB Part Information.** Collect design attributes of 10 to 15 currently running boards with various size and layers (see Table 19.3).

**19.5.2.4 PCB Production Yield Data.** Collect the first-pass yield information for these selected boards, for at least 10 runs (see Table 19.5)

**TABLE 19.5** Example of PCB Production Yields from 10 Runs

P/N Run	First pass yield (at Electrical test)										Average

For board: Divide by no. per PANEL

### 19.5.3 Example of a Complete PWB Complexity Matrix

This section presents an example of how one company approached this planning process as part of its PWB design for manufacturing program.

**19.5.3.1 PWB Fabrication Complexity Matrix (FCM).** The PWB fabrication complexity matrix that this company developed is shown in Table 19.8. This FCM is built on a "per panel" basis of 18 in. by 24 in. rather than a "per board" basis. Also, volume is assumed to be in a pre-set amount.

**19.5.3.2 PWB Complexity.** Figure 19.14 shows this company's first-pass yield. The curve with  $A = 11.5$  and  $B = 9.0$  was current for six months. Price index is the total points from the complexity matrix divided by the first-pass yield.

**19.5.3.3 Relative Costs.** The price index data for this company is shown in Fig. 19.15. The price index (PI) can vary from 150, which corresponds to a 70 percent price reduction, to a PI of 1,000 which corresponds to a 275 percent increase in price.

**19.5.3.4 PWB Fabrication Example.** Let's continue with the consumer electronics board example from Sec. 19.4.5. Table 19.9 lists the initial design characteristics of the printed circuit and the resultant total design points. Table 19.10 shows the calculation of the complexity index, estimated first-pass yield, and resultant price index and price adjustment.

The wiring demand indicates that a 0.007 in trace and a 0.008 in spacing (two track) for a 0.100 in grid (channel) represent more density than is required (see Sec. 19.4.5). A one-track wiring on two signal layers could achieve the required wiring density or a 0.012 in trace

**FIGURE 19.15** PWB relative price as a function of the price index.

with a 0.013 in spacing. The size required a panel layout, as shown in Fig. 19.16a, of six per panel. A reduction of 14 sq. in in the board size would allow eight boards on a 18 in × 24 in panel (see Fig. 19.16b).

A simple Gate Array ASIC was employed to reduce the small-scale ICs until 14 sq. in of space was freed up. The final optimized PCB had the fabrication factors seen in Table 19.11. The boards were eight up on a panel (Fig. 19.16b) and had a higher producibility by a 18 percent reduction in its complexity and an overall price reduction of 24.7 percent.

**TABLE 19.9** One Company’s Fabrication Complexity Makeup

Fabrication factors	PWB design #1	Points	FCM

## 19.6 ASSEMBLY TRADE-OFF PLANNING

The metrics of assembly trade-offs relates factors of process, component selection, and test to assembly prices. Yields and rework are factored into the points of the Assembly Report Card. The point total provides an estimation of the relative prices of assembly and test.

### 19.6.1 Assembly Complexity Matrix

The PCB assembler supplies the assembly complexity matrix. This matrix relates various process assembly and test choices that the assembler provides along with component size, orientation, complexity, and various other known qualities to the costs of providing for these design choices. To relate these qualities to the costs, the matrix allocates design points. Typical factors that affect assembly costs are:

- One-pass or two-pass infrared reflow
- Wave solder process
- Manual or automatic parts placement
- Odd-shaped parts
- Part quality level
- Connector placement
- Test coverage
- The ability to diagnose tests
- Assembly stress testing
- Repair equipment compatibility

By collecting all the costs associated with assembly, test, and repair and then normalizing these costs with the smallest nonzero value, a matrix such as shown in Table 19.12 can be produced.

**TABLE 19.12** Factors in an Assembly Complexity Matrix

Factors	Pts	Highest	Pts	Middle	Pts	Lowest
Solder Process	35	1 pass IR	20	2 pass IR	0	IR & wave solder
Placement	8	100% auto	5	99%–90% auto	0	>90% auto
Digital Test Coverage	9	<98%	3	98%–90%	0	>90%
Manual Attachment	8	100% Auto	25	Brackets	0	Post solder assembly

### 19.6.2 Example of an Assembly Complexity Matrix

An example of the assembly complexity matrix is the Assembly Report Card created by IBM-Austin. This complexity matrix has 10 factors that range in points from 0 to 35. The total points can affect the prices from a 30 percent discount to a 30 percent penalty. Table 19.13 illustrates this assembly complexity matrix trade-offs with design points.

**19.6.2.1 SMT Assembly Report Card.** The IBM Assembly Report Card’s<sup>13</sup> 10 assembly trade-off factors are shown in Table 19.13. The report card was the work of many assembly engineers with the help of the accounting department. The report card was introduced in early 1990s; within two years, through the use of the report card, assembly point scores were averaging around 75 instead of the earlier 50, with its Gaussian distribution. Remember, higher scores indicate more producibility. This effect can be seen in Fig. 19.17. The scores are no longer normally distributed.

**TABLE 19.13** Assembly Complexity Matrix Defined as an Assembly Report Card

Assembly Factors	Points	A	Points	B	Points	C	Points	D
Assembly process	35	2-pass IR	25	IR/wave B/S passives	20	IR/wave ≤ 5 B/S actives	0	IR/wave >5 B/S actives
<ul style="list-style-type: none"> <li>• 2-pass IR is lowest-cost process due to low defect/repair level.</li> <li>• Maximize SMT content, some PTH OK.</li> <li>• Back-side SMT attachment with a wave solder process requires the use of adhesive.</li> <li>• Back-side actives have a high defect level when the wave solder process is used.</li> </ul>								
Stress tests	15	0 hours	12	≤3 hours in situ	6	≤6 hours in situ and ≤3 hours static	0	<6 hours
<ul style="list-style-type: none"> <li>• Stress test is a high-cost process step due to cost of chambers, fixtures, and process time.</li> <li>• Stress test can be eliminated by using robust components, design, and process.</li> </ul>

## CHAPTER 20

---

# MANUFACTURING INFORMATION, DOCUMENTATION, AND TRANSFER INCLUDING CAM TOOLING FOR FAB AND ASSEMBLY

---

**Happy T. Holden**

*Mentor Graphics, Longmont, Colorado*

---

### 20.1 INTRODUCTION

---

The manufacturing of printed circuit boards (PCBs) and assemblies (PCAs) begins with the soft-tooling process. This process is the transformation of customer computer-aided design (CAD) data and specifications into the necessary tools required for manufacturing the bare printed circuit board and populating the assembly. The typical tools required for manufacturing printed circuit boards include artwork for photoprinting of inner conductive layers, outer conductive layers, and solder mask patterns. Artwork is also created for screen-printing patterns for nomenclature and via-plugging layers. Additional tools required include drill and routing numerical controlled (NC) programs, electrical testing netlists and fixtures, and CAD reference soft-tools.

The tooling process for assembly requires assembly drawings, bills of materials (BOM), and schematic or logic diagrams, and includes the solder-paste stencil design, assembly array layout, and the resulting computer numeric control (CNC) programs for component placement, in-circuit test program creations, and possibly the creation of a functional test program. Many of these procedures will be covered in subsequent chapters in the “Assembly” section of this Handbook.

During the tooling process, the customer part numbers are analyzed to determine the compatibility of the design features with the manufacturing process capabilities. Additionally, attempts to optimize the manufacturing of the product at the lowest cost are a primary goal. However, the majority of the costs have been defined before the design is transmitted to the manufacturing site by the PCB designer. An early investment in time by the PCB design team and the manufacturing tooling team can result in the most significant savings in overall product cost.

**FIGURE 20.1** The soft-tooling process (computer-aided manufacturing [CAM]) for PCB fabrication and assembly.

This chapter describes the PCB tooling process, as defined in Fig. 20.1, including the transfer of information, design reviews, optimization of materials, definition of BOM and routings, tool creation, and additional processes that are required.

## 20.2 MANUFACTURING INFORMATION

The tooling process begins with the receipt of information from the customer. Unfortunately, although the time required to send information to the manufacturer has decreased to minutes or hours from day(s), a significant issue with the provision of packages to manufacturers is the completeness of the information provided. The Institute for Interconnecting and Packaging Electronic Circuits (IPC) has a new document, IPC-2610, that defines a complete documentation package, including the following:

- IPC-2611, “Generic Requirements for Electronic Product Documentation”
- IPC-2612, “Sectional Requirements for Electronic Diagramming Documentation (Schematic and Logic Descriptions)”
- IPC-2613, “Sectional Requirements for Assembly Documentation (Electronic Printed Board and Module Assembly Descriptions)”
- IPC-2614, “Sectional Requirements for Board Fabrication Documentation (Printed Circuit Board Description Including Embedded Passives)”
- IPC-2615, “Sectional Requirements for Dimensions and Tolerances”
- IPC-2616, “Sectional Requirements for Electrical and Mechanical Part Descriptions (Specification and Source Control Part Descriptions)”
- IPC-2617, “Sectional Requirements for Discrete Wiring Documentation (Wire Harness, Point to Point and Flexible Cable Descriptions)”
- IPC-2618, “Sectional Requirements for Bill of Material Documentation (Complete Listing of Parts, Materials, and Procurement Documents)”

Timely tooling of a part number depends on having the correct information. All features required to exist on the PCB must be defined for the manufacturer. The information is defined via design data, drawings, and textual information. Automated data are encouraged whenever possible.

### 20.2.1 Required Information

The information and common data formats required to permit the tooling of the PCB include the following:

- Part number information
 

Information: This information defines the part number to be built, including revision number, releases, dates, etc.

Format: This information is typically provided in the part drawing or may be provided as an additional text file.

- Fabrication drawing

**Information:** This drawing describes the unpopulated printed board and all features that become part of the board. It may contain specific design requirements such as material requirements, multilayer stack-up diagram, dielectric separation between layers, controlled impedance requirements, solder mask type, nomenclature color, location, size requirements for the fabricator's ID, Underwriter's Laboratories (UL), electrostatic discharge (ESD), country of origin, and dimensional tolerances, as well as testing and electrical performance expectations. The dimensional datum (see Fig. 20.2) should be clearly identified.

**Format:** Common formats for drawings are Adobe PDF, HP-GL, HP-GL-II, and PostScript.

**FIGURE 20.2** Datum identification examples.

- Drill drawing

**Information:** Although the drill data are provided via data files, this information typically contains only the location of holes and the tool number. The drill drawing identifies the location of the datum reference planes and the coordinate dimensioning system of the board (see Fig. 20.2). The tool number is referenced against the drill drawings to determine the required sizes, plating status, size tolerances, and the total count for verification. This is for plated (TH), non-plated (NPTH), blind/buried vias, and countersink holes.

**Format:** Common formats for drawings are Adobe PDF, HP-GL, HP-GL-II, and PostScript.

- Subpanel drawing

**Information:** Many assembly operations require boards to be provided in a subpanel form (many parts on one shippable unit). The drawings define the orientation and position of each part, the subpanel dimensions, tooling hole information, special markings, and specific manufacturing processes and tolerances.

**Format:** Common formats for drawings are Adobe PDF, HP-GL, HP-GL-II, and PostScript.

- Manufacturing notes

**Information:** Manufacturing information is usually included on the fabrication drawing or attached documents. This document details the following:

- **Board details:** The type, size and shape of the printed board, bow and twist allowances, overall board thickness requirements including tolerances, tooling hole information, special markings, and specific manufacturing processes and tolerances.
- **Materials:** Type class and grade of materials, including color if applicable. Plating and coating material(s), type, thickness, and tolerances. Solder mask and marking inks type, minimum thickness, and permanency.
- **Conductors:** Shape and arrangement of both conductors and nonconductor patterns, thickness, dimensions, and tolerances, including conductor width and spacing allowances.
- **Acceptability:** Location of quality conformance coupons or circuitry, control documents for acceptability, X-OUTs accepted and assembly-panel concerns.

**Format:** Common formats for drawings are Adobe PDF, HP-GL, HP-GL-II, and PostScript.

- Artwork data

**Information:** These data consist of files for each circuit layer, coating (e.g., solder mask), marking (i.e., nomenclature), solder paste, hole plugging, and possible test-probing layer.

**Format:** The data required are usually RS-274X, commonly called Gerber data or ODB++ (Orbitech Data Base). Gerber and ODB++ data are provided as a standard output from most PCB CAD systems. Other possible formats include GenCAM and the new IPC-2581 (see Sec. 18.3.4 “Modern Data Exchange Formats” for more details).

- Aperture list files

**Information:** The definitions of the shapes used for drawing are required for each layer provided of artwork data. Special shapes such as thermal pads should specifically define their method of construction.

**Format:** This information is usually provided as a text file, although the information may also be defined in the beginning of the individual artwork files, including constructions of complex apertures.

- Drill data

**Information:** This information may consist of a single or multiple file(s), and defines the location and tool number used for each hole in the PCB. The files required should define all plated, unplated (which can be combined with plated if fully defined), buried via, and blind via layers.

**Format:** Common data files provided are in Excellon format.

- Drill tool files

**Information:** This information describes the size, plating status, layer-from, and layer-to (in the case of buried and blind vias) drill-data format and filenames. This information is referenced against the drill drawing.

**Format:** This information is usually provided as a text file, although the information may also be defined in the beginning of the individual drill files.

- Special requirements information

**Information:** The drawing or a file should describe any special requirements not defined in other information. Typical of such requirements would be the details and image enlargement of “break-away” tabs on a subpanel or details of “hole-plugging” requirements. It is important for the PCB designer not to assume that requirements are understood, but to refer to specifications or clearly define the requirements.

**Format:** This information is typically provided in the part drawing or may be provided as an additional text or drawing file.

- Netlist data

**Information:** Netlist data define the connectivity of the circuitry.

**Format:** This information can be provided from the CAD systems in various formats, or it can be extracted from the drill and artwork data. Contact the PCB manufacturer for compatible formats if the netlist data are to be provided directly. The IPC has defined a neutral format, IPC-356, that provides all the information necessary for netlist and electrical test fixture creation. (See Sec. 18.3.1 and 18.3.2.2 for examples)

In addition, the IPC has defined an alternative neutral standard format for most of the previously defined data. These formats provide simpler processing at the manufacturer. They include IPC-D-350, IPC-2511 (GenCAM), and IPC-2581 (the offspring of ODB++ and GenCAM). These formats can be generated by most PCB CAD systems and processed by most PCB CAM/tooling systems. The PCB customer should review the compatibility of these formats with the PCB manufacturer prior to sending data formatted with them.

## 20.2.2 Fabrication Information Formats

Formats for fabrication information include Gerber, ODB++, GenCAM, and IPC-2581.

**20.2.2.1 Gerber Data.** Gerber data format is the oldest artwork format. It was developed with the first NC photo plotters in the early 1970s. It is the “least complete” of data formats in

```

**20.2.2.2 ODB++ Format.** Orbitech developed ODB++ as a “complete” data description format used for design to manufacturing (DFM) and CAD/CAM data exchange. It contains all the relevant design data for manufacturing and assembly. See Sec. 18.3.4.1 for ODB++ details.

**20.2.2.3 GenCAM.** Developed by IPC to improve data transfer for manufacturing in the 1980s, GenCAM is an ASCII-based, English-readable, and universal vendor-independent data exchange format. IPC-D-350 was the first such format in the 1970s, followed by IPC-2511/GenCAM in the 1990s, and in the new millennium IPC-2581 evolved.

**20.2.2.4 IPC-2581.** This is the new IPC coordinated data transfer format. Started in the late 1990s, it is available on some CAD systems. A description is available in Sec. 18.3.4.2.

## 20.3 INITIAL DESIGN REVIEW

---

The purpose of the initial design review is to determine the potential fit of the product to the manufacturing facility, determine general cost information, and prepare for tooling. Proper upfront analysis of a product prior to manufacturing or tooling saves time and materials.

It is the responsibility of the manufacturing site to determine the fit of a given product to its capabilities. PCB manufacturing sites should monitor and maintain a list of manufacturing capabilities and a technology roadmap of where the facility is developing additional process capabilities. This list of capabilities defines the acceptability of a product for manufacturing or whether the product is a research and development project.

### 20.3.1 Design Review

Reviewing the incoming package for design and performance requirements (e.g., line width and spacing, impedance) versus the PCB manufacturing capabilities will define the capability for manufacturing and provide a prediction of the resulting yield. Among the design characteristics that should be reviewed against process capabilities are the following:

Item	Issue
Maximum number of layers	Higher-layer-count products require greater control of processes and tooling tolerances.
Board thickness	Some process or handling equipment may have limitations on board thickness (either too thin or too thick).
Minimum feature width	Finer line widths require better control of artwork and process tolerances. In addition, the relationship of line width to copper weight is significant in providing a well-defined line. Fine lines with lower copper weights are easier to manufacture than fine lines with higher copper weights. For normal impedances, like 50 ohm, thinner lines will require thinner dielectrics.
Minimum feature spacing	Finer feature spacing requires better control of artwork and process tolerances. In addition, the relationship of feature spacing to copper weight is significant. Fine spaces with lower copper weights are easier to manufacture than fine spaces with higher copper weights. Minimum feature spacings affect electrical cross-talk. Closer spacing to reference ground will minimize this cross-talk.
Minimum finished hole size	Smaller holes require higher manufacturing process capabilities and imply (due to design characteristics) finer tolerances on tooling and internal registration systems. The aspect ratio (AR) of diameter to board thickness is a major process concern.

Maximum aspect ratio	Small holes and thick boards result in difficulty during the plating processes and can result in defective products that may or may not pass electrical testing. Plating high-AR holes requires chemistry and process parameter enhancements.
PCB dimensional tolerances	Fine PCB profile or cutout tolerances may result in punching/blanking requirements versus routing, or changes in the routing parameters or programming.
Feature-to-feature tolerances	The location of features on the PCB relative to other features may require alternative materials or process changes to reduce the tolerances.
Hole size tolerances	Consistency in the plating process versus selected drilling hole size and plating densities has significant impact on the capability to control hole tolerances. Adjustments to the PCB design, drill hole size selection, or process parameters may be required to produce an acceptable product with tighter tolerances.
Impedance requirements	The multilayer stack-up thicknesses and tolerances, along with the copper thickness and line widths, must match the nominal impedance and the upper-and lower-acceptability limit. Often, various impedances cannot be fabricated on the same layer.

### 20.3.2 Material Requirements

Determination of the bill of materials is required during the initial analysis of the design. The determination of the BOM and other material-processing requirements will define the manufacturing facility's capability to produce and its material cost structure. In addition, the definition of the material requirements will be the basis for the generation of the process traveler requirements.

The primary materials requiring definition are those included in the BOM, including laminates, prepregs, copper foil, solder mask, and gold. The materials may be explicitly defined by the PCB customer (e.g., usage of a specific solder mask), or may be implied in the drawings or specifications provided with the tooling package.

Several factors impact the selection of the raw materials, including the following:

- Customer-defined physical constraints, for example, the definition of the physical dimensions between conductive layers
- Customer specification of electrical properties, for example, the definition of the impedance requirements on certain layers
- Manufacturing process capabilities related to lamination thicknesses and tolerances
- Specification of material dielectric requirements, for example, the usage of FR-4 or polyimide
- Specifications of physical operating parameters, for example, the minimum requirements of the glass transition temperature

The determination of the laminates, prepregs, and copper foils are based on the following:

- Standard constructions for the PCB manufacturer of a defined PCB layer count, final thickness, copper weight, and dielectric spacing.

- Custom constructions based on defined physical constraints (e.g., minimum dielectric spacing). These custom constructions are defined through knowledge of the lamination pressing thickness of materials versus copper circuitry densities and the availability of materials from suppliers.
- Custom constructions based on defined electrical property constraints, such as controlled impedances, cross-talk, or capacitance. These custom constructions are typically defined via equations or software models provided with certain product parameters.

The determination of solder mask is based on the customer specifications and drawings. Once the acceptability of the solder masks is defined, the PCB manufacturer selects the acceptable masks based on either preferred process (due to volume or cost) or the design characteristics' interaction with the solder mask. These design characteristics include the following:

- **Tenting or plugging of vias** A hole plugging epoxy may be preferred over liquid photoimageable solder mask with a secondary via plugging process.
- **Platable area densities/higher external copper weights** Thin solder masks may not be able to ensure coverage of high plating.
- **Secondary processes** Post-solder-mask processes may chemically or mechanically alter the appearance of certain solder masks.

The determination of gold requirements is based on the thickness and area of the gold. These factors can be used to calculate the requirement of gold per PCB product.

### 20.3.3 Process Requirements

The selection of the proper product routing (or traveler) is critical to the upfront analysis of the product acceptability to manufacturing. Considering a typical multilayer PCB product, the product routings can be broken into two parts: the innerlayer pieces and the outerlayer piece.

The product routings of the innerlayer pieces are fairly standard, and are typically as follows:

Step	Typical process requirements
Layer cleaning	Cleaning of the laminate surface via either mechanical or chemical cleaning processes
Imaging	Coating of the laminate with photoresist material and the exposure of the photoresist with artwork defining the innerlayer pattern
Develop-etch-strip (DES)	Developing of the photoresist, etching of the exposed copper, and stripping of the remaining photoresist
Innerlayer inspection	Inspection of the innerlayer piece to the PCB design intent
Oxide	Coating of the innerlayer piece with an oxide layer prior to lamination

One of the few decision points in innerlayer manufacturing is whether the product will require inspection. This decision can be based on the manufacturing facility's process capabilities and the design of the specific innerlayer piece. For example, if the process capability for innerlayer manufacturing of designs at 0.008 in. lines and spaces is 100 percent yield, and the product has been designed at or above 0.008 in. lines and spaces, then the product may not require inspection. Typically, the design package will identify the design technologies (e.g., line width and spacing); however, these should be confirmed during the design analysis and review stage.

The product routings of the outerlayer pieces define the finished product appearance and, as a result, are more complex. Assuming a pattern plating process, the typical outerlayer

process routings for a solder-mask-over-bare-copper (SMOBC)/hot-air-solder-level (HASL) product is as follows:

<b>Step</b>	<b>Typical process requirements</b>
Lamination	Lamination of innerlayer pieces with prepreg and copper foils to create the outerlayer piece
Drilling	Addition of the holes providing pathways for electrical conductivity between outer layer and innerlayer pieces and for other PCB design purposes
Electroless copper plating	Deposition of copper on the surface and in the holes of the product, providing the conductivity necessary for electroplating
Imaging	Coating of the panel with photoresist material, the exposure of the photoresist with artwork defining the outerlayer pattern, and the developing of the outerlayer pattern
Electroplate copper tin plating	The plating of the final circuitry of the product Sacrificial plating over the final circuitry of the product
Strip-etch-strip (SES)	Stripping of the remaining photoresist, etching of the exposed copper, and stripping of the sacrificial plating
Solder mask	Coating of the bare copper product with either dry film or liquid photoimageable solder mask, exposing of the panel with the PCB customer-supplied artwork pattern, developing of the pattern (exposing the sites requiring solder), and curing of the solder mask
Nomenclature HASL	Screening of the nomenclature onto the panel and curing Coating of the exposed copper sites with solder, leveling to the customer's requirements of thickness
Depanelization	NC routing of the PCB products from the manufacturing panel
Electrical testing	Electrical testing of the product for conformance to the PCB design
Inspection	Verification of product conformance to specifications prior to shipment to the PCB customer

After the electroplate copper operation, the process may change to meet the surface finish requirements. Some of the alternative steps affecting the outerlayer product routing include the following:

<b>Item</b>	<b>Typical process requirements</b>
Selective gold plating	Before the SES process, the panel is coated with additional resist and the selective sites are exposed. These exposed sites are then plated with nickel and gold. The panel will then proceed through the SES process. The HASL step would be omitted.
NPTH in planes without annular ring	A secondary drilling operation will be required to drill the holes, if the hole is to be located through the copper or the hole/feature size is beyond the process capabilities of tenting. This step may occur at the depanelization step.

Scoring	Additional tooling holes may be required to register the panel to the scoring machine blades. Programming of the scoring machine will be required to set the locations and depth of the cuts. This step may occur prior to NC routing of the product.
Countersink holes	The countersinking process is normally performed prior to depanelization.
Gold finger plating	Nickel and gold are plated over the finger area on connectors. This process typically requires shearing/NC routing separation of the panel to place the fingers at the edge of the remaining pieces, taping the product to expose only the fingers, stripping the solder, plating nickel, plating gold, and removing the tape. These operations occur prior to the depanelization process. Finger-plated products usually require chamfering of the fingers.
Via plugging	Plugging of vias may occur prior to solder mask or after the HASL operations.
Chamfer	After depanelization of the products from the manufacturing panel, the PCB products are processed through a machine to add an angle to the edge of the part or fingers.
Organic coating	Products requiring organic coating would omit the HASL step and be coated prior to inspection.

### 20.3.4 Multilayer Stack-Up

Multilayer stack-up, defined in Sec. 13.2.2 and Chap. 27, must be carefully specified. This is the function of the stack-up definition (see Figs. 13.9, 27.1, and 27.2), which is usually part of the fabrication drawing. Impedance specifications (from the electrical performance data block) should be compatible with the materials stack-up. Figure 20.5 shows a cross-sectional view of the finished multilayer. Figure 20.6 shows the stack-up code.

### 20.3.5 Panelization

The selection of the manufacturing panel is one of the most important steps in achieving product profitability. Several factors affect the selection of panel sizes to produce a specific product. These include:

- Material utilization
- Process-specific constraints
- Process limitations

All of these factors impact the selection of the manufacturing panel size and the profitability of the product.

**20.3.5.1 Material Utilization.** The material manufacturing costs, which correspond to 30 to 40 percent of total costs, are directly related to the square inches of material processed. The material costs can include the following: laminate, prepreg, copper foil, solder mask, photoresists, drill bits, chemicals, and so on. Generally, these materials are consumed relative to the panel area manufactured.

FIGURE 20.5 Stack-up drawing to define thickness, layer order, and tolerances for a multilayer.

The appropriate manufacturing panel size (see Fig. 20.7) should be selected such that the shippable product consumes the highest percentage of the manufactured panel as possible, thus reducing waste material and product costs.

During the design phase of the PCB, the board profile is defined. If the profile's design results in poor manufacturing panel utilization, it will significantly impact the cost of the product. When defining the PCB board profile, the PCB designer should ask the manufacturing site to provide

**FIGURE 20.7** Selection of the best panel to increase the material utilization of the shippable product.

DFM feedback. Oddly shaped PCB profiles can still result in good material utilization, through nesting of the PCB on the panel.

General limitations in the selection of appropriate panel sizes include the following: minimum spacing between products for depanelization processes (typically 0.100 in.) and minimum panel border-to-product spacing to permit tooling and registration systems (typically 1.0 in.).

In Asia, minimizing materials to minimize costs plays a much more important role than in North America or Europe, where rapid turnaround time may be the singular focus. Table 20.1 shows a typical set of multilayer panel sizes for a large Asian PCB manufacturer.

**TABLE 20.1** Typical Multilayer Panel Sizes for a PCB

Type	Panel size (inches)	Useable area (with soldermask)
Standard	12 × 14	10.2" × 12.2"
Standard	12 × 16	10.2" × 14.2"

Standard	18 × 24	16.2" × 22.2"
Chip packaging	12 × 18	10.0" × 16.0"
HDI-microvia	16 × 18	14.0" × 16.0"
Optional		

**20.3.5.2 Product Process-Specific Constraints.** In the selection of manufacturing panel sizes, there may be processing constraints that restrict the usage of specific panels or limit the method of placing the shippable product on the panel. For example, the manufacturing of products with gold tab plating may require additional spacing between products and restrictions on the rotation and nesting of products. These constraints may force the usage of panel sizes below the optimal material utilization.

**20.3.5.3 Process Limitations.** Process limitations may require the usage of nonoptimal panel sizes. For example, due to a product's registration requirements, additional tooling may be required, thus reducing the available area for shippable product and reducing the material utilization. Another example is the limitations of some processes to permit larger panel sizes due to the physical processing constraints of the equipment.

The panelization process results in the placement of the PCB single images in the locations defined in the panelization definition step during the initial design review. In addition to the placement of the PCB single images and rotated/nested images (Fig. 20.8), the following features may be added to the panel for manufacturing.

**FIGURE 20.8** Nesting and rotation of a multi-image panel.

## 20.3.6 Initial Design Analysis

After the initial design review, the basics of the design are known and a decision on whether to manufacture the design has to be made. If it is decided to proceed with manufacturing, the cost of the product must be determined. Once the cost has been determined, the product price can be provided to the PCB customer.

The material and process requirements with the manufacturing panel selection, combined with the prediction of yield based on the design review, define the basics of the product costs.

**20.3.6.1 Automated Design Analysis.** Many automated design analysis software systems exist. You can find them on the Internet by searching on key words such as “Automated Design Analysis,” “Computer Aided Manufacturing,” or “Design Validation.” Figure 20.9 shows a report resulting from a CAM macro executed on an ODB++ design file, “8-Layer.”

**20.3.6.2 Design Analysis Checklist.** Figure 20.10 shows a design analysis checklist for determining whether a PCB design is ready for manufacturing.

**20.4 DESIGN INPUT**

The input of the design into the CAM system is primarily performed by defining the apertures and shapes to be used and then loading Gerber data into the PCB CAM system. Alternatively, most PCB CAM systems accept the IPC-350 format.

The information loaded into the PCB CAM systems includes all artwork layers (e.g., circuitry layers and solder mask layers) and the drill files. Although some PCB CAM systems can accept NC routing files (i.e., board profiling), these files are normally not part of the PCB design system's capabilities to create, and therefore are not provided to the PCB manufacturer.

Before loading the PCB design files, the PCB CAM operator must relate the aperture codes within the design file to physical shapes within the PCB CAM system. These shapes are usually round, square, and rectangular, but may also include complex shapes (e.g., thermal relief pads for innerlayer planes). The complex shapes may need to be created on the CAM system from information provided by the PCB designer. The complete definition of these complex shapes by the PCB designer is critical to the success of the resulting design. Incomplete descriptions could result in nonfunctional designs.

During the loading process of the design files, it is important to review any log files and screen messages for missing aperture definitions or damaged design files. After loading the

files, the PCB CAM operator should review the design for any problems with the interpretation of the data or apertures while aligning the data for further processing. The PCB CAM operator also must ensure that the apertures match those defined by the PCB designer and that the design input process has proceeded without failure, since subtle errors may not be discovered within the manufacturing site but only at the PCB customer site, and such errors could result in nonfunctional designs.

## 20.5 DESIGN ANALYSIS AND REVIEW

---

Design analysis and review is a refinement of the initial design review performed earlier but is the first step in the CAM (soft-tooling) process. This step focuses on the actual design data submitted for fabrication and assembly. The design analysis and review step consists of the following tasks:

- Design rule checking
- Manufacturability analysis
- Single-image edits
- DFM enhancements
- Panelization
- Fabrication parameters extraction

These tasks provide the final checking of the PCB design requirements against the capabilities of the PCB manufacturer and preparation of the design for manufacturing.

Most fabrication problems occur or are discovered during the initial tooling (CAM) phase. The following are among the causes of such problems:

- Poorly documented designs
- Improperly formatted drill files
- Use of 274-D Gerber with separate aperture tables
- Lack of proper clearance on solder mask openings
- Inadequate drill-to-copper clearance
- Misaligned layers
- Inadequate manufacturing clearances
- Lack of an IPC-D-356 netlist
- Use of positive plane layers instead of negative ones
- Minimal communication between the designer and the fabricator

The best advice for these problems is to fix them during the design phase. Consider the following precautions and considerations:

- Try not to use 274-D with separate aperture tables.
- Because there are no standards for aperture tables, the fabricator must do extra work to accommodate the tables, with increased opportunity for error.
- Use 274-X whenever possible. The apertures are embedded and files are easier for the fabricator to work with. This provides better support for special aperture shapes.
- Better yet, if possible, use “intelligent” formats like GenCAM, DirectCAM, or ODB++. These formats should enable the fabricator to better understand your design. Also, such formats have the netlist information embedded.
- Design rules can be embedded in some formats.

## 20.6 THE CAM-TOOLING PROCESS

---

The CAM-tooling process consists of six or more distinct manufacturing engineering activities. These include the following:

- Design rule checking (DRC)
- Manufacturing review
- Single-image edits
- DFM enhancements
- Panelization
- Fabrication and assembly parameters extraction

### 20.6.1 Design Rule Checking

Design systems lay out circuits to defined rules; however, these systems may fail to adhere to these rules, because of either system failure or manual intervention. The purpose of reviewing the data package, in addition to reviewing the documented design constraints, is to confirm that the product can be produced at the manufacturing site and to the expected manufacturing yields. The analysis of the data describing the circuitry of the PCB to the manufacturing facility's production capabilities is critical to the success of the product.

Table 20.4 defines typical design rule checking that is performed, the reasons for checking, and the method of checking.

### 20.6.2 Manufacturability Review

The design rule checking results are reviewed against the PCB manufacturing capability matrix, with dispositions being made to the acceptability of violations. The PCB customer may be contacted regarding design violations, to correct and retransmit the design or to permit design changes to be performed by the PCB manufacturer.

Additionally, the factors reviewed during the initial design review are revisited to confirm the results based on design actuals. If differences are noted, product yields and/or cost predictions may need to be altered. During this step of tooling, several concerns are uppermost in the fabricator's mind: Does the board meet the intent of the design? Can it be built? Will it function as planned? Does it pass a master rule set? Can it be improved, that is, be made cheaper or better? Is there component interconnectivity? Does the IPC-D-356 netlist show any shorted nets or broken nets? Were any multiple plane ties not happening? Did a design work-around fool the system—or allow intentional errors to slip through?

**20.6.2.1 Bare-Board Analysis.** Several physical artwork problems are not discovered by design rule checking and are not strictly speaking the result of design rule violations. Nonetheless, these problems can affect the manufacturability of a board and its yield. Table 20.5 describes some of these issues.

Figure 20.14 shows examples of many of these problems. Most modern CAM-tooling systems can correct these manufacturability issues. Thus the manufacturing notes on the fabrication drawings should acknowledge this and allow for the fabricator to implement corrections. Other, less frequent, artwork errors discovered include:

- Signal integrity and performance issues
- Verification of last-minute changes [life savers and engineering change orders (ECO)]
- “Made in XX” and revision controls

**20.6.2.2 Printed Circuit Assembly.** In a similar situation, assembly tooling requires the checks and analysis of supplied BOM, machine files, and artwork for the assembly process. These actions are specifically designed to locate potential manufacturability problems during

**TABLE 20.4** Design Rule Checking

DRC item	Purpose of checking	Method of checking
Drill layer duplicate coordinates	Duplicate drill holes consume manufacturing capacity and may result in broken drill bits.	Most PCB CAM systems have an explicit check for this problem, provided a given radius of tolerance.
Minimum drill hole-to-hole spacing	Drill holes too close together may result in broken material between the holes.	Most PCB CAM systems have an explicit feature spacing check.
NPTH-to-board edge minimum spacing	Drill holes too close to the board edge may result in broken material at the board edge.	Merge the routing profile onto a copy of the NPTH layer and execute a spacing check of the pad to trace (the route layer would appear as a trace).
Missing drill holes	Missing holes may result in nonfunctional designs or products that cannot be used due to missing mounting or tooling holes.	Check the pad registration against a circuit reference layer, and verify pads without PTH holes.
Extra drill holes	Extra drill holes could result in nonfunctional designs due to cutting of traces or shorts (if the holes become plated).	Check the pad registration against a circuit reference layer, and verify PTH holes without pads.
Board edge-to-board edge minimum spacing	Routing cuts leaving minimal material may result in fractured or broken material between routing.	Check the feature spacing of the routing layer as a design layer, without considering electrical connectivity.
Copper-to-board edge minimum spacing	Tolerances of the routing operation may result in copper exposed at the edges of the product.	Check the feature spacing of the routing layer as a design layer against the circuitry layer.
Minimum annular ring	Most customer specifications define the minimum acceptable annular ring on PCB products. Annular ring is dependent on the design and the registration tolerances of the manufacturing processes.	Most PCB CAM systems have an explicit annular ring check.
Minimum pad-to-pad spacing	In addition to feature spacing and potential shorts, pad spacing affects the capability to test products electrically.	Most PCB CAM systems have an explicit feature-to-feature spacing check.
Minimum pad-to-track spacing	Feature spacing below manufacturing capabilities could result in shorts and poor product yields.	Most PCB CAM systems have an explicit feature-to-feature spacing check.
Minimum track-to-track spacing	Feature spacing below manufacturing capabilities could result in shorts and poor product yields.	Most PCB CAM systems have an explicit feature-to-feature spacing check.
Copper-to-NPTH minimum spacing	NPTH locations too close together may prevent proper tenting of holes and require secondary drilling operations. NPTH too close together may result in damaged features (e.g., cut traces).	Check the feature minimum spacing against a copy of the design layer merged with the NPTH layers.
Minimum line width	Line widths below manufacturing capabilities could result in poor product yields.	Some PCB CAM systems have an explicit check for this problem; others may require review of the apertures used and highlighting of the apertures for visual inspection.
Track termination without pad	Although this may be the design's intent, missing pads may be the result of poor design information or loading failures. These problems can result in nonfunctional designs.	Most PCB CAM systems have an explicit check for this problem.
Padstack alignment	Misaligned padstacks may result in unpredictable annular ring results, incorrect compensations of registration, and product scrap.	Most PCB CAM systems have an explicit pad registration check.

*(continued)*

**TABLE 20.4** Design Rule Checking (Continued)

DRC item	Purpose of checking	Method of checking
Minimum solder mask pad clearance	Solder mask pad clearances below manufacturing capabilities could result in solder mask on the pads and poor product yields.	Check the solder mask layer (as a circuit layer) against the circuitry layer using an annular ring check.
Minimum solder mask edge-to-feature spacing	Solder mask edge to feature spacing below manufacturing capabilities could result in exposed features and poor product yields.	Check the feature minimum spacing against a copy of the design layer merged with the solder mask layer.
Minimum solder mask annular ring for NPTH	NPTH solder mask clearances may need to be larger to prevent ghosting of the solder mask from light diffraction through the product mask.	Check the solder mask layer (as a circuit layer) against the NPTH layer, and verify that there are no matches of the NPTH to the solder mask layer.
Solder-mask-to-board edge minimum clearance	PCB edge clearances may need to be larger to prevent ghosting of the solder mask from light diffraction through the product.	Check the feature minimum spacing against a negative copy of the solder mask layer merged with the routing layer.
Solder mask minimum web	Solder mask webs below manufacturing capabilities could result in solder mask breakdown and poor product yields. This problem could result in a PCB assembler with solder bridging defects.	Use minimum feature-to-feature spacing on the solder mask layer.
Plane-to-board-edge minimum clearance	Spacing below the tolerances of the routing operation may result in exposure of copper at the edges of the product.	Check the feature spacing of the routing layer as a design layer against the plane.
Minimum plane layer annular ring	An annular ring below manufacturing registration and tolerance capabilities could result in open connections and poor product yields.	Most PCB CAM systems have an explicit annular ring check.
Minimum plane layer clearance	Plane clearances below manufacturing registration and tolerance capabilities could result in shorts and poor product yields	Most PCB CAM systems have an explicit annular ring check.
Plane-to-plane isolation	Plane layer isolation typically results from either incorrect designs or interpretation of aperture lists; the result is a nonfunctional product.	Most PCB CAM systems have an explicit layer-to-layer isolation check.
Nomenclature-to-NPTH minimum spacing	Nomenclature spacing below manufacturing capabilities may result in nomenclature in the hole, due to misregistration or bleeding of the nomenclature ink.	Check the feature minimum spacing against a copy of the nomenclature layer merged with the NPTH layers.
Nomenclature-to-solder mask minimum spacing	Nomenclature spacing below manufacturing capabilities may result in nomenclature on product features, due to misregistration or bleeding of the nomenclature ink.	Check the feature minimum spacing against a copy of the nomenclature layer merged with each solder mask layer.
Nomenclature-to-feature minimum spacing	Nomenclature spacing below manufacturing capabilities may result in nomenclature on product features, due to misregistration, bleeding of the nomenclature ink, or skipping of the screen over features, resulting in illegible markings.	Check the feature minimum spacing against a copy of the design layer merged with the nomenclature layer.
Nomenclature minimum feature sizes	Nomenclature sizes below manufacturing capabilities could result in illegible nomenclature and poor product yields.	Some PCB CAM systems have an explicit check for minimum line width; others may require review of the apertures used and highlighting of the apertures for visual inspection.

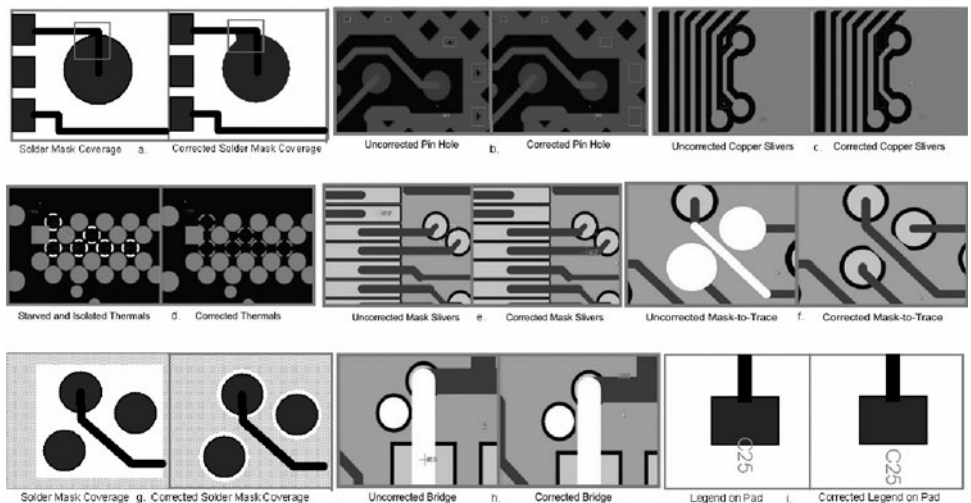

**TABLE 20.5** Physical Artwork Issues

Physical artwork issue	Description of issue	Illustration
Acid traps (photo-resist slivers)	Small pieces of photo-resist that have minimum adhesion and can break off, resulting in plating or redeposits	Figure 20.14a
Pin holes	Small openings in planes or pours that can result in loss of adhesion	Figure 20.14b
Copper slivers	Small features that may lose adhesion and break off	Figure. 20.14c
Starved/isolated thermals	Copper legs for thermals that are cut off from the rest of the plane	Figure 20.14d
Soldermask(S/M) slivers (web)	Small S/M features too tiny to image and adhere properly	Figure 20.14e
S/M to trace spacing	Small spacings that create S/M slivers	Figure 20.14f
S/M coverage	Features left open that could result in solder bridging	Figure 20.14g
Solder bridging	Small gaps between soldered features without S/M that could bridge solder	Figure 20.14h
Legend on pads	Silkscreen or legend on surface mount technology (SMT) lands	Figure 20.14i

board assembly and to collect design statistical data for quoting, planning, and allocating resources. Each action covers a specific aspect of board assembly, including component location, fiducial coverage, and testability issues.

These include but are not limited to the following:

- **Fiducial analysis** SMT component placement needs to align the machine to the individual board. By analyzing global and fine-pitch fiducials, you can identify and correct potential problems. Table 20.6a shows the checklist of a typical analysis.

**FIGURE 20.14** Typical producibility problems created in design (physical artwork).

**TABLE 20.6** Checklist of various assembly and test analyses that need to be performed in Tooling

A. Fiducial analysis	B. Component analysis	C. Padstack analysis	D. Testpoint analysis	E. Solder paste analysis
Global fiducial summary	Comp. max height	Toeprint to toeprint	Toeprint testpoints	Solder paste not on SMD pad
Local fiducial summary	Comp. pitch	Extra solder mask web	Via testpoints	SMD pad without solder paste
Non uniform local fiducial	Comp. rotation	No solder mask web	Other testpoints	Solder paste outside copper
Fiducial to copper	Comp. length Min	Special toeprints	Testpoint to rout	Solder paste not exposed by solder mask
Fiducial to hole	Comp. length max	Via to via center	Testpoint to NPTH	Solder paste to solder mask
Close fiducials	Comp. Spacing	Via to via edge	Testpoint to testpoint	Toe distance min (rect. pins)
Far fiducials	Comp. to toeprint	Via in SMD	Testpoint to toeprint	Heel distance mn (rect. pins)
Fiducial to like pad	Rout spacing	Via to toeprint	Testpoint to capped via	Left Distance min (rect. pins)
Fiducial close to rout	Carrier wall spacing	No thieving pad	Testpoint wrong shape	Right distance min (rect. pins)
Fiducial far from rout	PTH to carrier wall	Toeprint to plane	Testpoint to THMT toeprint	Toe distance max (rect. pins)
Fiducial to background	NPTH to carrier wall	Toeprint annular ring	Testpoint to tooling hole	Heel distance max (rect. pins)
Fiducial to solder mask	Via to carrier wall	Toeprint SM clearance	Testpoint to uncapped via	Left distance max (rect. pins)
Fiducial to solder paste	Label to component	Toeprint to rout	Testpoint to exposed copper	Right distance max (rect. pins)
Fiducials to silk screen	Assembled board thickness	Hole in SMD	Testpoint to unexposed copper	Pin area/pad area min
Fiducial to conveyed edge	Comp. touch silkscreen	Flow solder orientation	Testpoint under component	Large pin area/pad area min
Component center fiducial	Component to conveyed edge	Gold fingers to capped via	Testpoint to component	Pin area/pad area max
Component covers fiducial	SMT component to conveyed edge	Gold fingers to thru TP	Testpoint to component angle	Large pin area/pad area max
Component local fiducial	Other side area keepout	Gold fingers to surface TP	Testpoint to solder mask	Pin width/pad pitch
Component global fiducial	Other Side pins keepout	Gold Fingers to uncapped via	Capped testpoint vias	Pin Pitch/pad pitch

Coarse-pitch component global fiducial	Comp. to gold fingers	Shadowing of inline components	Nets with one testpoint	Direct connection to plane
Fine-pitch component global fiducial	Component to tooling hole	Shadowing of staggered components	Nets without testpoints	No clearance in plane
	Component to mounting hole	Toeprint to v-cut rout	Nets with multiple testpoints	ET pin without PTH
	Hole under component	Toeprint to conveyed edge	Via capped on both sides	MP pin on PTH
	Uncapped via under component	Toeprint to conveyed edge	Uncapped nontestpoint vias	Edge to edge
	No orientation indication	Toeprint to conveyed Edge	Testpoint to conveyed edge	Missing hole
	Component uncommon orientation	Toeprint to break tab rout	Testpoints outside keep-in area	Extra holes
	Wrong orientation indication	Exposed Via to exposed toeprint	Testpoint to silkscreen	Pin too large
	No square pad on THMT pin #1	Irregular exposed toeprint	Testpoints within keep-out area	Pin too small
	Chip edge protection missing	Via to toeprint masked trace	Nets with missing testpoints	Pin touching
	Chip corner protection missing	Testpoints/via Clusters	Nets with necessary testpoints	No pad for pin
	Comp. outside keep-in area	Nonuniform SMD pads size	Nets with extra testpoints	Multiple pads for pin
	Comp. within keep-out area		Net testpoint summary	Pin center to pad heel
	Comp. exceed max height		Net testpoint count report	Pin center to pad toe min
	Comp. under min height			Pin center to pad heel min
	Component to exposed via			Pin center to pad toe max
	Trace under component			Pin diameter vs. hole diameter
	Comp. to reference designator			Large pin right distance max (rect. pins)
	Comp. without reference designator			Large pin toe distance vs. heel distance (rect. pins)

(continued)

**TABLE 20.6** Checklist of Various Assembly and Test Analyses That Need to Be Performed in Tooling (Continued)

A. Fiducial analysis	B. Component analysis	C. Padstack analysis	D. Testpoint analysis	E. Solder paste analysis
	Misplaced reference designator			Large pin left distance vs. right distance (rect. pins)
	Wave solder component orientation			Pin diameter/pad diameter min (%)
	Component relative orientation			Pin diameter/pad diameter min (abs)

				Max pin width/pad width min (%)
				(rect. pins)

(Source: Valor Computerized Systems)

- **Component analysis** SMT components can have a multitude of missing, incorrect, or incomplete characteristics or properties. Component analysis looks for these potential problems, such as one component extending under another component. Table 20.6b provides a typical checklist for such an analysis.
- **Padstack analysis** SMT components have critical toeprints (TPs) and need to be checked with respect to vias, planes, solder mask, fabrication edges, and gold fingers. Table 20.6c shows a checklist for a typical analysis.
- **Testpoint analysis** SMT components need to be tested by in-circuit test (ICT). These analysis check testpoints to vias, surface features, tooling holes, and electrical nets. See Table 20.6d for a typical checklist for testpoint analysis.
- **Solder paste analysis** SMT components have to be soldered correctly. This is the second most important aspect of assembly, just behind placing the right part in the right place. Many checks are necessary to ensure manufacturability, as seen in Table 20.6e.

The benefits of performing a comprehensive and thorough assembly analysis include the following:

- Estimation of cost can be derived from the results of the analysis.
- Manufacturing defects can be identified and corrected prior to construction on the assembly line.
- Such analysis can help detect potential problems so that any necessary reworking can be implemented early in the design process. Each analysis category is governed by a set of engineering reference file (ERF) values, usually unique to each production facility, thereby supporting full job portability between different assembly sites.

The design rule checking results are reviewed against the PCB or assembly manufacturing capability matrix, with dispositions being made to the acceptability of violations. The PCB and assembly customer may be contacted regarding design violations; the designer may need to send corrected designs or to allow design changes to be performed by the PCB manufacturer or assembler.

Additionally, the factors reviewed during the initial design review are revisited to confirm the results based on design actuals. If differences are noted, product yields and/or cost predictions may need to be altered.

When issues are addressed during the fabrication or assembly stage, the design database may not get updated to reflect vital changes, thus compromising the integrity of the design. If the design is respun in the future, this issue might be overlooked, resulting in scrap, or worse, faulty boards.

### 20.6.3 Single-Image Edits

Almost all designs include information that must be removed before they can be manufactured. Most of these items of information are used as references during the PCB layout phase to assist the designer in understanding the available real estate. However, these references must be removed or modified in order to manufacture the board to design intent. Among these typical items are the following:

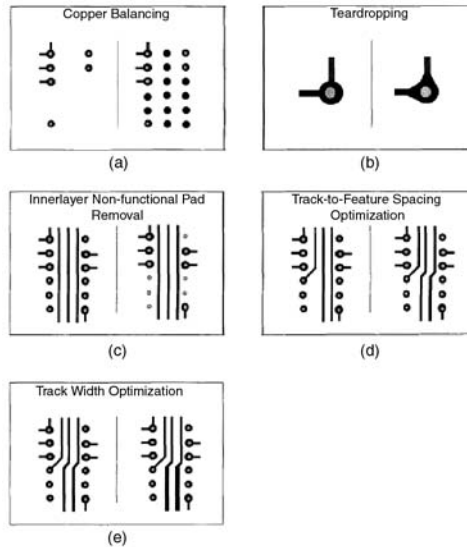

<b>Item</b>	<b>Impact if not removed/modified</b>
NPTH pads on outerlayers	Plated holes
Routing crop marks	Copper at board edge
Direct contact plane markings of drilled holes	Open circuits
Clip nomenclature withsolder mask data	Nomenclature on pads or in holes
Scaling and compensation	Finished traces or geometries that are the wrong size

### 20.6.4 DFM Enhancements

The manufacturability of the PCB can be improved through design enhancements. Many of the enhancements can be performed on CAD systems (or through specialized post-CAD software); other enhancements can be performed at the manufacturing site.

Ideally, all design enhancements would be performed at the design site to maintain the consistency of products from multiple manufacturers; however, some of the DFM enhancements can impact the CAD system's capability to provide further design changes. Specifically, the optimization of track-to-feature spacing could result in blocked routing channels, preventing an autorouter from performing. The following are typical DFM enhancements (see Fig. 20.15):

Item	Result from enhancement
Copper balancing	The balancing of copper on the surface of the design will improve the distribution of plating (in the pattern-plating process), preventing areas of overplating due to the isolation of features. This improvement enables the manufacturer to control the plated hole diameters to tolerances and reduce plating heights, which impact solder mask coverage. (See Fig. 20.15a.)
Teardropping	As annular rings decrease due to tighter design specifications, the probability of defects occurring due to registration/annular ring failures increases. The addition of teardropping increases the pad-to-trace junction size, improving the reliability of the connection and improving product yields. (See Fig. 20.15b.)
Removal of nonfunctional pads on innerlayers	Innerlayer shorts result from several factors, among them the proximity of circuitry to other circuitry. The occurrence of shorts can be correlated to the running length of the circuitry versus the running length at some minimum spacing between circuitry (at the process capability of the operation). Reducing the total distance at minimum spacing will reduce the probability of shorts, resulting in improved yields. (See Fig. 20.15c.)
Optimization of track-to-feature spacing	As described in the nonfunctional pads discussion, the occurrence of shorts can be correlated to the running length of the circuitry versus the running length at some minimum spacing between circuitry (at the process capability of the operation). Reducing the total distance at minimum spacing will reduce the probability of shorts, resulting in improved yields. (See Fig. 20.15d.)
Track width optimization	The occurrence of opens can be correlated to the running length of the circuitry versus the running length at minimum track width (at the process capability of the operation). Reducing the total distance at minimum track width will reduce the probability of opens, resulting in improved yields. (See Fig. 20.15e.)

**FIGURE 20.15** Typical producibility problems created in design.

### 20.6.5 Panelization

In the panelization process, the PCB single images are placed in the locations defined in the panelization definition step of the initial design review. In addition, the following features may be added to the panel for manufacturing:

Item	Purpose
Customer coupons	These coupons are provided to the customers for their inspection of the PCB product. These coupons are typically treated as separate PCB single images.
Internal coupons	During the manufacturing process, destructive testing may be required to confirm product quality. These coupons are typically treated as separate PCB single images.
Tooling holes	Holes used for registration of manufacturing panels to artwork, drilling, or routing operations are added to the panel borders.
Outerlayer thieving patterns	Plating thieving patterns are sometimes needed to balance the platable area across the panel.
Innerlayer venting patterns	The addition of copper to innerlayers outside the PCB single image provides more consistency in the lamination process.
Textual markings	Operator aides may be provided outside the PCB single image to improve manufacturing quality.

### 20.6.6 Fabrication and Assembly Parameter Extraction

Additional manufacturing information must be extracted or calculated from the design file before fabrication or assembly can begin. This information is loaded and stored in several files

and databases used to run various fabrication and assembly equipment. In addition to requiring the basic tooling steps already defined, most PCB manufacturing sites also require the designer to provide the following information:

- Raw materials shearing and labeling instructions
- Copper foil thicknesses and etch rates
- Automatic optical inspection files
- Lamination lay-up BOM and order/stack height
- Lamination press cycles, heat input, and pressure settings
- Drill-file location and revision levels
- Plating area calculations and current density settings
- Copper foil thicknesses and etch rates
- Router-file location and revision levels
- Electrical test programs
- Quality control procedures and coupon disposition
- Final packing and shipping instructions

**20.6.6.1 AOI Files.** The CAD reference files, if required, are generally created at the PCB manufacturing site. These files prepare automated optical inspection (AOI) systems with data that confirm that manufactured pieces match, within tolerances, the PCB design.

**20.6.6.2 Lamination Parameters.** Each multilayer stack-up and material may require specific lamination processes. Modern multilayer presses have microprocessor-controlled time, temperature, and pressure. These parameters require selection in the tooling process.

**20.6.6.3 Drill Files.** Drill files and the respective drill bit tools must be archived and available for download to the appropriate drilling machine when production needs them. Drill bit preparation precedes the actual drilling operation in order to create the drill cassette.

**20.6.6.4 Plating Coefficients.** Plating requires specific direct currents (DC) to be applied to this part. The current density of the appropriate plating bath is multiplied by the plated area on each production rack. After the first actual run, direct measurement of the plated metals is used to adjust the plated area to achieve the correct thicknesses.

**20.6.6.5 Routing Files.** Router files and the respective router cutting tools have to be archived and available for download to the appropriate routing machine when production needs them. Router tool preparation precedes the actual routing or secondary drilling operation in order to create the final fabrication cassette.

**20.6.6.6 Electrical Test Programs and Fixture Creation.** An electrical test netlist file may be either created internally from the artwork or prepared from a supplied IPC-D-356 file. This test file has to be compared to the netlist extracted from the artwork supplied. Any difference must be resolved before the actual electrical test file is finalized. In addition, the electrical test fixture must be constructed or sent to an outside contractor to prepare.

**20.6.6.7 CAD to Assembly Processes.** The assembly tooling operations include CAD interfacing to component data and BOM. These operations include the generation of manufacturing documentation (see Fig. 20.16) and assembly engineering for component machine management, program optimization, and line balancing (see Fig. 20.17).

## 20.7 ADDITIONAL PROCESSES

Because of variations in the PCB manufacturing process, additional CAM-tooling operations may be required. Variations in manufacturing that may call for additional tooling include the following:

- Rivet lamination versus pin lamination
- Laser drilling
- Multiple panel sizes
- Very large lamination presses (48 in. × 48 in.)
- A very high degree of automation

New processes or PCB product features that may require additional tooling processes include the following:

- Embedded passives
- Embedded waveguides

Embedded passives and embedded waveguides are complicated to implement in production. Alignment and overlap are critical. Proper scaling for the particular embedded materials is especially important, depending on whether the materials are additive or subtractive. Figure 20.18 shows some of the critical tooling dimensions.

**FIGURE 20.18** Critical tooling data for embedded passives.

An important step in all the processes already defined is the necessity for proper information management. Archival of PCB customer-supplied information and the files generated from the tooling process are critical for disaster recovery. Archiving systems available on the market also provide for centralized data management and distribution of the information to the various departments within an organization.

### 20.7.1 Macros

Macros (or scripts, as they are sometimes called) are used to automate tooling operations. Most modern CAM systems come with the facility to create, edit, debug, and exercise macros. One example of a macro was shown in Fig. 20.9. This macro automatically scans all the CAM information (artwork and NC files) and reports minimum, maximum, and critical geometries.

### 20.7.2 Design-to-Fab and Assembly Automation

Although a vast number of sophisticated CAD and CAM software packages are available today, experienced operators are still needed to exercise this software. During the era of captive printed circuit manufacturing by original equipment manufacturers (OEMs), internally developed software tools were created that actually automated the entire CAM tooling process. This level of automation was made possible through the development of software that automatically created drill, rout, fabrication, and panel drawings and manufacturing notes from the CAD database. In doing all this, the software captured in a digital header file all the pertinent information on the drawings. The header file could then automatically supply macros that would complete all the tooling. Although this software was never extended to the commercial market, today new automatic blueprint creation software is available that works off of the CAD database.

## 20.8 ACKNOWLEDGMENT

I would like to thank Jeff Miller, WISE Software Solutions ([www.wssi.com](http://www.wssi.com)), DownStream Technologies ([www.downstreamtech.com](http://www.downstreamtech.com)), and Julian Coates of Valor, Inc. ([www.valor.com](http://www.valor.com)) for their invaluable contributions to this chapter.

# CHAPTER 21

---

# EMBEDDED COMPONENTS

---

**Dennis Fritz**

*MacDermid Incorporated, Waterbury, Connecticut*

---

## 21.1 INTRODUCTION

---

Historically, electrical components have been mounted on the outside of printed circuit boards, either with through hole leads or with terminations all on a single side (surface mount) with the interconnection traces embedded inside the board. Technology, however, has been developed to embed electrical components inside the board also. The earliest components to be embedded were resistors, which are made by etching a pattern on a sheet of resistive material and then connecting them with the rest of the circuit through the standard multilayer process. In addition, capacitors are formed from thin dielectric material between closely spaced copper-foil planes, and inductors are formed by etching coils of the copper conductive foil during innerlayer manufacture. These fabrication techniques have expanded to include the ability to “place” small, discrete passive components inside the board. This allows the normal multilayer board pressing operation to encapsulate these placed components.

---

## 21.2 DEFINITIONS AND EXAMPLE

---

- **Components** These are the electrical units that make up all electrical devices.
- **Passive components** These components—including resistors, capacitors, or inductors—influence electrical flow in a circuit, but do not cause a gain in current or voltage.
- **Active components** In contrast, these components can provide gain in an electronic circuit.
- **Integrated passive arrays** Multiple passive devices may be packaged in either a leaded or surface-mount technology (SMT) package or sometimes in arrays of all the same value. *Integrated passive component* is a general term for multiple passive components that share a substrate and packaging. Most typically, integrated passives are on the surface of a separate substrate that is then placed in an enclosure and surface-mounted on the primary interconnect substrate, in which case they are called *passive arrays* or *passive networks*. This chapter discusses only embedded components.

- **Embedded components** Components formed or inserted inside the primary interconnect substrate are said to be embedded. Embedded components can be either passives or actives (see the preceding definitions).
- **Formed components** A component that the circuit board fabricator manufactures inside the primary interconnect substrate (as opposed to on the surface) is said to be *formed*. Such components are made from raw materials at the same time as the board.
- **Placed embedded components** In contrast to formed components, components (both discrete passives and small actives) can also be “placed” inside the board using conventional placement machines and technologies. This manufacturing technique integrates very well with the “any layer via” type of construction.

See Fig. 21.1 for a cross section of a multilayer board with all types of embedded components.

**FIGURE 21.1** Cross section of a multilayer board showing the use of all types of embedded components, both passive and active. (Courtesy of Jisso International Council [JIC].)

## 21.3 APPLICATIONS AND TRADE-OFFS

Embedding components is not appropriate for all electronic packaging. A board designer must consider several factors when deciding whether to use embedded components or not. Use of discrete components, whether on the surface or placed inside the board, involves incremental costs in that the more components that are used, the higher the cost. However, the trade-off is that the cost of fabricating one formed embedded component is about the same as that of forming an entire layer of those components. Another factor to consider is that surface-mount components can have the same size and shape for widely differing electrical values. Formed embedded components on a single layer are larger and can increase electrical value. Widely differing electrical values may require more than one layer of embedded formed material.

### 21.3.1 Advantages

Advantages from embedding components inside the board include:

- **Reduction in board area (enabler)** Reduction in surface area results in more circuits per fabrication panel. Reduction in board size can yield a smaller board for the same functions, as components are now inside the board.

- **Increase in functionality, higher density (enabler)** The surface area is the same, but some other function can be added. For example, the designer can increase cell phone capability by adding a Bluetooth connection to the ear piece receiver.
- **Improvement in performance (enabler)** Higher speeds, shorter paths, and lower noise are possible. For example, cell phones can be enhanced with built-in digital cameras or even video cameras.
- **Improvement in total assembled costs** System cost is key; the higher board price is often offset by a lower bill-of-materials purchased for the system, as fewer standard components are needed.

### 21.3.2 Disadvantages

Disadvantages of embedding components include:

- Quality can be affected; in particular, meeting tolerances can be more difficult.  
Trimming embedded resistors is slow and expensive.
- Design tools are lacking.  
The design is “parametric” where designer sizes components.
- Technology implementation does not give all values needed.  
Some capacitance values are not obtainable commercially ( $>100$  nF/cm<sup>2</sup>).  
Manufacturers of sheet resistor materials make only one decade of values.
- The cost of prototypes can be high.  
Resistors cost the same whether one or thousands are made per layer.
- Test tools are lacking.  
Test voltages may cause dielectric breakdown.  
Charge-up time for capacitors may limit test speed.
- Rework is not possible inside the board.
- Additional capital investment is required.

### 21.3.3 Principles of Cost Trade-Off

The circuit design tools identify the resistors and capacitors that must be added to make an electronic circuit functional. The tools simulate circuit operation and “size” the resistors and capacitors as appropriate. Whether a resistor is purchased and mounted on the board surface or formed inside the board from a layer of resistive material has little effect on the electrical operation of a circuit. Therefore, if many resistors can be formed inside the board from the same series of chemical steps, the inclusion of perhaps thousands of internal resistors costs no more than adding one internal formed resistor. The critical economic analysis is to find the cost of adding internal formed resistors and then dividing by the number that can be used internally to see whether embedded resistors inside the board make sense.

## 21.4 DESIGNING FOR EMBEDDED COMPONENT APPLICATIONS

---

### 21.4.1 Resistors

Resistors were the first component to be embedded in a multilayer board, making it a truly three-dimensional interconnection and circuit system. While early designs were custom for

each application, over time design standards and “best practices” have been developed, which allow for successful inclusion of resistors, and other components, without the need to start from the beginning. The following discussion provides these for resistors, with subsequent sections providing similar information for other components.

**21.4.1.1 Resistor Terminology.** The designer must size embedded formed passive resistors. This is in contrast to the “library selection” of conventionally manufactured resistors that are selected from a table of available components. The principle of embedded resistors is given by the following formula for a term *ohms per square*; this means that any square area defined in the material will have the same resistance and that by grouping squares appropriately, the designer can define the resulting resistance.

Resistance in any resistor is determined by Eq. 21.1

$$R = \rho L/A \quad (\text{Eq. 21.1})$$

where  $R$  = resistance in ohms

$\rho$  = resistivity in ohm meters (inches)

$L$  = length of the resistor

$A$  = cross-sectional area (resistor thickness times resistor width)

*Note:* Resistivity ( $\rho$ ) is a material property. It is a constant at a given temperature and expressed in resistance units (ohms) for area and length. For instance, the resistivity of copper is  $\rho = 7.09 \times 10^{-7}$  ohm in.<sup>2</sup>/in.

Sheet resistance is a commonly used term to describe raw materials used in embedded formed resistors. These materials are manufactured in sheet form with a constant thickness, giving a uniform  $R$  value for any square resistor. Therefore, the material is specified by its sheet resistance value, given in ohms/square ( $\Omega/\square$ ). The resistance of a specific resistor is simply designed by changing the ratio of length to width. For instance,  $100 \Omega/\square$  material forms a 100 ohm resistor in any square configuration. A resistor three squares long by one square wide would be  $300 \Omega$ , and a resistor two squares wide by one square long would be  $50 \Omega$ .

**21.4.1.2 Resistor Design Parameters.** The circuit board designer is responsible for sizing the resistor to give the appropriate value. Material suppliers have given their sizing parameters to computer-aided design (CAD) software companies for entry in their component libraries. Also, manufacturing tolerances for each supplier product have been communicated to computer-aided manufacturing (CAM) suppliers. Figure 21.2 gives typical design parameters for sizing both the active embedded formed resistor area and the termination pads for the traditional copper innerlayer upon which the resistor is built.

## 21.4.2 Capacitor Design

All production formed capacitors use laminate-like materials. Most typically, the capacitor manufacturer starts with an especially flat copper foil on at least one side. This copper foil is precisely coated with the dielectric material: filled polymer. Either the top foil electrode is then laminated or two layers of coated foil are bonded polymer to polymer.

**21.4.2.1 Capacitor Terminology.** Capacitors are electrical elements that store charge on parallel electrode plates. They are not batteries that operate chemically. Capacitors store more charge with closer parallel plates, and the higher the dielectric constant, the more charge is stored.

Embedded passives-designing for the future

**FIGURE 21.2** Resistor terminations.

Again, the value of embedded capacitors must be designed to the correct size. The value of a formed embedded capacitor is given by the Eq. 21.2.

$$C = A \times D_k \times K/t \tag{21.2}$$

where  $C$  is the value of the capacitor  
 $A$  is the area of the planar capacitor  $L \times W$   
 $D_k$  is the dielectric constant of the capacitor material  
 $t$  is the thickness between the capacitor plates  
 $K$  is a conversion constant =  $8.854 \times 10^{-14}$  Farads/cm

**21.4.2.2 Capacitor Design Parameters.** Similar design tolerancing for capacitor design parameters (compared to resistors in Sec. 24.4.1) is available for capacitors, as shown in Fig. 21.3.

**FIGURE 21.3** Capacitor design features.

Even conventional epoxy glass laminate has some capacitance value, and the oldest formed embedded capacitors were carefully controlled thin conventional glass/epoxy laminate layers. Both epoxy resin and E-glass have dielectric constants of about 4, not a particularly large value. However, by eliminating the glass and adding compounds such as barium-titanate to the epoxy or polyimide resin, dielectric constants can be improved to the 10 to 20 range. If really high capacitance values are needed, ceramic or inorganic compositions must be used. Newer technologies demonstrate dielectric constants in the 100 to 2,000 range, capable of forming large value capacitors inside the circuit board. These larger capacitors are useful for decoupling, one of the largest uses of capacitors.

Thickness is the divisor in the capacitance formula. The smaller the dielectric thickness, the higher the device capacitance. Early formed embedded distributed capacitors simply used the readily available 100 micron (4 mil) epoxy/glass innerlayer construction, common in multi-layer circuit boards. Then, thinner woven glass allowed 50 micron glass/epoxy layers, doubling the device capacitance. Finally, polymer only or barium-titanate-filled polymer demonstrated thicknesses down to 8 microns, improving capacitance 6 to 20 times the value of the original 100 micron epoxy glass. With the thinner materials comes a higher price tag for precision laminate manufacture and special fabrication/handling techniques. The cost/benefit analysis is a trade-off between these premium materials and the smaller-size/higher-capacitance values of the filled polymers.

### 21.4.3 Inductors

Inductors use the magnetic effects of electrons traveling in wires to influence the travel speed of other electrical signals. Typically inductors are a coil configuration. No special material technology has been demonstrated for inductors. These spirals of copper circuitry are typically formed similarly to the copper-conductive traces of innerlayers. Again, design software must determine the line width, length of the coil, and the number of “turns” of copper to size the proper inductor.

## 21.5 MATERIALS

---

### 21.5.1 Resistor Materials

Resistors, discrete or formed, are actually very poor electrical conductors when compared to copper. Their function is to restrict the flow of electricity in a circuit. Common compositions of resistors include metal oxides, carbon particles, or small conductive particles separated widely by an organic polymer. Conventionally, the value of a resistor is rated in ohms ( $\Omega$ ), with higher values restricting more current. Also, resistors are sized by tolerance in percentage, allowable maximum current, and parameters that deal with the electrical frequency of operation.

Material suppliers have designated the range of resistance values that are optimum for their material. The designer determines the length and width that is allowable in the design, and then determines which material to specify for manufacture so that the final resistor value is achieved in the allocated circuit board space.

Formed embedded resistors of similar values are designed on one specific layer so that the maximum economic value is achieved for that layer.

Materials are also available that can combine mixed values of resistance on one layer. Polymer thick films (PTF) are applied by successive screen print/cure cycles so that all the desired resistance values can be made on one layer. Also, some sheet capacitance manufacturers laminate a layer of resistor foil as one electrode in their construction. Therefore, a fabricator can mix resistance and capacitance on one sheet type raw material.

## 21.5.2 Resistor Fabrication Details

Several different raw materials and processing systems are used to fabricate embedded resistors. The most commonly used are listed in this section.

**21.5.2.1 Photoprint.** Photoprint involves a supplier coating a thin, resistive layer on a copper-foil sheet and selling this to either a laminate supplier or directly to the board fabrication shop. The fabricator uses two imaging and etching steps: the first to image the copper conductors on the layer, and the second to size individual resistors by using a second, different etchant solution, specifically for the resistor composition. Typically, alkaline etchants are used in step one, and acidic etchants are used in step two.

**21.5.2.2 Screen or Stencil Print.** Screen or stencil print is the operation of adding specific resistive paste compositions directly to the etched innerlayer. Polymer compositions (PTF) are cured directly at normal board exposure temperatures (150–200°C). Ceramic compositions cure at much higher temperatures (900°C), so the sequence of manufacturing operations is changed. Copper foil first has the uncured ceramic paste screened. Then firing of the paste occurs in a nitrogen blanketed oven. The foil, with cured ceramic resistors, is laminated to B-stage epoxy, and the epoxy layer cured to C stage with resistors pressed into the resin. Finally, the innerlayer copper traces are etched, exposing the embedded ceramic resistors.

**21.5.2.3 Plating.** Plating is an additive process where the copper layer is first etched. Then the layer is catalyzed for electroless plating, and photoresist is applied. Resistor locations are imaged into the resist and the pattern developed. Exposed catalyst in the proper areas then initiates plating of the resistors. The resist is stripped, background catalyst is removed, and the resistors are in the proper locations.

**21.5.2.4 Inkjet Printing.** Inkjet printing is the additive process of applying appropriate resistor materials (usually PTF-type compositions) directly to etched innerlayers. Resistors are applied one at a time, in contrast to the mass screening of conventional PTF. It is also possible to print several resistor value compositions before a final single cure step.

**21.5.2.5 Photoimageable Discrete.** In a photoimageable discrete process, resistive compositions have been dispersed in traditional solder mask–like materials, which are applied to the surface of an etched layer. Imaging and development leave the desired geometry resistor after the development step.

**21.5.2.6 Resistor Trimming.** Resistor trimming is a necessary step. All of the resistors given here have been shown trimmable to very precise values. This is normally done with a modified laser machine, adapted from trimming ceramic surface mount discrete resistors. Either the machine uses a probe card pattern to measure the values of a number of resistors at one time or it uses a flying probe technology from electrical test to measure and trim a single resistors. The flying probe system is used in hybrid circuit manufacture, and the probe card system is standard for arrays of resistors from discrete component suppliers. An interpretation of the laser trim process is shown in Fig. 21.4.

## 21.5.3 Capacitor Fabrication

Normally, embedded formed polymer capacitors are made from purchased sheet materials. It is difficult for the board fabricator to apply a liquid dielectric formulation precisely to laminate, but one photolithographic capacitor formation technique has been developed. Unneeded dielectric is removed with a developer solution similar to liquid photoimageable solder mask.

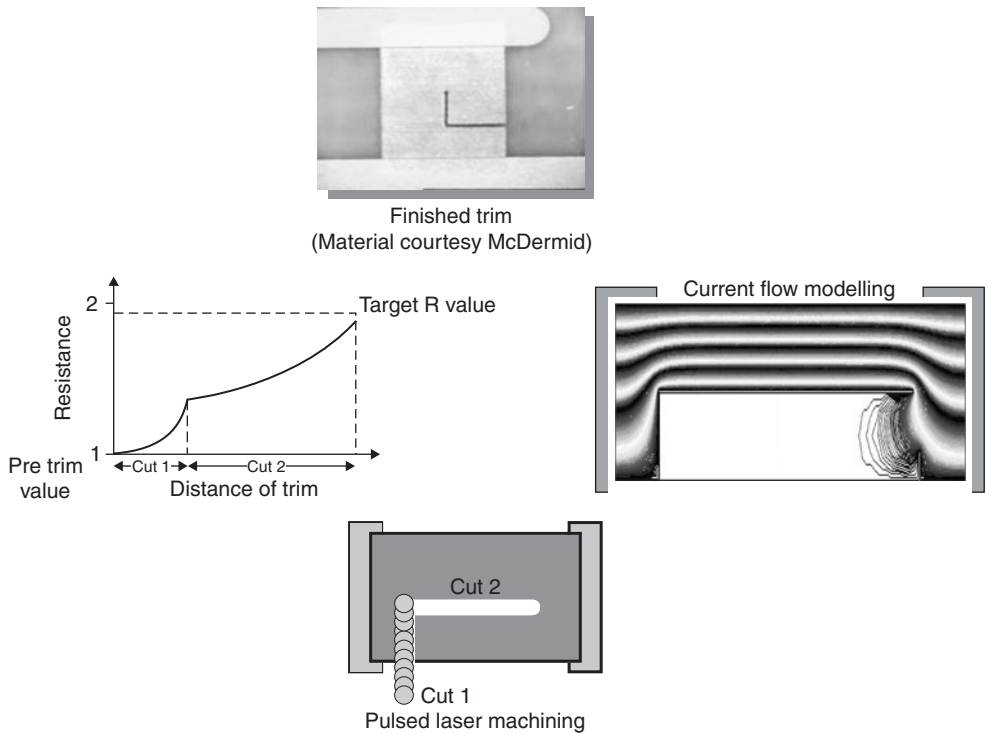

FIGURE 21.4 Resistor trimming.

Embedded formed ceramic capacitors have been demonstrated, but the cure step for the ceramic capacitor composition (900°C) may limit this technology to very large shops that install the “cure on copper foil” technology also needed for ceramic resistors.

#### 21.5.4 Inductor Fabrication Process

Formation of inductors simply involves the design in copper circuitry, and then careful imaging and etching to ensure close tolerance conductors.

#### 21.5.5 Active Integrated Circuit Fabrication

Manufacture of formed embedded active devices has been demonstrated, but not produced commercially. An example is polymer semiconductor radio frequency identification (RFID) tags. Conventional RFID devices, now in mass production, use a tiny silicon integrated circuit, made conventionally and bonded to the antenna. Semiconducting polymers make up the source, drain, and gate of the integrated circuit and are applied by inkjet or screen printing.

## 21.6 MATERIAL SUPPLY TYPES

### 21.6.1 Resistor Materials

Formation of the resistor by the designer, working with the board fabricator, involves making a material selection. All resistor values are not possible with each raw material technology. Table 21.1 shows the various forms of the raw resistor material.

**TABLE 21.1** Embedded Formed Resistor Supplier Types

Process	Technology
Photoprint (Sheet resistor material)	Thin-film etch (NiCr, Pt, NiP)
Screen or stencil print	Polymer thick-film addition (PTF) Ceramic thick-film addition (CTF)
Plating	Selective addition
Inkjetting	Selective addition
Photoimageable discrete	Photopolymer (filled)

Table 21.2 gives the range capability of the various resistor manufacturing technologies.

**TABLE 21.2** Embedded Formed Resistor Ranges

Resistance in Ohms	10	100	1,000	10e4	10e5	10e6
Photoprint (NiCr, NiP)	X	X	X			
Photoprint (Pt)		X	X	X		
Screen or stencil print (PTF)	X	X	X	X	X	X
Screen or stencil print (CTF)	X	X	X	X	X	X
Plating	X	X	X			
Inkjetting	X	X	X	X		
Photoimageable discrete	X	X	X	X		

Where materials are sold in foil form or plated, only one value of resistors can be produced per layer. Since the resistive material is consistent across the panel, the final value of the finished resistor is determined by the length-to-width ratio. If the resistive material is made at 100 ohms per square properties, a resistor that is one unit wide and five units long will have a value of 500 ohms. Or, if the resistor is one unit long and five wide, the value will be 20 ohms. Practical resistor ranges evolve from the basic properties of the starting foil material.

Paste compositions, both polymer and ceramic, can have different dispersions of resistive particles, thus giving widely variable resistance values. However, to limit manufacturing steps, selection of certain paste values, usually 10 to 15 times apart, are used. Thus, a design with resistors from 10 ohms to 100,000 ohms could use pastes of 100  $\Omega/\square$ , 1,000  $\Omega/\square$  per square, and perhaps 50,000  $\Omega/\square$ .

A graphical representation of various formed resistor configurations is shown in Fig. 21.5.

### 21.6.2 Capacitor Materials

Capacitors are needed in a great range of values. Capacitors may be the conventional “discrete” or a whole capacitance sheet may be used—*distributed capacitance*. Distributed capacitance is quite useful electrically, when high-speed integrated circuits need voltage immediately to turn on or off. The distance to voltage planes may in fact be too long in some designs to allow efficient electrical operation of very fast integrated circuits.

FIGURE 21.5 Embedded formed resistor configurations.

Since the area used to make the formed embedded capacitor can vary, to compare the capabilities of each technology, we must choose a standard area. Therefore, the capacitance at 1 sq. cm is convenient, as shown in Table 21.3.

Capacitor values typically vary from a picofarad to a few microfarads. Thus, low picofarad applications in timing, decoupling, and filtering are the best applications for formed embedded capacitors inside circuit boards.

TABLE 21.3 Embedded Formed Capacitor Technologies

Process	Technology	Dielectric Constant	Micron Thick	Capacitance of a 1 sq. cm Area
Etched copper planes	FR-4/glass, copper clad laminate	4.5	50	78 pF/cm <sup>2</sup>
	Polyimide (filled) copper-clad laminate	11.0	14	156 pF/cm <sup>2</sup>
	Polyimide (unfilled) copper-clad laminate	3.5	25	700 pF/cm <sup>2</sup>
	Proprietary dielectric (filled) copper-clad laminate	4.2	24	122 pF/cm <sup>2</sup>
	Epoxy (filled) copper-clad laminate	15	12	140 pF/cm <sup>2</sup>
	Ceramic thick-film	1500	16	310 pF/cm <sup>2</sup>
				850 pF/cm <sup>2</sup>
Screen or stencil printed discrete			25	93 nF/cm <sup>2</sup> (93,000 pF/cm <sup>2</sup> )
Photoimageable discrete	Photopolymer (filled)	22	11	1.5 nF/cm <sup>2</sup> (1,500 pF/cm <sup>2</sup> )
Emerging	Sol gel formation	150	0.5	150–300 nF/cm <sup>2</sup>

## CHAPTER 22

---

# INTRODUCTION TO HIGH-DENSITY INTERCONNECTION (HDI) TECHNOLOGY

---

**Happy T. Holden**

*Mentor Graphics, Longmont, Colorado*

---

### 22.1 INTRODUCTION

---

The use of more complex components with very high input/output (I/O) counts has pushed the board fabricator to reexamine techniques for creating smaller vias, and many new or redeveloped processes have appeared on the market. These processes include revised methods of creating holes, such as laser drilling, micro-punching, and mass etching; new methods for additively creating dielectric with via holes using photosensitive dielectric materials; and new methods for metallizing the vias such as conductive adhesives and solid post vias. All of these methods share some common traits. They all allow the designer to increase significantly routing density through the use of vias in surface-mount technology (SMT) pads, to reduce size and weight of product, and to improve the electrical performance of the system. These types of boards are generically called high-density interconnects (HDI). An HDI board typically will have, as an average, over 110 to 130 electrical connections per square inch (20 connections per sq. cm) on both sides of the board.

---

### 22.2 DEFINITIONS

---

Printed wiring boards (PWBs) with microvia hole structures are called different names, such as HDI, SBU (sequential build-up), and BUM (build-up multilayer). However, HDI covers a broader range of high-density wiring boards such as extremely high-layer-count multilayer boards (MLBs) without microvia holes. MLBs with microvia holes are not necessarily built sequentially, nor do they necessarily have build-up structures. These definitions are not appropriate for the discussions in this chapter, and therefore we shall address MLBs with microvia holes simply as *microvia hole boards* (all microvia hole boards are essentially multilayer boards).

Some trade and academic organizations define the microvia hole to be a hole of a certain diameter or less. For example, IPC defines a microvia hole as a hole with a diameter equal to or less than 150  $\mu\text{m}$ . However, when a surface blind via (SBV) hole is formed between layer 1 (L1)

and layer 3 (L3), the diameter of such a hole is typically 250  $\mu\text{m}$  in order to facilitate reliable plating, but the hole is still considered a microvia hole. Since all microvia holes are essentially SBVs and are normally small in diameter in order to increase circuit density, it seems more appropriate to define the microvia hole as an SBV without limiting its diameter. As long as a hole has SBV structure, it is defined as a microvia hole throughout this chapter.

The first microvia PCB in general production: (a) Hewlett Packard's FINSTRATE was put into production in 1984. It was a copper-core, build-up technology that had direct wire-bonded integrated circuits (ICs). After laminating layers of plasma-metallized polytetrafluoroethylene (PTFE) to the copper core, vias were mechanically drilled through the copper core and then insulated with PTFE. Additional through holes were then drilled along with 5 mil blind vias. (b) The first photodielectric microvia board was produced in volume in Japan by IBM-Yasu. This is the SLC technology with two build-up layers on one side of the four conventional FR-4 layers. These can be seen in the 5th Edition of the PCB Handbook, Fig. 21.1.

### 22.2.1 HDI Characterization

This generation of printed boards is characterized by very small blind, buried, and through vias made by techniques other than mechanical drilling. To turn blind vias into buried vias, these process techniques are repeated and the layers are "built up," hence the name *build-up* or *sequential build-up circuits (SBU)*.

This type of printed circuits actually started in 1980, when researchers started investigating ways to reduce the size of vias. The first innovator is not known, but some of the earliest pioneers include Larry Burgess of MicroPak Laboratories (developer of LaserVia), Dr. Charles Bauer at Tektronix (who produced photodielectric vias),<sup>1</sup> and Dr. Walter Schmidt at Contraves (who developed plasma-etched vias). Laser-drilled vias were used in mainframe computer multilayers in the late 1970s. These were not as small as the laser-drilled vias today and were produced only in FR-4 with great difficulty and at great cost.

The first production build-up or sequential printed boards appeared in 1984, starting with the Hewlett Packard laser-drilled FINSTRATE computer boards, followed in 1991 in Japan with Surface Laminar Circuits (SLC)<sup>2</sup> by IBM and in Switzerland with DYCOstrate<sup>3</sup> by Dyconex. Figure 21.1 in the 5th Edition of the PCB Handbook shows one of those first Hewlett Packard FINSTRATE boards and one of the first IBM SLC boards.

Since the introduction of SLC technology in 1991 (see Chap. 5; Fig. 5.5), many variations of methods for mass producing HDI wiring boards have been developed and implemented. However, if one technology is to be picked as a winner judged in terms of volume produced, laser-drilling technology is the one. Other methods are still used by a number of PWB manufacturers, but in a much smaller scale.

The purpose of this chapter is to examine a variety of microvia hole formation technologies, structures, and materials.

However, a greater emphasis will be placed on the laser-drilling process (*laser via* hereafter) since it is the most popular process today and it seems its popularity will grow in the future. It must be understood that via hole formation is just one element of fabricating HDI wiring boards. Fabrication of HDI wiring boards with microvia holes involves many new processes not common to conventional board fabrication. Therefore, additional emphasis will be placed upon these new fabrication processes that are common to other microvia technologies.

### 22.2.2 Advantages and Benefits

Four main factors drive printed boards to require higher wiring densities:

- More components can be placed on both sides of the printed circuit.
- Components are closer together.

- Size and pitch of components are smaller while the number of I/Os is increasing.
- Smaller geometries allow faster transmission of signals and reduce signal crossing delay.

At the same time, enhanced performance is required for faster signal rise times, reduced parasitics, reduction of radio frequency interference (RFI) and electromagnetic interference (EMI), fewer layers, and improved high-temperature performance and reliability. HDI provides all of these advantages and more.

### 22.2.3 HDI Traditional PCB Comparison

The interactions among printed circuit boards, components, and assemblies are best seen by the packaging technology map (see Chap. 2; Fig. 2.2). Components are characterized by the average I/Os per part, assemblies by the components per sq. cm and I/Os per sq. cm, and the printed circuit by its wiring density in cm per sq. cm. Fig. 22.1 shows the approximate crossover between the traditional printed circuit board and the next generation with microvias.<sup>4</sup>

**FIGURE 22.1** The through-hole density barrier. If the ends of an electrical net contain an SMT pad connected by a trace and a via hole, then there is only so many such connections (using conventional design rules' spacing) that can be placed in any square area. This *through-hole barrier* is shown crossing this technology roadmap. To cross the barrier (and prevent via starvation), the fabricator must stack vias using blind and buried vias and such.

### 22.2.4 Design, Cost, and Performance Trade-Offs

The HDI structure is cost-effective for higher-density assemblies shown throughout this chapter. The relative price of HDI versus relative density is depicted in Fig. 22.2. Cost parity (for similar wiring densities) is achieved with a four-layer HDI microvia at approximately an eight-layer, through-hole printed circuit multilayer. Wiring capacities and densities greater than an eight-layer multilayer can be achieved at a lower price with a properly designed HDI substrate. At very high densities, there are no through-hole multilayers that can meet the wiring capacities and density demand necessary, whereas HDI can easily meet the requirements.

**FIGURE 22.2** Relative price and density comparison between conventional through-hole (TH) boards and HDI microvia boards with different structures. The relative cost index (RCI) is actual production pricing of boards normalized to the eight-layer price. The density (DEN) is a measure of the maximum average pins (leads) per sq. in. (for both sides of the PCB). The diagonal lines are equivalent density boards. These are for FR-4 printed circuits.

### 22.2.5 Specifications and Standards

The Institute for Interconnecting and Packaging Electronic Circuits (IPC) has been working on standards and specifications for high-density interconnecting structures. Three standards and a guideline are the documents that are available from the IPC. The four documents are:

- **IPC-2315** “Design Guide for High Density Interconnecting Structures and Microvias”
- **IPC-2226** “Design Standard for High Density Interconnecting Structures and Microvias”
- **IPC-4104** “Standard for Qualification and Conformance of Materials for High Density Interconnection Structures and Microvias”
- **IPC-6016** “Standard for Qualification and Performance Specification for High Density Interconnection Structures”

The IPC standards that cover HDI design rules, materials, and specifications are:

- **IPC-2226** This specification educates users in microvia formation, selection of wiring density, selection of design rules, interconnecting structures, and material characterization. It is intended to provide standards for use in the design of printed circuit boards utilizing microvia technologies.
- **IPC-4104** This standard identifies materials used for high-density interconnection structures. A series of specifications (slash sheets) are defined for specific available materials. Each sheet outlines engineering and performance data for materials used to fabricate high-density interconnecting structures. These materials include dielectric insulator, conductor, and dielectric/conductor combinations. The slash sheets are provided with letters and numbers for identification purposes. For example, if a user wishes to order from a vendor and reference the specification sheet number 1, the number “1” would be substituted for the “S”

in the preceding designation example (IPC-4104/1). To start the ordering process, one can use the slash sheets in the IPC-4104 document in combination with relevant IPC documents for each material sets (e.g., IPC-CF-148, IPC-MF-150, IPC-4101, IPC-4102, IPC-4103, etc.).

- **IPC-6016** This document contains the general specifications for high-density substrates not already covered by other IPC documents.

### 22.3 HDI STRUCTURES

The IPC HDI Structure Subcommittee, which is responsible for defining performance requirements, used the following methodology to specify HDI products. Since a microvia can be any shape—including straight wall, positive or negative taper, or cup—determining the methods used for producing microvias can be segmented into three methodologies (A, B, or C), as noted in Table 22.1.

**TABLE 22.1** Ten Process Methods Utilized to Produce Microvias

Hole formation	Microvia process*
Mechanically drilled	A
Dry-etched (plasma)	A
Mechanically punched	A
Abrasive blast	A
Laser-drilled	A
Post-pierced	B
Photo-formed	A
Insulation displacement	B, C
Wet-etched	A
Conductive bonding sheets	C

\*A: create hole, then make conductive; B: create conductive via, then add dielectric; C: create conductive via and dielectric simultaneously.

All of these technologies provide approximately the same high-density design rules. These design rules endow build-up technologies with four to eight times the wiring density of conventional, all-drilled through-hole vias. The ten via profiles are depicted in Fig. 22.3.

**Mechanically Drilled - 1**   **Wet Etched - 2, 3, 6**   **Insulation Displacement - 8**  
**Mechanically Punched - 1**   **Dry Etched (Plasma) - 2**   **Conductive Paste Via - 9**  
**Laser Drilled - 1, 4, 5**   **Abrasive Blast - 3**   **Conductive Bonding Sheets - 10**  
**Photo Formed - 5, 6, 7**   **Post Pierced - 8**

**FIGURE 22.3** Representative microvia profiles and the processes that produce them.

The structure of the high-density interconnection is by type: Type I, Type II, Type III, Type IV, Type V, and Type VI (see Table 22.2). However, some of these type constructions are based on which microvia material is to be used. Thus, the following definition applies to all high-density interconnect substrates (HDIS).

**TABLE 22.2** Description of the 6 IPC HDI Type Structures of IPC-2226

Type I	1[C]0 or 1[C]1, with through-vias from surface to surface
Type II	1[C]0 or 1[C]1, with through-vias buried in the core and from surface to surface
Type III	$\geq 2[C] \geq 0$ , 2 or more HDI layers added to through-via in core or from surface to surface
Type IV	$\geq 2[P] \geq 0$ where P is a passive “substrate with no electrical connecting functions”
Type V	Coreless construction using layer pairs
Type VI	Alternate construction using conductive pastes

[C], printed circuit core; [P], passive substrate core; 0, 1, and 2, number of build-up layers on each side of the core [C] or [P].

The core, defined as [C], can be identified as an A, B, or C type core. Thus, [CA] is a core with internal vias only; redistribution makes contact with the surface. [CB] is core with internal and external (through microvia structures). High-density interconnecting structures make contact with the innerlayers of the core. [CC] is passive core, in which there are no interconnections.

**22.3.1 Construction**

Type I to Type VI constructions currently describe all known HDI build-up structures, but as the technology evolves, new ones are likely to be created. The notation used is as follows:

$$x[C]x$$

where  $x = 0, 1, 2, 3, \text{etc.}$  (that is, the number of build-up layers on that side of the core)  
 [C] = a standard laminated core of materials, with or without vias of  $n$  layers

**22.3.1.1 Type I Constructions.** This construction (1[C]0 or 1[C]1) describe an HDI in which there are both plated microvias and plated through holes used for interconnection. Type I constructions describe the fabrication of a single microvia layer on either one side (1[C]0) or both sides (1[C]1) of an underlined printed circuit substrate core. The printed circuit core substrate is typically manufactured using conventional printed circuit techniques. The substrate may be rigid or flexible and can have as few as one circuit layer or be as complex as a prefabricated multilayer printed circuit with buried vias. A single layer of dielectric material is then placed on top of the core substrate. Microvias are formed in the dielectric connecting layer 1 to layer 2 and layer  $n$  to layer  $n-1$ . Through holes are then drilled, connecting layer 1 to layer  $n$ . Then the microvias and through holes are metallized or filled with conductive material. Layer 1 and layer  $n$  are circuitized and fabrication is completed. Figure 22.4a shows this construction as illustrated in IPC-2226.

**22.3.1.2 Type II Constructions.** Type II (1[C]0 or 1[C]1) has the same HDI layers as Type I. The difference is the core, [C]. Type II allows through vias to be placed in the core before the HDI layers are applied. The processes are the same except for the cores through vias being

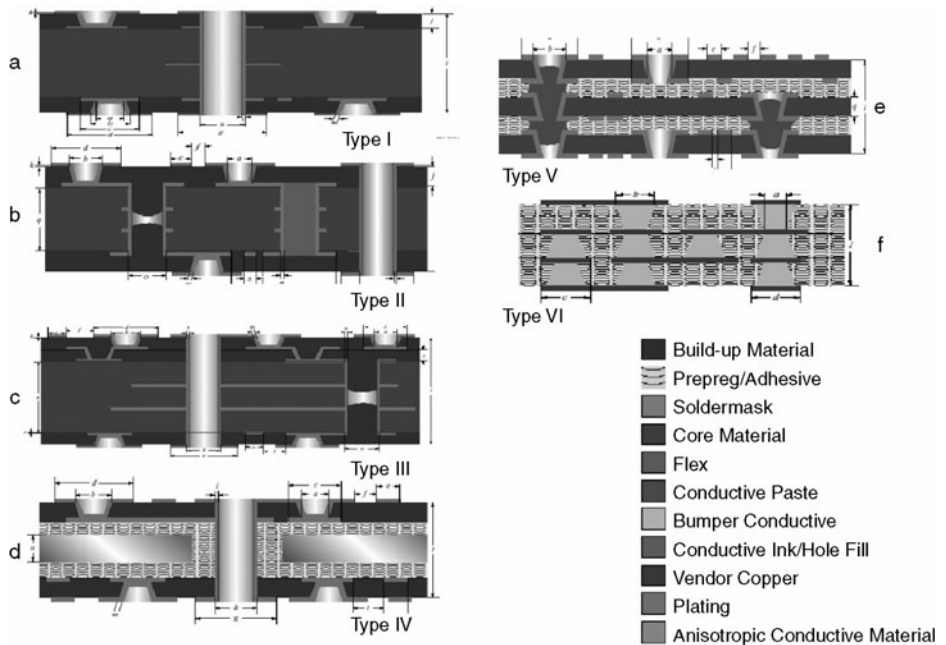

FIGURE 22.4 IPC-2226 microvia structures from Type I to Type VI.

filled before the HDI layers are applied. Figure 22.4b shows this construction as illustrated in IPC-2226.

**22.3.1.3 Type III Constructions.** This construction (2[C]0) describes an HDI in which there are both plated microvias and plated through holes used for interconnection. Type III constructions describe the fabrication of two microvia layers on either one side (2[C]0) or both sides (2[C]2) of an undrilled or drilled printed circuit substrate core. The printed circuit core substrate is typically manufactured using printed circuit techniques. The substrate may be rigid or flexible and have as few as one circuit layer or be as complex as a prefabricated multilayer printed circuit with buried vias. A single layer of dielectric material is then placed on top of the core substrate. Microvias are formed in the dielectric, connecting layer 2 to layer 3 and layer  $n-1$  to layer  $n-2$ . This first microvia layer is either metallized or filled with conductive material and then circuitized. A second layer of dielectric material is then placed on top of this circuitized layer and microvias are formed connecting layer 1 to layer 2 and layer  $n$  to layer  $n-1$ . Through holes are then drilled connecting layer 1 to layer  $n$ . The microvias and through holes are then metallized or filled with conductive material. Layer 1 and layer  $n$  are circuitized and fabrication is completed. Figure 22.4c shows this construction as illustrated in IPC-2226.

**22.3.1.4 Type IV Constructions.** This construction (1[P]0 or 1[P]1 or  $>2 [P] > 0$ ) describes an HDI in which the build-up layers are used over an existing drilled and plated passive substrate. The printed circuit or metal core substrate is typically manufactured using conventional

printed circuit techniques. This substrate may be rigid or flexible. Figure 22.4d shows this construction as illustrated in IPC-2226.

**22.3.1.5 Type V Constructions.** The Type V construction describes an HDI where there is no core. Both plated and conductive paste layer pairs are interconnected through a co-lamination process. The multilayer is created with an even number of layers (two-sided flex or rigid layer pairs) laminated together at the same time that the interconnections between the even and odd layer are made. This is not a build-up process; it is essentially a single-lamination-parallel process. Figure 22.4e shows this construction as illustrated in IPC-2226.

Layer pairs are prepared using conventional processes of etching, plating, drilling, and so on, or by conductive paste processes. The layer pairs are laminated together using B-stage resin systems or some other form of dielectric adhesive into which conductive paste vias have been placed.

**22.3.1.6 Type VI Constructions.** Type VI describes constructions of HDI in which the electrical interconnections and wiring can be formed simultaneously. Another variety forms the electrical interconnections and the mechanical structure simultaneously. The layers may be formed sequentially or co-laminated. The conductive interconnect may be formed by means other than electroplating, such as anisotropic films/pastes, conductive pastes, dielectric piercing posts, and so on. Figure 22.4f shows this construction as illustrated in IPC-2226.

## 22.3.2 Design Rules

The designer should be aware that not all fabricators have equal capabilities in the areas of fine-pitch imaging, etching, layer-to-layer alignment, via formation, and plating. For this reason, the HDI design guide categorizes design rules into two categories: the preferred producibility range and the reduced producibility range. For simplicity of design, this *Handbook* will further divide the design rules into three category ranges: A, B, and C, with A being the easiest to produce and C being the most difficult. If more stringent design standards are selected, the number of fabricators that can produce such a board is limited. Circuits produced with design rules in the A category will be easier to produce, will have higher yields, and therefore can be fabricated at lower cost. To keep costs at a minimum, you should select the design rules most appropriate for the application:

- **Category A** This specification allows conventional HDI processes to be used with relaxed tolerances. It should have the highest yield and lowest cost. It is estimated that 100 percent of HDI fabricators can meet these design rules.
- **Category B** This is the conventional HDI process. It is estimated that 75 percent of HDI suppliers can meet these design requirements under production conditions.
- **Category C** Top-level fabrication shops, representing 20 percent of the total HDI fabricators, can meet these design rules. Panel sizes are often reduced to increase yield, which increases the final cost. Production volumes are presently limited, with special attention required during the production process. These rules require smaller panels and more exotic fabrication techniques. They are generally required only in electronic packages, chip-on-board (COB), flip-chip interposers, or MCM applications. At present, yields are lower and costs are high. It is estimated that fewer than 20 percent of all fabricators can achieve these design rules in limited production or prototype volumes.

Typical HDI design rules are given in Fig. 22.5. This figure bridges the two design categories from the specification IPC-2226, "Design Standards for HDI and Microvias."<sup>5</sup> This is a Type III HDI structure.

Symbol	Feature	Category A micron [mil]	Category B micron [mil]	Category C micron [mil]
a	Microvia hole diameter at target land (as formed)	125 - 200 [5-8]	100 - 200 [4-8]	75 - 250 [3-10]
b	Microvia diameter at capture land (as formed, no plating)	350 / 14	300 / 12	250 / 10
b-1	via in SMT pad width	300 / 12	250 / 10	250 / 10
c	landing pad diameter	350 / 14	300 / 12	250 / 10
d-1	conductor/landing pad spacing on rigid innerlayer	125 / 5	100 / 4	75 / 3
d	pad to pad spacing on innerlayer	125 / 5	75 / 3	75 / 3
e-1	conductor line width on landing layer	125 / 5	100 / 4	75 / 3
e	conductor width on innerlayers	125 / 5	75 / 3	75 / 3
f	min. finished hole size - fhs (plated through-hole)	250 / 10	200 / 8	150 / 6
g, o	surface via pad (fhs + annular ring x 2)min. through-hole pad diameter	fhs + 350 / 14 600 / 24	fhs + 300 / 12 500 / 20	fhs + 250 / 10 400 / 16
h	trace spacing on rigid outerlayer	125 / 5	100 / 4	87 / 3.5
l	trace width on rigid outerlayer	125 / 5	100 / 4	87 / 3.5
k	fhs drill hole plane clearance on innerlayer (fhs + annular ring x 2)* surface conductor to unplated hole	250 / 10	200 / 8	200 / 8
n	min. unplated hole diameter	350 / 14	300 / 12	300 / 12
m-1	min. HDI dielectric thickness	75 / 3	62.5 / 2.5	50 / 2
ar	Min. aspect ratio, (m-1) / a	<1.0	1.0	1.0
z	min. board thickness	725 / 29	600 / 24	500 / 20
m	min. core thickness	100 / 4	62.5 / 2.5	50 / 2
p	min. prepreg thickness	100 / 4	62.5 / 2.5	50 / 2
	min. plated thickness	25 / 1	25 / 1	30 / 1.2

**FIGURE 22.5** Typical HDI design rules with corresponding dimensional symbols for IPC-2226 figures. Illustrated is an IPC Type III HDI structure for categories A, B, and C. (Source IPC-2226, “Design Standards for HDI and Microvias.”)

## 22.4 DESIGN

HDI and microvias place a new burden on printed circuit design. The various IPC types impose significant changes in the multilayer stack-up from a conventional board. But additionally, microvias can be implemented in many different ways and with different design rules. This section presents just a few of the design issues.

### 22.4.1 Multiple Layers of Microvia Holes

For interconnecting IC substrates with hundreds of I/O terminals, a single layer of microvia holes may not be sufficient to satisfy interconnection requirements. Double, triple, or even quadruple microvia hole layers may be necessary whether the board is a motherboard or a chip package substrate. When microvia holes are made only between adjacent layers (see Fig. 22.6), all three microvia processes—photovia, plasma via, and laser via—can be used. However, when a design requires microvia holes that must connect beyond adjacent layers—such as L1 and L3 (skipvia)—laser via processing is the only practical option.

**FIGURE 22.6** Microvia connections beyond adjacent layers.

## 22.4.2 Design Tools

Printed circuit design has become one of the most important functions in the electronic product realization process.<sup>6</sup> The demands on printed circuit design keep mounting. The reasons for this increasing demand include the following:

- To regain time for product schedules
- To lower the cost of fabrication and assembly
- To enable new area-array components, such as chip scale packages (CSPs), micro-BGA, and flip-chip interposers
- To decrease the time to market
- To improve electrical performance for high frequency and to reduce EMI

Bringing the process back under control requires a methodology that involves planning the printed circuit layout process with predictive wiring density models. The other benefits include reducing printed circuit fabrication and assembly costs.

**22.4.2.1 Required Features of HDI CAD Toolsets and Autorouters.** A partial list of features that computer-aided design (CAD) tools require to design HDI boards includes the following:

- Optimization of a mixed via by a router
- Autorouting of cost budget for mass via generation
- Buried or blind via control on the layer
- Via padstack control (landless)
- Staggered via control
- Pad within pad
- Blind via push/shove during manual routing
- Any angle routing
- Manufacturing process rules at all design phases
- Buried components

Some of these features have already been discussed in previous chapters.

**22.4.2.2 Autorouters.** Autorouters have been a part of printed circuit design systems for many years. An autorouter will automatically place vias and traces on the printed circuit based on the schematic and part geometries. Elaborate configuration menus drive the appropriate placement of these features. A special autorouter is required for HDI structures, because many HDI processes employ mass via generation as used for SLC technologies. These processes produce all the vias simultaneously and at any desired diameter. Since the cost of vias is rather insignificant, the autorouter should have the capability of achieving a near-zero via cost. When the routing is done, a different but more optimized design results.

## 22.4.3 Trade-Off Analysis

After a product has been partitioned, the circuit has been designed, and the components have been selected, the physical design must be planned with an eye toward achieving the lowest manufacturing cost while meeting all performance and operating boundary conditions. This is especially true for HDI designs. Conventional through-hole printed circuit design has not changed too much over the years. Finer geometries, more layers, and surface mounting have been added, but the conventional design process remains essentially the same. Microvias and HDI, however, introduce many changes to the design process and require new design rules

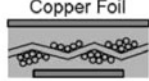

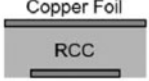

and layer structures. Experience and history will not help here. The unfortunate truth about printed circuit layout is that there is an almost infinite number of combinations of layer structures and design rules that can satisfy the schematic and bill of materials. With all these choices, especially the new ones that HDI offers, a trade-off tool is required to find the best set of design rules and features that allows the rapid design of a printed circuit board, is producible, and meets all the performance expectations while providing the lowest total manufacturing costs. When used early in the design process, before the actual physical design of the printed circuit, the tools require predictive models that can anticipate cost and performance. Information and processes for planning a HDI design can be found in Chap. 19 of this *Handbook*. Trade-off information of through-hole density and relative costs can be seen in Fig. 22.2.

**22.5 DIELECTRIC MATERIALS AND COATING METHODS**

This section provides an overview of the dielectric and applied conductive materials used in microvia and via filling. Some of these materials can be used in both IC chip carrier and PWB HDI applications. The discussions are focused on the HDI PWB arena and on materials for which information is readily available. In section 22.5.2, cross-references are made to the relevant material specifications of the IPC/JPCA-4104 specification for HDI and microvia materials. A brief material roadmap discussion is included to illustrate material property trends.

Figure 22.7 shows the compatibility of laser via, photovia, and plasma via methods with four basic surface dielectric structures on which microvia holes are to be formed. Although laser via methods can cope with all four dielectric structures, photovia and plasma via methods are applicable to only one structure, respectively, as shown in the figure. This is one reason why laser via is more widely used today. Another wiring layer is built over the existing microvia holes, which become buried via holes (BVHs).

	Standard Configuration 	RCC 	Thermally Curable Resin 	Photoimageable Resin 
Photovia	X	X	X	O
Laser Via, CO <sub>2</sub>	O	O	O	O
Laser Via, Yag	O	O	O	O
Plasma Via	X	O	X	X

**FIGURE 22.7** Compatibility of via hole formation methods with four basic dielectric layer structures.

The specification IPC-4104 will define material requirements for HDI applications. This IPC specification applies only to the *surface HDI layers*, the conventional multilayer core materials are covered by IPC specification IPC-4101B.

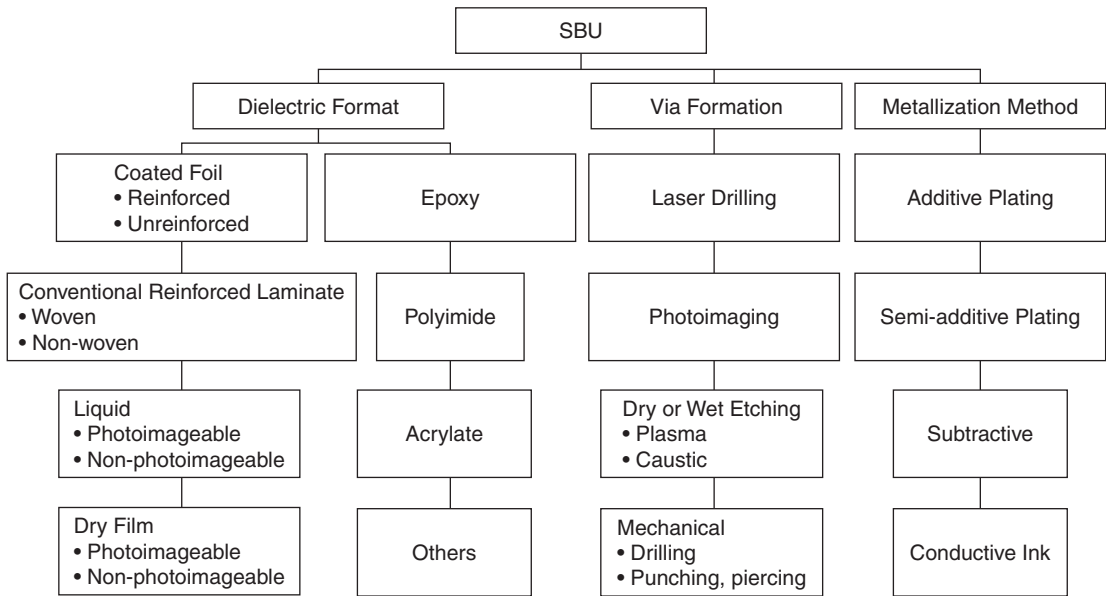

FIGURE 22.8 Material and technology choices for SBU fabrication. (Courtesy of DuPont.)

### 22.5.1 Materials for HDI Microvia Fabrication

Figure 22.8 shows a material and technology selection flowchart for use when choosing dielectric materials. In using the flowchart, you should ask the following questions regarding the dielectric you are considering:

- Will the dielectric use chemistry compatible with current chemistry used by core substrate material?
- Will the dielectric have acceptable plated copper adhesion? (Many original equipment manufacturers [OEMs] want  $\geq 6$  lb/in [1.08 kgm/cm] per 1 oz. [35.6  $\mu\text{m}$ ] copper.)
- Will the dielectric provide adequate and reliable dielectric spacing between metal layers?
- Will it meet thermal needs?
- Will the dielectric provide a desirable “high”  $T_g$  for wire bonding and rework?
- Will it survive thermal shock with multiple SBU layers (i.e., solder floats, accelerated thermal cycles, multiple reflows)?
- Will it have platable, reliable microvias (that is, will it have latitude to ensure good plating to the bottom of the via)?

**22.5.1.1 Copper-Clad Dielectric Materials.** Due to relative ease of implementation, copper-clad dielectrics are used on a larger scale than unclad dielectrics. Copper-clad dielectrics provide a method that requires the least number of changes in manufacturing flow because they typically use the same dielectric and reinforcements found in standard PWBs. Copper-clad-based materials have a longer history in making blind vias than any other method. This makes many designers, OEMs, and PWB fabricators more comfortable with copper-clad-based materials.

These materials can be nonreinforced or reinforced. The reinforcement can be woven or non-woven and can be aramid, glass, and so on. These dielectrics are suitable for via formation by laser or other mechanical removal methods.

Due to its wide availability and familiarity, FR-4 material is often initially evaluated in laser-drilling microvias. Reinforced with thin 106 or 1080 woven glass (since thicker glass is more difficult to vaporize with lasers, but there is 1086 uniform-woven glass just for laser ablation), one- or two-ply laminates are selected with a resin content close to 70 percent. The “laser drilling” is done by ablation of the via using a conformal mask or a directly focused beam, with either an ultraviolet (UV) Nd:YAG or a CO<sub>2</sub> laser. These materials may also be coated on a copper foil. Typical applications use single-side clad material where the copper clad is used as the outer layer and the C stage is bonded to the subcomposite. These materials are suitable for via formation using methods such as plasma or laser. To meet fine circuitry and smaller via needs, very thin copper is available. Another approach, practiced by many Asian PWB fabricators, is to thin down incoming copper clad by etching and/or planarizing the copper surface precisely.

**22.5.1.2 Unclad Dielectric Materials.** If the dielectric is reinforced, microvias are formed by laser drilling or other mechanical means. If it is nonreinforced, it can be photoimageable in addition to the previous choices. To add conductivity, subtractive processing is the standard manufacturing practice in the United States and Europe. Semi- or fully additive techniques have been practiced in continuous high volume only in Asia, most notably Japan. In Japan, which leads the world in microvia production, about 22 percent of manufacturing begins with a non-copper-clad dielectric material.

Japan has long accepted the additive manufacturing methodology for creating circuits on the board surface as well as the through-hole connection.

The trade-off between clad and unclad dielectric materials follows a benefit analysis similar to that used for subtractive versus additive processing. Copper-clad-based material is fabricated using standard practices familiar to most shops. However, it innately generates more waste and has a higher cost due to the subtractive nature of the manufacturing sequence. In addition, copper-clad materials demonstrate limitations in fine-line capability similar to those seen with standard manufacturing methods used today.

Unclad dielectrics require considerable resources for optimized plating of copper to achieve reliable and consistent copper peel strengths. Unclad dielectrics and thin copper-clad dielectrics, however, gain in importance as the requirements for line and space geometries reach  $\leq 75 \mu\text{m}$  and required via sizes are lower than  $75 \mu\text{m}$  in diameter. Figure 22.9 depicts the influence of base copper on the aspect ratio of a via. The base copper increases the aspect ratio, making it more difficult to plate the via, and can cause issues with bottlenecking whereby the via plates shut at the top without sufficient plating in the bottom. Other data show that thinner copper etches more uniformly, which helps the cause for controlled impedance.

**FIGURE 22.9** Impact of 1.2 oz. base copper on the aspect ratio of a 50 μm via. (Courtesy of Vantico.)

**TABLE 22.3** Utilization of Unclad Dielectrics by Key Market Segments<sup>4</sup>

	Chip package substrates	Cellular, camcorder, PDA	Computer/telecommunication*
HDI penetration	High	High	Low
Line/space and via diameter (year 2000)	50- $\mu\text{m}$ lines and spaces; 50- $\mu\text{m}$ via diameter	75- $\mu\text{m}$ lines and spaces; 100- $\mu\text{m}$ via diameter	100- $\mu\text{m}$ lines and spaces; 125- $\mu\text{m}$ via diameter
Use of unreinforced dielectrics	High	High	Low
Use of unclad dielectrics	High	Low, but increasing	Very low

\*Excluding laptop computers

**22.5.1.3 Clad versus Unclad Dielectric Materials.** Table 22.3 compares the utilization of clad versus unclad dielectric materials as circuit geometry shrinks. This table shows that as the technology requirements get tougher, the trend toward using unclad dielectrics increases. As line and space requirements get denser, and via diameters get smaller, requirements for chip package substrates to use unclad or thin copper dielectrics increase. In the case of mobile phones and other portable applications, for example, it is foreseen that by the year 2005 lines and spaces will be down to 50 to 75  $\mu\text{m}$ , respectively, and via sizes to 50  $\mu\text{m}$ , with a subsequent high usage of unclad material.

**22.5.2 Examples of HDI Microvia Organic Substrates**

From a mechanical standpoint, materials may be grouped as reinforced and nonreinforced laminates and prepregs, as in Fig. 22.8. Reinforced materials are generally better in dimensional stability, lower in coefficient of thermal expansion (CTE), and less sensitive to thermal cracking, whereas nonreinforced materials often have a lower dielectric constant ( $D_k$ ) and may be photoimageable. This can be seen in Fig. 22.10, which shows the  $D_j$  versus  $D_k$  (at 1 MHz) of various resins and reinforcements.

**FIGURE 22.10** Dielectric options of resins and reinforcements by dissipation factor ( $D_j$ ) versus dielectric constant ( $D_k$ ). (Source: Holden Consulting.)

**22.5.2.1 Nonreinforced Dielectric Materials.** Nonreinforced dielectric materials include resin-coated copper foils, unclad photoimageable dielectric materials, and non-photoimageable dielectric materials.

**22.5.2.1.1 Resin-Coated Copper Foils.** Resin-coated foils are the most common materials used for build-up multilayer microvia applications. Many product variations are available and fit well within the existing multilayer-manufacturing infrastructure. Epoxy-based coated foils are the most common and have performance properties similar to FR-4 but with no glass reinforcement. Peel strengths, thermal performance, and electrical properties are excellent. A variety of other resin systems are also being developed and starting to be used for coated foil build-up applications. Resin-coated foils come in two general types with either one or two resin layers. One-pass coated foils have a single B-stage layer designed to flow, fill, and provide thickness control at the same time. Two-pass coated foils have a C-stage resin layer adjacent to the foil and a B-stage layer for flow and fill. The fully cured C-stage layer acts as a “stop” during the lamination process, typically enabling better thickness control. Resin-coated foils are available in a variety of thicknesses, yielding between 1.0 mil (25 micron) and 3.0 mil (76 micron) thick, finished dielectric layers. Copper foils most commonly used are  $\frac{1}{2}$  oz. (18 micron) and  $\frac{3}{8}$  oz. (13.34 micron), but there is substantial interest in thinner copper foils for improved laser efficiency and better fine-line circuitry definition.

**22.5.2.1.2 Other Resins.** Since build-up technology is still in its relative infancy but evolving rapidly, many different and diverse approaches are being investigated for the resins used and variations on the via-formation process. Low- $D_k/D_f$  resins such as polyphenylene ether (PPE) are being used to address signal speed and integrity demands in resin-coated foil build-up structures. Another approach is to use additively plateable resin and use the copper as a sacrificial carrier, eliminating the need to laser through copper. An additively plateable resin has the characteristic of high surface adhesion to electroless copper or direct metallization. The sacrificial foil makes it compatible with normal multilayer lamination processes, saving the need for expensive coating machinery, while also protecting the thin dielectric from harm until it is laminated to the printed circuit. This also gives excellent surface topography for good peel strength. The properties of a resin-coated foil are given in Table 22.4. See IPC- 4104 specification sheets 12, 13, and 19 through 22 for more complete material performance information.

**TABLE 22.4** General Properties of Resin-Coated Copper (RCC)

	Units	Via foil	Conditioning
Dielectric constant at 1 MHz	—	3.4	C-24/23/50
Dissipation factor at 1 MHz	—	0.0205	C-24/23/50
Electrical strength	V/mil	1776	D-48/50
Insulation resistance	M $\Omega$	$2.65 \times 10^5$	C-96/35/90
Surface resistivity	M $\Omega$	$6.60 \times 10^8$	E-24/125
	M $\Omega$	$4.71 \times 10^8$	C-96/35/90
Volume resistivity	M $\Omega$ -cm	$7.17 \times 10^7$	E-24/125

Source: Allied-Signal

Laminate suppliers should be contacted when special needs arise, as the resulting composite will require understanding of fabrication and design issues.

Resin-coated foils come in two general types:

- One-pass coated foils have a single B-stage layer designed to flow and fill and to provide thickness control, all at the same time.
- Two-pass coated foils have a C-stage resin layer against the foil and a B-stage layer for flow and fill. The fully cured C-stage layer acts as a “stop” during the lamination process, typically enabling better thickness control.

With the exception of the laser process, all the basic technology to produce SBU using resin-coated foil is the same as, and found in, most multilayer PWB production operations.

Another alternative is to use additively platable resins. In this approach, the copper foil acts as a sacrificial carrier. The process is similar to that described earlier, but the first step after lamination is to etch off all the copper chemically. This eliminates the need to laser through copper and makes acquisition of registration targets simpler. The structure left behind by the copper also gives excellent surface topography to the resin for good peel strengths from the subsequent additive plating step. This approach allows for extremely fine feature definition and much greater laser efficiency.

**22.5.2.1.3 Unclad Nonreinforced Photoimageable Dielectric Materials.** Material chemistry options for this group include epoxies, epoxy blends, polynorborenes, and polyimides. They can be applied as liquid or dry film, negative or positive imaging, and can be solvent- or aqueous-developable. To improve the dielectric's adhesion to copper, most dielectric suppliers require a copper pretreatment with a black oxide or conversion coating (oxide replacement) prior to application of the dielectric. Most of these materials are either epoxy or epoxy- and novolac-based to provide high  $T_g$  and good plating, and most provide adhesion values for plated copper of at least 1.1 kg/cm at a 25  $\mu\text{m}$  copper thickness. Typically these dielectrics are metallized using conventional solvent swell and permanganate etching techniques. The liquid materials use only safe solvents (those not known to lead to harmful health effects with prolonged exposure. Typical microvias are seen in Chap. 23; Fig. 23.27. and Chap. 29; Figs. 29.5 and 29.12.

A unique advantage for photoimageable materials is that the speed used to make small or large vias is the same. With the growing need to make embedded reactivities (passives), large rectangular areas need to be opened up to place these devices. Currently, this is only economical with photoimaging. Most photoimageable materials are easy and fast to laser-drill because they are nonreinforced. See IPC-4104 specification sheets 1, 2, 7 through 10, and 16 for more complete material performance information. A partial list of available materials is shown in Table 22.5. Properties of photodielectrics can be seen in Tables 22.6 and 22.7.

**22.5.2.1.4 Nonphotoimageable, Nonreinforced Dielectric Materials.** This group can be laser-drilled, plasma-etched, and/or mechanically treated to form microvias. As stated earlier, many of the photoimageable dielectrics are laser-drillable.

As with the photoimageable group, to improve the dielectric's adhesion to copper, most dielectric suppliers require a copper pretreatment with a black oxide or conversion coating (oxide replacement) process. See IPC-4104 specification sheets 6, 11, 17, and 18 for more complete material performance information. A partial list of materials is seen in Table 22.8.

**22.5.2.2 Reinforced Dielectric Materials.** Copper-clad dielectrics for HDI can be reinforced, as in FR-4, or unreinforced, as in coated copper foil. The dielectrics can be epoxy, as in FR-4, or polyimide, cyanate ester, bismalene-triazine (BT), PPE, or PTFE. Reinforcements are typically glass cloth, but there are a variety of glass as well as aramid paper and exotic fibers such as quartz or carbon fiber.

**22.5.2.3 Laser-Drillable, Woven-Glass Laminate.** A new family of prepregs for HDI consists of uniform-glass prepregs such as 1086 and 1087 glass. This glass is a thinner fabric than the typical 1080 glass cloth; it has more glass plies but they are spread uniformly across

**TABLE 22.9** Comparison of Conventional 1080, 1080 LD, and the New 1086 LD Prepregs (*Courtesy of NanYa Plastics*)

Fabric type	Base weight (g/cm <sup>2</sup> )	Resin content	Warp × Fill (W + F)	Warp	Width	Fill	Width	Thickness	
				mm	mil	mm	mil	mm	mil
1080	48	62	60 × 48	0.19	7.48	0.264	10.39	0.057	2.24

the fabric. Table 22.9 describes the differences between the conventional 1080 glass cloth and the 1080 LD (laser-drillable) and the new 1086 LD prepreg. Figure 22.11 shows these two glass prepregs. Table 22.10 compares the performance of RCC, conventional 1080 prepreg (PP), and the new 1086 LD prepreg, whereas Fig. 22.12 shows laser-drilled microvias in the two different prepregs.

**FIGURE 22.11** Photos of conventional 1080 prepreg and the new laser-drillable 1086 LD uniform-glass prepreg. (*Courtesy of NanYa Plastics.*)

**22.5.2.4 Aramid-Reinforced, Non-Woven, Non-Glass Laminate.** In 1965, scientists at DuPont discovered a method for producing an almost perfect polymer chain extension using the polymer poly-p-benzamide. The key structural feature of this molecule is the paraorientation on the benzene ring, which allows it to form rod-like structures with a simple repeating molecular backbone. The term *aramid* now refers generically to organic fibers in the aromatic polyimide family. Kevlar was the first para-aramid fiber to become familiar, due to its use in bullet-resistant vests and as a lightweight, high-strength structural reinforcement. Aramid-reinforced prepregs and laminates have proven their functionality for a number of years in high-reliability applications and more recently in consumer electronics.

The low CTE of aramid non-woven reinforced prepreg and laminate provides a closer match to the CTE of the silicon chip. Depending on the type of resin and the resin and copper

content of the laminate and the prepreg, the CTE of the PWB can be tailored to between 10 and 16 ppm/°C (Fig. 22.13). This allows the designer the option of finding a best fit of the CTE of the PWB to the CTE of the components.

Reliability can be designed in by PWB designers, as they know which component packages are used, what the CTE requirements of these packages are, and what the life-expectancy requirements of the electronic equipment are. The ability to tailor in-plane CTE has made non-woven aramid-reinforced PWBs one of the most favorable material options for avionics, satellites, and telecom applications where long life expectancy and high reliability are needed.

In mobile phone applications, where chip scale packages (CSPs) are commonly employed, low-CTE non-woven aramid reinforcement extends solder joint life as much as three times over FR-4 and resin-coated foil (RCF). After more than 1,000 thermal cycles (−40 to +125°C), non-woven aramid-reinforced epoxy resin does not crack, as is common with nonreinforced dielectrics.

Aramid-reinforced laminate and prepreg allow fast microvia hole formation and at the same time maintain the performance characteristic of a smooth surface for fine-line conductor imaging. The ablation speed of non-woven (aramid) laminates and prepregs is close to that achieved when using nonreinforced materials such as resin-coated foil, dry film, or liquid dielectrics. Since aramid laminates are very stable, they allow the fabrication of double-sided, very thin, etched innerlayers, which are then pressed to a multilayer package in a single

**FIGURE 22.13** Impact of copper and resin content on in-plane CTE. (Source: DuPont.)

pressing cycle. Thus, these thin innerlayers can be processed in parallel. Aramid-reinforced material is a cost-effective alternative when laser hole formation is used to form single- and multiple-layer interconnects, and is compatible with FR-4 materials used in the core of aramid-FR-4 mixed constructions. Laser drilling of stepped microvia holes is accomplished in one subsequent operation (see Fig. 22.14). This allows the designer to interconnect up to four layers on each side of the inner core without sequential processing—a substantial productivity advantage for the PWB fabricator that results in the lowest possible manufacturing cost. See IPC-4104 specification sheets 5 and 23 for more complete material performance information.

### 22.5.3 Via Filling

The demand for filling of through holes with epoxy resin or conductive paste has been rising ever since surface-mount technology became widely adopted in the PWB industry.

**22.5.3.1 Basics.** Following are the traditional examples of the types of applications that require via filling processing capability:

- Preventing acid residue from attacking the Cu plating at the through-hole opening, which can in turn cause an open circuit
- Averting mishandling due to loss of vacuum during board-level assembly or during vacuum-assisted transport in production
- Avoiding blowout of flux and/or solvent residue during assembly and solder reflow
- Stopping flux from dripping from the through holes to the opposite side of the PWB
- Keeping solder resist ink from migrating into through holes during screen printing, which can cause formation of nodules at the through-hole opening during solder plating and/or gold plating
- Enhancing the planarity of solder resist on the surface of filled through holes and the planarity of core layer for SBU PWBs
- Improving the stability of solder paste printing volume for via-in-pad designs
- Preventing the migration of solder into through holes in via-in-pad designs

The filling of through holes with nonconductive resin and conductive materials using dispensing, screen-printing, and roll-coating methods has been extensively evaluated and tested. Of the three basic methods described earlier, screen printing is the most common process. It allows for efficient, selective filling of large numbers of through holes.

**22.5.3.2 Via-Filling Materials.** Selection of the proper resin-based material is the most important objective when using a screen-printing process to fill through-hole vias in build-up multilayer cores. In particular, the primary issues to be considered when choosing an appropriate fill material are:

- Ease of printing
- Ease of grinding (planarizing)
- Adhesion to hole wall and panel surface

The most commonly used materials for permanently filling through holes include single-cure (thermal) resins, photoimageable dielectrics, conductive pastes, and the dual-cure (UV + thermal) epoxy resin utilized in the Noda screen flat plug process. Following are brief descriptions and comparisons of the characteristics of each of these types of via-fill materials.

**22.5.3.2.1 Conventional Prepregs and RCC.** In fabricating a base core with a pattern, the core panel is usually panel-plated and the pattern is made with a dry-film tenting process. Some fabricators seem to prefer pattern plating, however. The choice depends on the fabricator's familiarity with these processes. After the pattern is formed, dielectric material is laminated over the core (in the case of prepreg, with copper foil) and the holes can be filled with resins, depending on the plated hole diameter and the thickness of the core. It is generally agreed that when the diameter of plated holes is equal to or less than 0.3 mm *and* the core thickness is equal to 0.6 mm or less, these holes can be filled effectively by the lamination process (although the resin thickness of 80  $\mu\text{m}$  is preferred in the case of RCC). See Fig. 22.15.

When the diameter/thickness conditions are not met, it is necessary to fill the holes using a separate process. A screening process does this from one side of the panel with polyester screen with an oversized hole pattern. After hole filling and curing the resin completely, the fabricator removes excess resin using a belt sander (#600 to #800) or a ceramic brush. Figure 22.16 illustrates the process. This is a tricky but necessary operation for microvia board makers, particularly for photovia processing.

Hole filling is costly but yields a few advantages over simultaneous hole filling by lamination of RCC or prepreg. The edge of the plated holes is well protected; therefore, forming

**FIGURE 22.15** Conditions under which the through hole can be filled with resin by RCC lamination.

**FIGURE 22.16** Hole filling and surface scrubbing.

finer annular rings on the base core by tenting is easier. There is no concavity problem over the hole that can cause difficulties in later processes.

**22.5.3.2.2 Dual-Cure (UV + Thermal) Epoxy Resin.** The main purpose for using a dual-cure epoxy resin is the stability of the B-cured material and the ease with which it can be removed by grinding during planarization. A homogeneous, semicured state can be reached because the liquid environment within the UV exposure system helps to control the temperature and stabilize the intensity of UV light. Furthermore, because the temperature of the liquid environment is kept low, the expansion of air bubbles that may have been trapped in the fill material at room temperature is prevented.

In formulating epoxy resin via-fill ink, one must consider the adhesion between the fill material and the copper plating in the hole barrel. Normally it may seem suitable to use a material that does not include an acrylic component. However, some suppliers have found it more beneficial to add an acrylic component because of its resistance to moisture absorption. They determined that it would be preferable to improve the ink's adhesion to copper by pre-treatment with a black oxide or chemical etching process. This is similar to the approach taken by many dielectric suppliers.

**22.5.3.2.3 Photoimageable Dielectrics.** An advantage of a dielectric being photoimageable is that unwanted material is washed off during development, thus eliminating the planarization step. Typically, one screen pass is sufficient to fill or plug vias, but two passes can also be used to maximize hole filling. Standard screen-printing equipment is needed with a bed-of-nails or dimple plate to maximize air release out of the plugged holes. If a squeegee is being used, single-sided application is recommended. Two coats are recommended to minimize the effects of material. Cores as small or smaller than 0.030 in. (0.76 mm) require a secondary coating application.

**22.5.3.2.4 Conductive Paste.** In addition to the previous advantages of via filling stated earlier, conductive via fills also dissipate heat, increase electrical conductivity in the hole, and allow a via-in-pad design option (Fig. 22.17). The latter advantage is another way to recover real estate.

**FIGURE 22.17** A via-in-pad option with conductive via fill: (a) traditional “dog-bone” design; (b) via-in-pad design. (Courtesy of DuPont.)

One example is a screen-printable paste made of silver, copper, and epoxy. The optimum mix of metal particle shapes and sizes bonded together with epoxy resin produces essentially zero shrinkage. In general, the plated or unplated through hole is filled with paste using a stencil-printing process. After drying and curing, the plugged through holes are planarized and plated to make them solderable. Some typical design rules are an aspect ratio of 1:1 to 6:1 with vacuum assist, a via size of 6 to 25 mil (152 to 635  $\mu\text{m}$ ), and a core thickness of 6 to 85 mil (152 to 2159  $\mu\text{m}$ ). The product is extremely reliable during assembly.

**22.5.3.2.5 Single-Cure (Thermal) Resin.** Typically, thermally cured resins exhibit good adhesion strength to copper. Unfortunately, the rate of heat dissipation throughout the filled core material is unstable, making it difficult to achieve a reliable semicured state prior to planarization.

As a result, a rapid and unpredictable rise in temperature is likely to occur; as such, it is imperative to fill the holes completely, leaving no voids, if this type of material is to be used.

**22.5.3.2.6 Solder Mask Ink.** Using this type of material, it is relatively easy to fill the hole. However, the presence of volatile elements (solvents) and the degree of shrinkage during curing have a significant effect on the stability of the manufacturing process. In the case of small diameter through holes, the solvent residue may remain in craters or dishes at the mouth of the hole opening. Furthermore, the copper adhesion strength of these materials is typically lower than that of other hole fill materials.

**22.5.3.2.7 Resin-Coated Foil (RCF).** Similar to the potential problems faced with photoimageable dielectrics, there is a divergence between the material characteristics required for hole filling and the characteristics that are desirable for an innerlayer dielectric-copper material. Nonetheless, it is likely that the RCF foil materials will prove to be acceptable for filling vias in the limited range of specific applications that exhibit a low-aspect ratio between hole diameter and core thickness.

Liquid dielectric resin is coated more or less the same way as in photovia. However, there is a fundamental difference between photovia and laser via dielectric. In laser via processing, the resin is fully cured before laser drilling (microvia formation). This is a big advantage over photovia materials since the resin movement after hole formation is much more stable than in the case of photovia processing in which resin is fully cured after holes are formed. This resin (hole) movement makes pattern-imaging registration difficult for photovia processing.

## 22.6 HDI MANUFACTURING PROCESSES

---

This section discusses processes that employ non-drilling via-hole formation techniques. Through-via drilling is possible below 0.20 mm (0.008 in.), but cost and practicality discourage this. Below 0.20 mm (0.008 in.), laser and other via-formation processes are more cost-effective. Each of the five major via-hole formation processes used for printed circuits is discussed in the following sections.

- Photovia
- Plasma via
- Laser via
- Solid (paste) via
- Insulation displacement via

The manufacturing process for each microvia technology begins with a base core, which may be a simple double-sided board carrying power and ground planes or a multilayer board carrying some signal pattern in addition to power and ground planes. The core usually has plated through holes (PTHs). These PTHs become BVHs. Such a core is often called an *active core*.

### 22.6.1 Photovia Process

Prior to dielectric material coating by any of the methods described previously, the copper surface of the base core must be treated by an adhesion promotion process to ensure good adhesion of dielectric material to the copper surface. Today, very few manufacturers use oxide treatment for this purpose. The most popular adhesion promotion treatment is a special etching process offered by many suppliers of chemicals. This step is common to all microvia processes.

Dielectric resin is semicured after coating to eliminate tackiness, and then the hole pattern is exposed by photoexposure processing. The usual photodeveloping process creates microvia holes and the dielectric is fully cured, typically at 160°C for about 1 hour. Then, the panel goes through a permanganate etching process to remove any residual resin at the bottom of the hole and simultaneously create microporous surfaces that act as an anchor and ensure desirable peel strength after copper plating.

The level of peel strength is controversial. Minimum peel strength required for chip package substrates is about 600 g/cm<sup>2</sup>, but motherboard users, particularly cell phone makers, demand a minimum of 1.0 kg/m<sup>2</sup> or more in order for cell phone handsets to withstand drop tests. Laser via materials usually yield stronger peel strength because of fillers that can be added to dielectric resin. When etched, these fillers generate a superior microporous surface structure needed for strong peel strength.

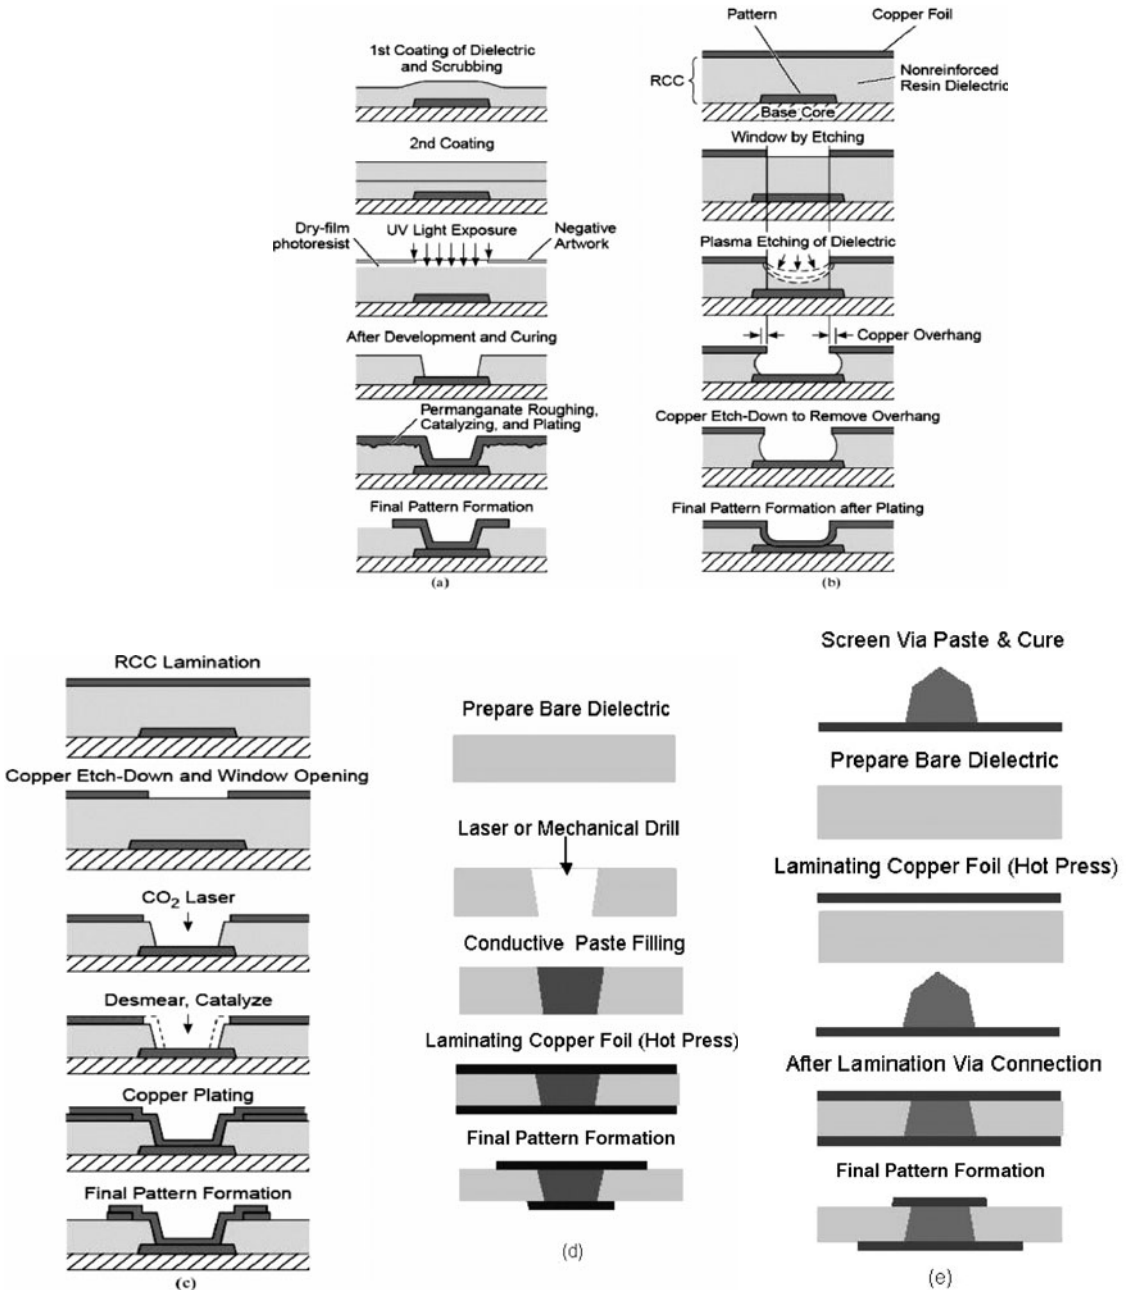

After permanganate etching, the panel is catalyzed and metallized in an electroless copper bath and panel-plated galvanically to desired thickness. Some photovia process practitioners roughen the resin surface mechanically by brushing or liquid honing prior to catalyzing. Then, the conductor pattern is formed by dry-film tenting and etching. Some manufacturers prefer to use the pattern-plating method for this purpose. Very few microvia board manufacturers use direct metallization methods for metallizing holes prior to galvanic plating. Several Japanese manufacturers use electroless copper all the way to the desired thickness in panel plating and use a positive electrodeposited (ED) system to achieve fine lines and very small annular rings.

One important step in microvia hole board fabrication when resin is the dielectric choice, whether the process is photovia or laser via, is the removal of residual catalysts (normally palladium) entrapped in a microporous surface that can cause migration. The process used in this step is normally a trade secret.

Photovia processing is now used primarily to fabricate semiconductor chip package substrates because a large number of holes can be formed in one photoexposure and development step. However, as mentioned previously, photovia processing suffers more from material shrinkage than laser via processing after full cure, and hole locations tend to move randomly, which makes subsequent registration for patterning difficult. Because of this problem, photovia users limit the size of the panel to be much smaller than the usual panel size prevalent in motherboard fabrication to about 400 mm × 400 mm. Small hole formation is also difficult with the photovia process. As a result, even makers of package substrates are now resorting more to laser via processes as the laser-drilling speed is being improved. Photovia process users engaged in mass production are found only in Japan today. All photodielectric processes have certain characteristics in general. Table 22.11 lists the typical processing factors. A standard photovia process sequence is described in Fig. 22.18a.

### 22.6.2 Plasma Via Process

Plasma via processing was developed by a Swiss PWB maker, Dyconex. Products made with the plasma via process are called DYCOstrate.

There are many variations to the plasma via process, one of which is illustrated in Fig. 22.18b. Today, it is mainly used to fabricate sophisticated flex and flex-rigid wiring boards in small quantities.

First, an opening or window is made through copper foil by a normal etching process. When plasma etching is applied through this window, the shape of holes tends to be like a bowl (as shown in Fig. 22.28b), which is not suitable for reliable plating (although new plasma-etching equipment claims to have solved this problem).<sup>7,8</sup> Another problem is related to how the microvia hole is formed. The copper edge of the window hangs out over the hole, which results in poor reliability after panel plating. Therefore, to ensure reliable plated holes, a secondary etching is necessary to remove this copper overhang. One good thing results from this secondary etching, however: Since surface copper is thinned, formation of finer conductors is made easier. Nevertheless, by the time the panel is ready for plating for subsequent conductor pattern formation, it takes several times longer than other processes in a mass-production environment.

Plasma via processing is effective for forming through holes on flexible materials since holes are formed by plasma etching from both sides of the film and the bowl effect is minimized.

Plasma via etching evolved from the traditional process of plasma desmearing of through holes. Different gas, magnetrons, and equipment fixturing are employed by current plasma via-etching equipment. The plasma is generated in a partial vacuum filled with a mixture of oxygen, nitrogen, and chlorofluoro ( $CF_4$ ) gasses. Microwave magnetrons create the plasma field and special low-frequency kilowave units help provide rapid etching of organics.

### 22.6.3 Laser Via Process

Laser via processing is by far the most popular microvia hole formation process. But it is not the fastest via formation process. In Fig. 22.19, the chemical etching of small vias is the fastest, with an estimated rate of 40,000 to 50,000 vias per second. This is also true of plasma via

**FIGURE 22.19** The various rates of via formation based on diameter and method of via ablation, from chemical, plasma, photo and laser techniques.

**Wavelength**

**FIGURE 22.20** The wavelengths used by laser via drilling from infrared to ultraviolet region, including the harmonics of Nd:YAG lasers.

formation and photovia formation. These are all *mass-via-formation* processes. Laser drilling is one of the oldest microvia generation techniques.<sup>9</sup> The wavelengths for laser energy are in the infrared and ultraviolet region. Figure 22.20 shows the five major wavelengths used in current laser drills. The absorption curves of many organic dielectrics epoxy, polyimide, matte copper, and glass fibers are shown in Fig. 22.21. Laser drilling requires programming the beam fluence size and energy. High-fluence beams can cut metal and glass, whereas low-fluence beams cleanly remove organics but leave metals undamaged. A beam spot size as small as approximately 20 microns (<1 mil) is used for high-fluence beams and about 100 microns (4 mil) to 350 microns (14 mil) for low-fluence beams.<sup>10,11</sup>

However, there are many variations. For the purpose of drilling microvia holes, there are four laser systems: UV/Yag laser, CO<sub>2</sub> laser, Yag/CO<sub>2</sub>, and CO<sub>2</sub>/CO<sub>2</sub> combinations. Then there are three dielectric materials: RCC, resin only (dry-film or liquid resin), and reinforced prepreg. Therefore, the number of ways to make microvia holes by laser systems is driven by the permutation of four laser systems and these three dielectric materials.

**FIGURE 22.21** The absorption wavelength of different materials respond to different wavelength of laser energy. Epoxy, copper and glass of laminate are ablated by the UV wavelength but only the resin is ablated by the CO<sub>2</sub> wavelengths .

There are several factors to observe in laser via processing: position accuracy of lased holes (microvia holes), uneven diameters of holes, dimensional change of the panel after curing dielectric, dimensional change of the panel due to temperature and humidity variations, alignment accuracy of the photoexposure machine, unstable nature of negative artwork, and so on. These should be carefully monitored and are important for all microvia hole processes.

**22.6.3.1 UV/Yag Laser.** A Yag laser can penetrate copper; therefore, it is not necessary to pre-etch the window when the choice of dielectric is RCC or a copper-foil/prepreg combination.

Positioning accuracy in relation to the capture pad is good, but there are weaknesses associated with the Yag laser. The speed of drilling (ablation) is slower than the CO<sub>2</sub> laser, particularly when a hole diameter is equal to or larger than 125 μm, because the laser beam is very small. Therefore, it is necessary to do trepanning (spiral drilling pattern), which results in longer drilling time. Another weakness is the Yag laser's sensitivity to the thickness of dielectric material. If the thickness of the RCC's resin is not even, the Yag laser beam, the power of which is adjusted to remove the thicker part of the resin, may damage the capture pad. If adjusted to the thinner part, it may not reach the capture pad.

Although the Yag laser can penetrate copper and glass-reinforced prepreg, the situation is worse in this material than with RCC. The laser power must be adjusted to penetrate through the crossover part of woven glass. Then, when the laser beam hits the part of prepreg where there is now a glass bundle (opening), the beam can really damage the capture pad. To avoid this problem, the operator must reduce the laser power and apply laser ablation for a longer duration, which increases drilling time considerably. Depending on the construction of the dielectric layer through which the Yag laser beam must penetrate, the drilling speed must be adjusted to about 3 to 50 holes per second when glass-reinforced dielectric is used.

When the dielectric is RCC, the speed of the currently available UV/Yag laser is somewhere around 100 to 300 holes per second.

When the dielectric is resin without copper foil, a CO<sub>2</sub> laser is the best since a CO<sub>2</sub> laser can offer much faster drilling speed (a single-head CO<sub>2</sub> laser can drill as many as 25,000 holes per minute, including overhead such as loading a panel onto the drilling table and registering the panel).

The best feature of the UV/Yag laser drilling machine is its ability to drill a very small hole (down to 20 to 30 μm, whereas the smallest hole a CO<sub>2</sub> laser can drill is 50 μm in a mass-production environment) and its superior position accuracy through RCC.

For higher-speed drilling, even Yag laser users are now etching copper foil down to 6 to 9 μm, the process more frequently seen in CO<sub>2</sub> drilling.

**22.6.3.2 CO<sub>2</sub> and Twin CO<sub>2</sub>.** A CO<sub>2</sub> laser beam cannot penetrate copper foil unless the foil is very thin, less than 5 μm, and the surface is treated to be dark to absorb the CO<sub>2</sub> laser beam (this process is called CO<sub>2</sub> laser direct drilling and will be treated later).

When the surface is resin only, a single-headed CO<sub>2</sub> laser machine can drill holes at the rate of 20,000 to 25,000 per minute depending on hole density and distribution. The drilling speed continues to increase. The denser the hole, the faster the drilling speed because time lost by table motion is minimized. A dual-head CO<sub>2</sub> machine can boost drilling productivity by about 70 percent compared to a single-head machine.

Manufacturers of dielectric resins mix fillers in the resins to enhance peel strength. Some fillers can slow down the drilling speed of a CO<sub>2</sub> laser beam (beam absorption is weaker in this case). For example, when the required dielectric thickness is 60 μm, resin is coated twice, which is a frequent practice to produce a thick coating. The first coating is made with resin without filler (40 μm), and the second coating (20 μm) is resin with filler. Since the laser beam goes through a thin layer of filled resin, the speed degradation is minimized.

The most desirable shape of drilled microvia holes is tapered, which is accomplished by pulse drilling. Normally, two to three pulses are used. When three pulses are applied on the same spot continuously, the capture pad may be overheated and excessive epoxy smear may result. Therefore, when three pulses are to be applied, the entire panel is drilled first by two

pulses and then the third pulse is once again applied to all holes. This way, the quality of the holes is ensured, although it takes longer to drill.

When the choice of dielectric is RCC, the opening or window must be formed first on copper foil, as in the case of plasma via. Prior to window formation, an etching process thins the surface copper, usually down to 6 to 7. This process is sometimes called *half-etching*.

Half-etching yields a few benefits. Window formation is made easier, and formation of fine-line conductors is also made easier.  $H_2O_2/H_2SO_4$  etchant is often used for this purpose for even thickness. As mentioned previously, this half-etching procedure is also becoming common for Yag laser users.

There are two variations to  $CO_2$  laser drilling through a window opening. One is called *conformal* and the other *semiconformal* (see Fig. 22.18c).

In the conformal method, a laser beam with a diameter larger than the window opening is used. Straight ablation of dielectric results in a bowl-shaped hole, as in the case of plasma via. Therefore, improved systems use laser beam diameters slightly larger than the window opening, and beams are pulsed to minimize the bowl effect.

In the semiconformal method, a laser beam with a diameter slightly smaller than the window opening is used. This results in a slight step when plated afterward, as shown in Fig. 22.18c. To minimize this step, half-etching is important in semiconformal drilling.

Some manufacturers using  $CO_2$  drilling etch down copper completely after RCC lamination. The dielectric surface below copper is already microporous, which generates good adhesion except prior to the RCC stage. Therefore, some special treatment is applied to the resin surface, such as electrolessly plated nickel layer, prior to copper plating, but such treatment is kept secret.

The RCC approach suffers from misregistration of window opening to capture pad when the surface and capture pad diameter becomes less than 250  $\mu m$ , which causes serious defects (see Fig. 22.22). Laser via process practitioners have several solutions to this problem. They can use liquid resin or resort to a Yag or Yag/ $CO_2$  laser. Since a Yag laser can break through copper foil, the beam can be directed to the capture pad position accurately. Another choice is to use laser direct imaging (LDI) for window etching in order to benefit from the speed of the  $CO_2$  laser.

**FIGURE 22.22** Misregistration of laser hole to capture pad. (Courtesy of *Ibiden*.)

Another solution is to use  $CO_2$  laser direct drilling. The advantage of using RCC is the pre-established peel strength. Manufacturers go through delicate steps to establish the appropriate peel strength when using liquid resin. The degree of resin cure, permanganate etching, control, and regeneration of the permanganate solution affects the resultant peel strength as well as cost.

In this laser direct drilling method, copper foil is etched down to about 5  $\mu\text{m}$  and its surface goes through oxide treatments such as black oxide or other methods, typically as alternatives to oxide treatment, which is normally an etching process. The copper thickness is further reduced by 1  $\mu\text{m}$ , and the surface color becomes dark, allowing the  $\text{CO}_2$  beam to penetrate.

Alternatively, ultrathin copper RCC may be used. Carrier foil, usually copper foil of 70- $\mu\text{m}$  thickness (2 oz.), is coated with a very thin layer (10 to 20  $\mu\text{m}$ ) of current conductive release film, and a thin foil of 3 to 5  $\mu\text{m}$  is plated. After such RCC is laminated to the core, the carrier film is peeled off and the surface condition is the same as etched-down copper. Drilling speed in this direct  $\text{CO}_2$  laser drilling method is degraded by 30 to 40 percent compared to that of straight resin drilling, but the registration to the capture pad is ensured.

**22.6.3.3 Yag/ $\text{CO}_2$ .** This combination is particularly useful for a copper/prepreg structure. The Yag laser offers good position accuracy and cuts through copper, but it tends to leave glass fibers sticking out in the hole after prepreg drilling. And as mentioned before, it is sensitive to dielectric thickness variation. The  $\text{CO}_2$  laser beam cuts through glass fiber more cleanly than the Yag. In this combination laser drilling, the power of the Yag laser beam is adjusted to cut through copper and remove a portion of glass fiber and leaves the finishing to the  $\text{CO}_2$  laser. The speed of drilling is governed by the speed of the Yag laser and is therefore slower than a pure  $\text{CO}_2$  laser. However, this is the preferred laser-drilling machine for fabricating infrastructure types of PWBs, such as ones used for servers, network routers, and base stations that typically have copper/prepreg surface structures. The size of the panels used to fabricate such boards is usually large; therefore, the positioning accuracy of the Yag laser is preferred. Microvia hole boards used by the automotive industry also have this copper/prepreg structure.

The speed of drilling by a Yag/ $\text{CO}_2$  machine is much slower than that of a  $\text{CO}_2$  laser. However, the number of microvia holes to be drilled for infrastructure boards is normally one magnitude less than that seen in cell phone applications, in which the number of microvia holes can reach as many as 650,000 to 700,000 per  $\text{m}^2$ . Furthermore, the price of infrastructure boards is much more than that of mass-produced cellular phone motherboards. Therefore, slower speed of drilling, which means higher drilling cost, does not affect the total cost of manufacturing.

Residual glass fibers in the hole that can affect reliability may be removed chemically or mechanically. Mechanical removal is preferred. Blasting with aluminum oxide (about 20  $\mu\text{m}$  diameter particles) is commonly used to remove glass fibers and smears as well. An excimer laser is also used to remove smears in the hole by a sweeping motion through the copper opening. In both cases, it takes about 30 sec. to desmear one side of the panel.

#### 22.6.4 Dry Metallization (Conductive Inks, Conductive Paste, and Insulation Displacement)

Three types of dry metallization are covered: conductive ink, conductive paste, and insulation displacement. Conductive ink describes a single-layer dielectric with microvias formed by photoimaging, laser, or insulation displacement. A conductive paste is used to fill the microvias and act as the conductive path between layers. Surface metallization may be accomplished either by laminating copper foil onto the dielectric surface or by chemical deposition. This process is shown in Fig. 22.18d.

Insulation displacement is a unique process in that the silver conductive paste is screened on copper foil and cured. The conductive paste forms a “pointed” via that penetrates conventional prepregs during lamination and adheres to the copper foil on the reverse side, forming a via. Figure 22.18e shows this via formation process.

Standard activities concentrate on the use of photoimaging and screen printing while overcoming the limitations and expense associated with processes such as plating and etching. The concept is built on the use of a photoimageable dielectric to produce both vias and circuit

channels that are then filled with a conductive ink. These approaches eliminate the need for a separate dielectric and clad-metal layer that requires either etching or a combination of plating and etching to produce a circuit. They also eliminate the resist deposition and stripping previously required to define that circuit. The conductive ink technique of metallization virtually eliminates the generation of metal waste streams.

Conventional multilayer printed wiring boards must be subjected to drilling and through-hole plating to create interconnections. These holes represent inefficient use of PWB area. In addition, to connect the printed wiring with part connection lands, some through holes must be provided in areas other than where the lands are located.

## CHAPTER 23

---

# ADVANCED HIGH-DENSITY INTERCONNECTION (HDI) TECHNOLOGIES

---

**Happy T. Holden**

*Mentor Graphics, Longmont, Colorado*

---

### 23.1 INTRODUCTION

---

Since the introduction of HDI in the mid-1980s (HP-Finstrate, Siemens's MicroWiring, and IBM's Surface Laminar Circuit [SLC] technology; see Figs. 22.1, 22.2, and 22.3), many variations of making high-density interconnect (HDI) wiring boards have been developed and implemented for mass production. However, if one technology is to be judged in terms of volume produced and picked as a winner, laser-drilling technology is the one. Other methods are still used by a number of printed wiring board (PWB) manufacturers, but on a much smaller scale.

The purpose of this chapter is to examine a variety of HDI fabrication processes as seen in Fig. 23.1. However, a greater emphasis will be placed on the laser-drilling process (hereinafter *laservia*) since it is the most popular process today and it seems its popularity will grow in the future. It must be understood that interconnect via hole (IVH) formation is just one element of fabricating HDI wiring boards. The other two important factors are the various dielectric materials and the methods of metallization. Fabrication of HDI wiring boards with microvia holes involves many new processes not common to conventional board fabrication. Therefore, additional emphasis will be placed upon these new fabrication processes that are common to other microvia technologies.

---

### 23.2 DEFINITIONS OF HDI PROCESS FACTORS

---

The 21 different HDI processes shown in Fig. 23.1 have three basic fabrication factors in their process makeup:

- Dielectric materials
- IVH formation
- Methods of metallization

**FIGURE 23.1** The HDI technologies in use today are made up of three factors: the dielectric materials, the methods of IVH formation, and the method of metallization of those z-axis via connections. In recent years up until now, 21 different HDI processes have been used.

**23.2.1 Dielectric Materials**

Eight different general dielectric materials have been used in the current or past HDI processes. IPC slash sheets such as IPC-4101B and IPC-4104 cover many of these, but many are not yet specified by IPC standards. The materials are:

- Photosensitive liquid dielectrics
- Photosensitive dry-film dielectrics
- Polyimide flexible film
- Thermally cured dry films
- Thermally cured liquid dielectrics
- Resin-coated copper (RCC) foil
- Conventional FR-4 cores and prepregs
- Thermoplastics

### 23.2.2 Interconnect Via Hole Formation

Seven different methods of forming the IVHs have been used in current or past HDI processes. Laser drilling is the most prominent, but the other six come into use also. The methods are:

- Photo processes to define vias in photodielectrics
- Various laser-drilling methods, including UV-Yag, UV-Eximer, and CO<sub>2</sub>
- Mechanical drilling
- Plasma drilling
- Screen printing of via pastes
- Photo and etch of solid vias
- Toolfoil

### 23.2.3 Method of Metallization

Four different methods of metallizing the IVHs have been used in the current or past HDI processes. The methods are:

- Fully additive electroless copper
- Conventional electroless and electroplating copper
- Conductive pastes
- Fabricating solid metal vias

## 23.3 HDI FABRICATION PROCESSES

---

The three basic and original HDI processes are laser drilling laminate (Finstrate) and flexible materials (microwiring), photodielectrics with SLC and plasma-etching polyimide (Dycos-trate). These and the other 18 HDI processes have been integrated into standard printed circuit manufacturing flows. There is no standard way to organize these processes, but the method of IVH formulation is the most unique characteristic of each process and will be used for this purpose.

### 23.3.1 Photo-Via Technologies<sup>1,2</sup>

**23.3.1.1 IBSS-AAPI0 System.** The Interpenetrating Polymer Network Build-Up Structure System (IBSS) is a new photodielectric. This photo-imageable dielectric (PID) is a proprietary photodielectric developed by Ibiden of Japan. It complements Ibiden's older epoxy type of photo-redistribution layer technology, IP-10.

**23.3.1.1.1 Structure.** IBSS is specifically formulated for integrated circuit and flip-chip packages and has a high  $T_g$  and flexibility. The bismalene-triazine (BT) core also provides high-temperature resistance. A typical IBSS structure and its features are illustrated in Fig. 23.2.

**23.3.1.1.2 Manufacturing Process.** IBSS is a liquid system applied by roller coater to a rigid core, typically BT. The coating is cured and photodeveloping creates the vias. The IBSS requires an aggressive swell-and-etch because of the higher-temperature nature of the photo-dielectric (PD). The metallization is fully additive copper, also proprietary to Ibiden.

FIGURE 23.2 The IBSS/AAP10 multilayer substrate structure.

The imaging for additive metalization uses a permanent dry-film photoresist. For additional layers of dielectric, an adhesion promoter is applied to the surface copper. Figure 23.3 outlines the IBSS process.

**23.3.1.2 Surface Laminar Circuits.** SLC technology was the first of the PID microvias, build-up technologies to reach the interconnect market in high volume. Development of SLC technology began during the late 1980s at IBM (Yasu, Japan), and the first product was introduced in 1990.<sup>1</sup> The first flip-chip, direct-chip-attach (FC/DCA) product employing SLC technology was shipped from Yasu in 1992, and in 1995 IBM Endicott, New York, shipped its first printed wiring boards that utilized SLC technology.<sup>2</sup> Used by many original equipment manufacturers (OEMs) in Japan, the SLC process provided the high-density interconnect technology for Sony's first digital Camcorder, the DCR-PC7, seen in Fig. 23.4. This eight-layer build-up structure had two SLC layers on each side of a four-layer core. The assembly density of this was over 612 pins per sq. in. due to the wall-to-wall 0.5 mm. pitch chip scale package (CSP) used.<sup>3</sup>

The most suitable photosensitive dielectric was the photo-imageable solder masks, due to their proven compatibility with printed circuit assembly processes, ability to withstand exposure to service environments, and possession of the necessary via-imaging characteristics. SLC technology was originally developed and implemented with a liquid PID solder mask applied by curtain coating. In 1995, it was also qualified with a dry-film PID with virtually identical electrical properties. The dry-film version did not require the extensive surface grinding processes that the liquid PID process required.

PID technology is based on photoimageable polymeric systems to form blind microvias in dielectric material between layers of circuitry. The use of PIDs allows all microvias on a panel to be formed simultaneously, with no incremental-per-via cost. Its use is particularly advantageous on applications with high densities of vias (e.g., more than 50,000 on an 18 in.  $\times$  24 in. panel).

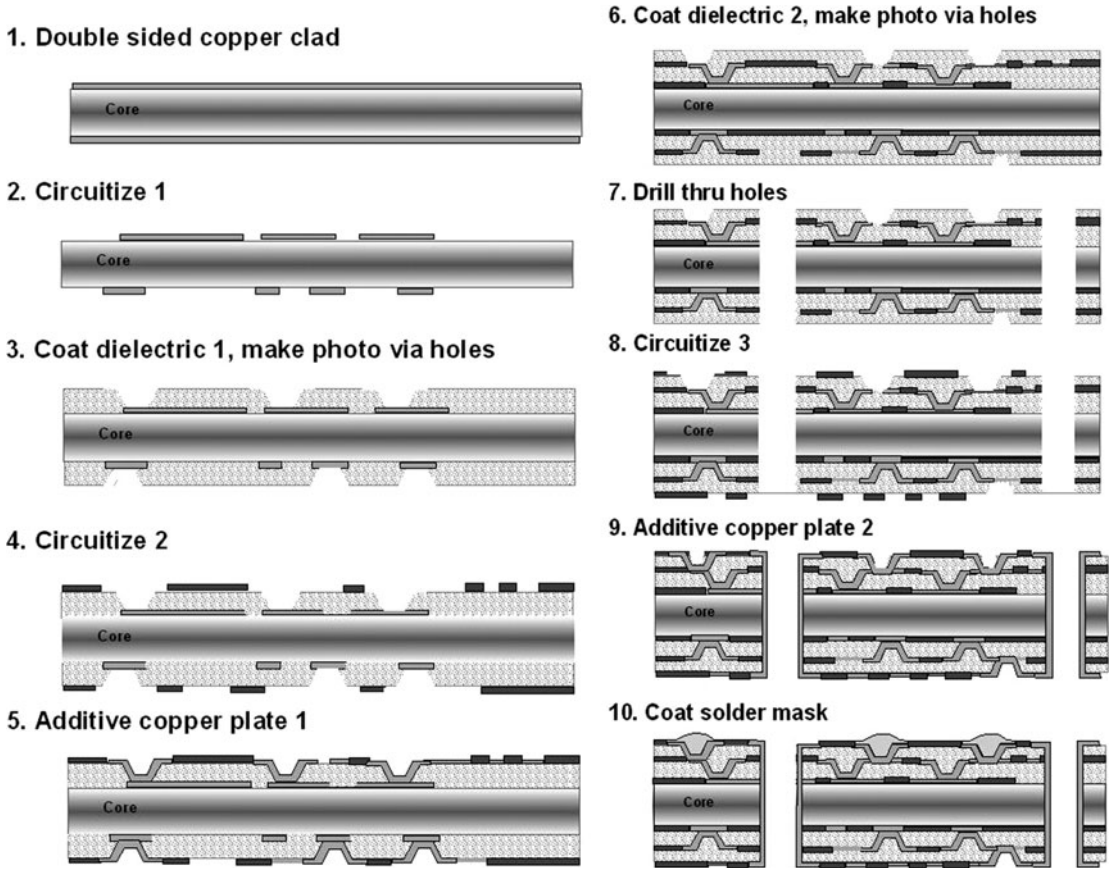

FIGURE 23.3 The IBSS/AAP10 multilayer substrate fabrication process.

23.3.1.2.1 *Liquid Versus Dry PID.* A typical flowchart of the PID technology fabrication process, including options for multiple build-up layers and a multilayer core, is shown in Fig. 23.5. At this level in the process, PID technology is the same whether a liquid or dry-film PID is used.

Liquid and dry-film PIDs do provide slightly different via wall profiles. The liquid PID has tapered via walls, whereas the dry-film PID has essentially vertical via walls. The tapered via walls provide good plating coverage on the via walls and base. Vertical walls allow for a smaller via top opening, and correspondingly smaller capture land for a given via bottom diameter.<sup>4,5</sup>

23.3.1.2.2 *Tools.* The use of a liquid PID requires two unique pieces of equipment: a coater of some variety, either curtain, slot, roller coater or screen printer (with associated drying ovens), and a leveling tool (surface sander). A leveling tool is required to planarize the surface of the cured liquid PID to accommodate fine-line photolithography on the surface. Liquid PID provides a conformal coating over underlying circuit features, producing nonuniform planarity. The leveling operation also removes a lip of exposed PID that overhangs the via openings in these processes. Many liquid PIDs have a self-leveling characteristic and do not require any other leveling.

**FIGURE 23.4** The Sony DCR-PC7 digital camcorder utilized the SLC process for the 2+4+2 build-up structure and 0.5 mm CSPs to achieve over 600 connections (pins) per sq. in.

The use of a dry-film PID requires only one unique piece of equipment: a vacuum laminator. Vacuum laminators are common at printed circuit fabrication shops; in addition, the capital to obtain one is significantly less than for a curtain or slot coater. The dry-film PID has excellent planarization and does not require a leveling process due to the film's low solvent content, low shrinkage, and vacuum lamination process.<sup>6,7</sup>

PID technologies were originally conceived as an alternative to multilayer lamination as a way to make multilayer PWBs. PID technology builds up each surface signal layer on top of the previous layers in a sequential fashion. The base under all of the outer build-up layers is a conventional double-sided or multilayer circuit board containing voltage, ground planes, and even signal layers. Mechanically drilled and plated holes are used only in the core layers, to make connections to the backside of the laminate base and accommodate mounting pinned components. There is greater wiring density to use plated through holes (PTHs), which extend only through the base printed circuit structure and not through the build-up layers, especially when two or more build-up layers are used. Figure 23.6 provides additional details of the SLC manufacturing process of multilayer printed circuit boards.<sup>8,9</sup>

**23.3.1.3 DV Multi-PID.** DV Multi-PID is from NEC. This structure uses a PID primarily as an integrated circuit (IC) substrate and for high-density electronic products. It is capable of three build-up layers per side. Figure 23.7 shows a typical NEC high-density board. The use of a dry-film PID requires only one unique piece of equipment: a vacuum laminator. Vacuum laminators are common at printed circuit fabrication shops; in addition, they cost much less than a curtain or slot coater. The dry-film PID has excellent planarization, does not require a leveling process due to the film's low solvent content, low shrinkage, and vacuum lamination. The modified structure of DV Multi-AD uses laminates and RCC for the build-up layers and fully additive electroless plating. Figure 23.8 illustrates this structure and manufacturing process.

FIGURE 23.5 The manufacturing flows for the two-major SLC manufacturing processes.

**23.3.2 Laser Via Technologies**<sup>(3-5), [3-6], [7-10]</sup>

Circled processes 3, 4, and 5, as well as squared 3 through 10 in Fig. 23.1, utilize a laser drill via generation technique. This process was first used in the late 1970s to drill small holes in G-10 laminate for buried vias in mainframe computer boards by IBM for its 3081 system and by Burroughs. (Attempts to find pictures of these products proved unfruitful.) The Hewlett

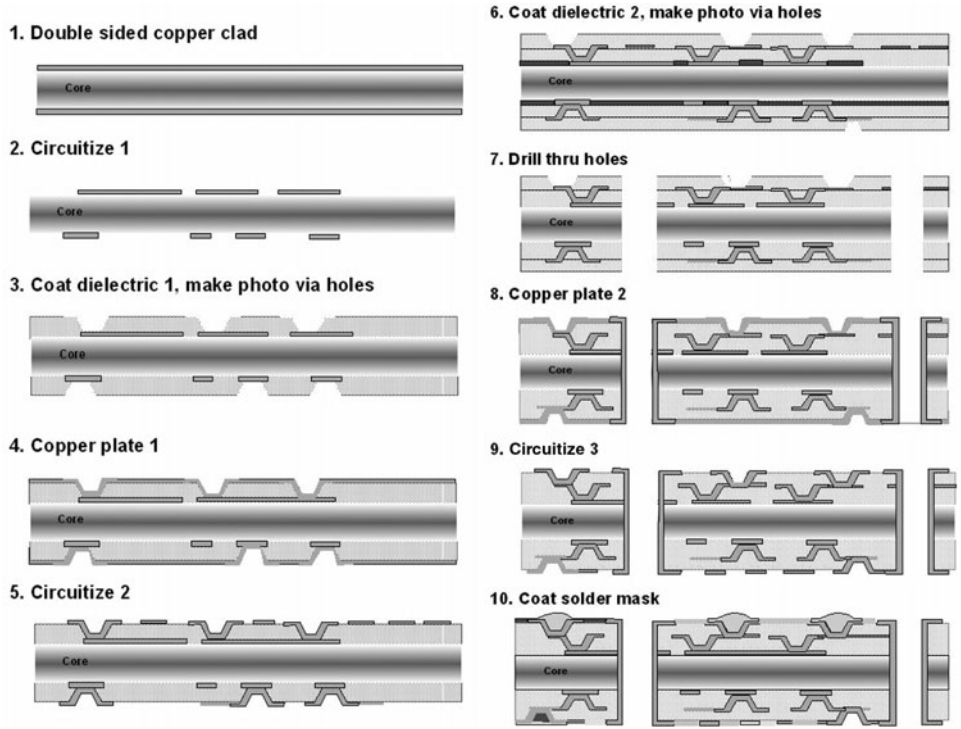

FIGURE 23.6 Additional details of the SLC manufacturing process.

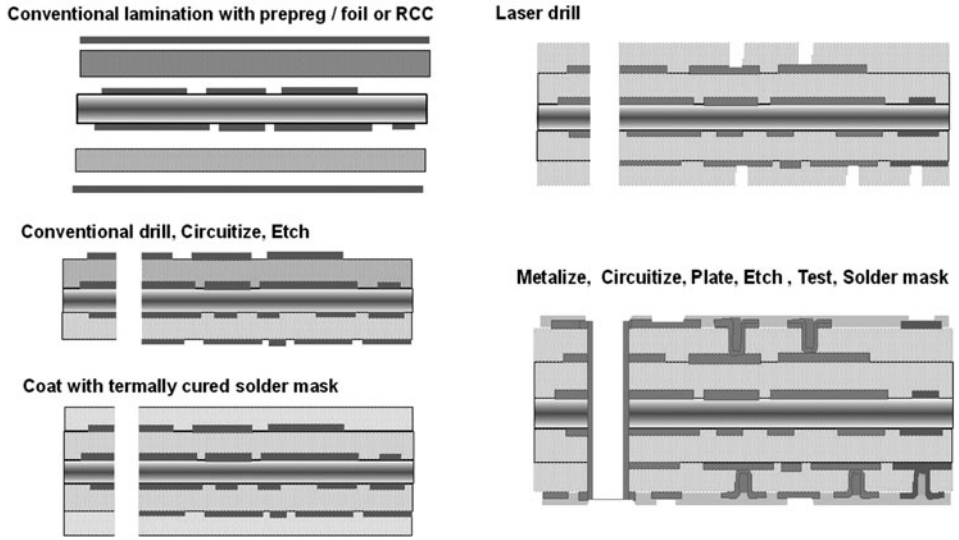

FIGURE 23.7 A typical high-density DV Multi-PID board from NEC.

**FIGURE 23.8** The DV Multi-PID board manufacturing process.

Packard laser-drilled Finstrate family of boards, first produced in 1983, is shown in Chapter 22. Siemens’ laser-drilled microwiring was produced since 1987.

**23.3.2.1 High-Density Interconnect (HDI).** The HDI process developed by General Electric and now owned by Lockheed Martin is the one most similar to IC processes. This process is what is called a “chips first,” as the assembly is done before the substrate is completed and the IC bonding is direct to the substrate. It does not use flip-chip or wire bonding, but can utilize unmodified chips directly. A number of build-up layers and very fine geometry are possible. There are obvious advantages in making multichip modules and in using standard chips. The materials and bonding technologies have proven to be very reliable and suitable for military applications. The disadvantage is the maximum panel that can be sputtered. Future use of PVD/CVD metallization may make this process more cost-effective.

**23.3.2.1.1 Structure.** The circuit structure of HDI consists essentially of common conventional flex circuits or more advanced microvia flex structures. These are purchased for this process. The polyimide film is usually 25- or 50-micron adhesiveness. The laser ablates away the polyimide to produce blind and through vias. The through vias are stopped by the aluminum bonding pads of the integrated circuits. By doing this, integrated circuits designed for wire bonding can be directly attached. Figure 23.9 shows a typical HDI structure.

**23.3.2.1.2 Manufacturing Process.** The process starts with a finished single-sided, double-sided, or multilayer polyimide flex circuit. An adhesive is applied to the flex circuit. All the ICs and components are bonded to the polyimide film layer pair flex circuitry and cured. The assembly is turned over and a laser drills down through the flex circuitry to make blind and through vias including opening up the bonding pads on the IC chip. Gold, under-bump metallurgy, or C4 bumps are not required. The panel goes through tungsten sputtering to metalize the vias and seed the top layer. Circuit pattern can be applied, plated, and then etched to complete the circuit. The process is diagrammed in Fig. 23.10.<sup>10,11</sup>

FIGURE 23.9 Structure for the HDI multilayer substrate with lasered blind vias and direct connection to the ICs.

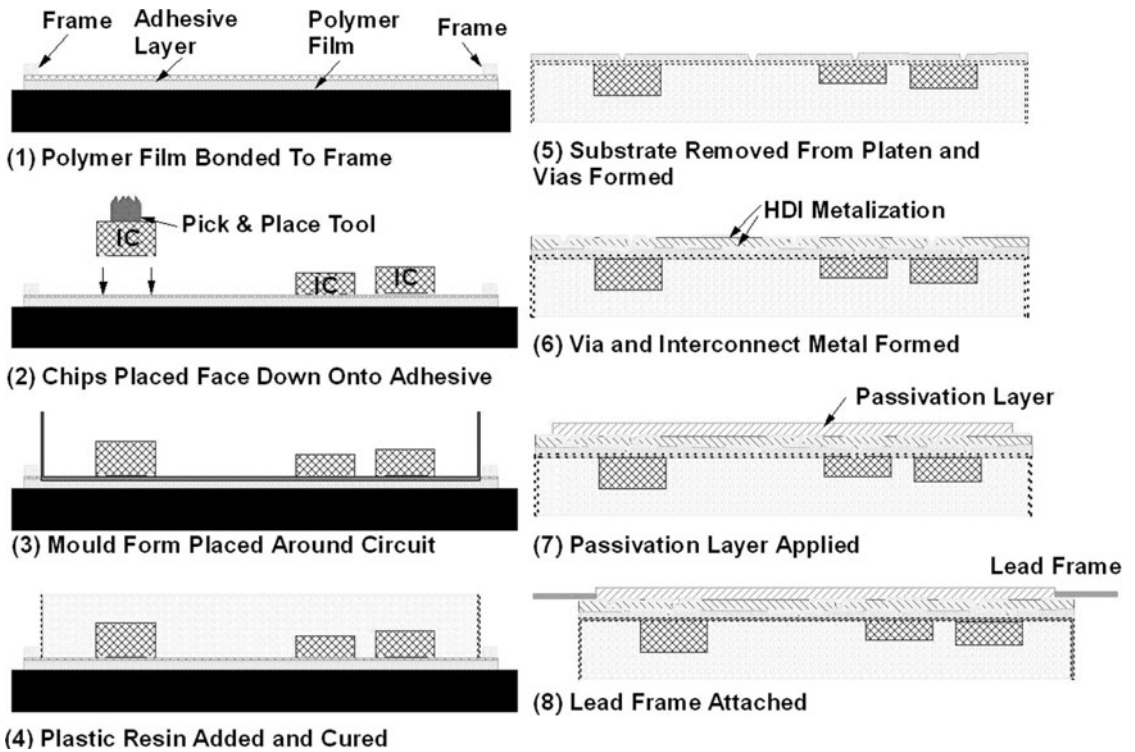

FIGURE 23.10 Manufacturing sequence for the HDI multilayer substrate with lasered blind vias.

**23.3.2.2 Meiko-BU.** Meiko Circuits of Japan takes a photoresist and coats it onto a stainless steel panel. This starts the process to produce high density interconnect structures (HDIS) in a remarkable way. The advantages of this process is that surface geometries are not determined by etching or full additive metallization, the vias are under the surface lands, and the circuits are all flush with the dielectric, permitting the elimination of solder masks. On the negative side, this is a more expensive process that involves carriers.

**FIGURE 23.11** The carrier-formed circuit multilayer structure.

**23.3.2.2.1 Structure.** Figure 23.11 shows the structure of Meiko's build-up circuits. These are called carrier-formed because a stainless steel carrier serves as the base for the photo-dielectric even though they are laser-drilled to form the vias. The resulting structure is similar to other HDIs. The core is still a rigid board and the build-up layers are PID.

**23.3.2.2.2 Manufacturing Process.** The manufacturing process (see in Fig. 23.12) starts by taking a photoresist and coating it onto a stainless steel panel. The surface pattern is exposed and developed in the photoresist. First gold is plated, then nickel, and finally copper is plated on the panel. When the resist is stripped, the PID is applied over the entire panel and via holes are laser-drilled in the dielectric. Once metalized and plated, photoresists can define the circuitry by etching. The process can be repeated until the circuitry is complete or it can be laminated to FR-4 materials as rigidizers.<sup>12</sup> [13]

**23.3.2.3 CLLAVIS.** The CLLAVIS build-up technology is marketed by CMK of Japan. This laser-drilled microvia technology is the most common of HDI processes. The cross-sectional view in Fig. 23.13 shows the filled buried vias in the multilayer core, as well as the optional filled microvias that can be stacked. This structure is also available with the simpler, unfilled staggered microvias.

**23.3.2.3.1 Manufacturing Process.** The CLLAVIS manufacturing process is outlined in Fig. 23.14 and is identical to most of the laser-via-build-up technologies used.<sup>[14–28]</sup>

**23.3.2.4 SSP.** The SSP technology was developed by Ibiden of Japan. It used standard FR-4, copper plating, and laser drilling. The additional step is the application of a thin adhesive to each finished single-sided, pump-plated core. The process sequence is as follows:

1. Start with single-sided copper-clad laminate.
2. Laser drill from the non-copper side.
3. Desmear laser holes and run through the electroless copper process.
4. Plate up bumps on the clad side.
5. Image and circuitize the copper side.
6. Apply a thin adhesive to the unclad side.

FIGURE 23.12 The fabrication process for carrier-formed circuit multilayer substrate.

FIGURE 23.16 The typical manufacturing process for FACT-EV boards.

**23.3.2.5 FACT-EV.** FACT-EV (Fujikiko Advanced Chemical Technology-Etched Via Post) is from Fujikiko of Japan. As with the SSP process, the via is a solid-plated copper post. In this case, the process uses standard dry-film photoresist to define the posts and a thin-liquid dielectric to coat the plated posts. Unlike SSP, however, the process is sequential and each two sets of layers are processed on the prior layers. The process is outlined in Fig. 23.16.

**23.3.2.6 PPBU.** The PPBU (Prepreg Build-Up), from CMK, is a standard sequential lamination process using laser-drilled vias similar to the CLLAVIS process. The diagrams in Fig. 23.17 show two of the structures, a standard 2+4+2 build-up and an advanced 3+2+3 stacked build-up.

**23.3.2.7 Solid Conductive Via Fill.** The next group of HDI technologies all utilize metallic copper pastes or a solid sheet of metal to form the via connections. Table 23.1 presents these alternatives to copper plating for forming IVH connections.

**23.3.2.8 OrmeLink.** CTS's co-lamination process and Ormet's transient liquid phase sintering (TLPS) process (OrmaLink) are similar to the ALIVH process conductive paste in that it is a via paste copper-tin organometallic matrix that sinters into a solid metallurgical via.

FIGURE 23.17 The typical manufacturing process for FACT-EV boards.

CTS’s process is called ViaPly. Past users, in addition to Sheldahl, included Litronics, now called Allied-Signal Substrates, in Costa Mesa, California. Up to four layer pairs have been connected (eight metal layers) using OrmeLink.

23.3.2.8.1 *Structure.* The Ormet structure is made up of polyimide or FR-4 layer pairs. Different materials can be mixed if a rigid core or heat spreader is required. The conductive paste is a TLPS ink of copper-tin. The structure is shown in Fig. 23.18. Figure 23.19 shows the cross-sections of two finished circuits with lasered-via polyimide layer pairs, with TLPS solid metallurgical vias connecting the layer pairs and FR-4 innerlayer cores with buried TLPS vias.

23.3.2.8.2 *Manufacturing Process.* The manufacturing process is shown in Fig. 23.20. The microvias are lasered or punched in the polyimide adhesive and then filled with the TLPS paste. The structure can now take layer pairs from any other HDIS process (such as Sheldahl’s) and turn them into a multilayer structure through sintering. The conductive pastes have to be sintered in a condensing vapor of fluorocarbon at 215°C for 2 min. The structure is then postcured by baking for 40 min. at 175°C. Table 23.2 details the process.

TABLE 23.1 Alternative HDI Technologies

Fabricator	Trade name	IVH process	Metalization
Dyconex	DYCore	Copper etching	Etched copper bumps
Ormet	OrmeLink	Laser, plasma, or photodielectric	Cu/Sn organo-metallic
Matsushita Comp.	ALIVH	Laser	Copper particles in epoxy
Toshiba	Bbit	Insulation displacement	Silver/epoxy paste
Parelec	PARMOD	Drill, laser, or photodielectric	Metallo-organic decomposition, Cu or Ag
Namics	Unimec	Punch, drill	Silver, palladium, and copper particle pastes
North Corp.	NMBI NMTI (Neo-Manhattan)	Image and etch	Etched copper bump
Denso	PALUP	Laser	Cu organo-metallic
Ibiden	SSP	Laser	Plated copper bumps
Fujikiko	Fact-Ev	Photoprocessing	Plated copper posts

TABLE 23.2 Properties and Curing Processes for the Ormet Type of TLPS Conductive Pastes

Property	Curing process
Ormet 2005 series ink	Specification and processing parameter
Electrical conductivity	Bulk $4.0 \times 10^{-3}$ Ohms-cm. Sheet resistance $10.0 \times 10^{-3}$ Ohms/sq. in.
<i>Adhesion (Tensile Pull) on Various Materials</i>	
FR-4 ( $T_g = 125^\circ\text{C}$ )	1,300 psi (minimum)
Copper	2,921 psi (average)
Printability	With 230 stainless steel wire mesh and emulsion thickness of 7.5 $\mu\text{m}$ Sintered thickness 28–38 $\mu\text{m}$ 200 $\mu\text{m}$ traces on 400 $\mu\text{m}$ pitch
Cure cycle	30 min. drying at $85^\circ\text{C}$ 2 min. vapor cure at $215^\circ\text{C}$ 40 min. postcure at $175^\circ\text{C}$

**FIGURE 23.21** The parallel-bonded solid via structure of the ALIVH multilayer with cross-sections of examples.

**23.3.2.9 ALIVH.** The ALIVH (Any Layer Interstitial Via Hole) process has been in development for many years by Matsushita Components of Osaka, Japan. The novel process eliminates additive metallization and plating, but defines all features by subtractive etching of the copper foil. The build-up process is not sequential, though; it uses layer pairs and aramid-epoxy prepreg with copper-paste vias that can be laminated at one time into a three-dimensional structure. CMK (the second largest PCB maker in the world) and other Japanese firms have licensed the process. Six to 10 layers have been laminated in this way.

**23.3.2.9.1 Structure.** Figure 23.21 shows the structure and cross-sections for an ALIVH product. The PCB consists of laser-produced blind vias. The core material is an epoxy-aramid laminate. The man-made aramid filaments are ideal to be cut with a CO<sub>2</sub> or UV laser. If the DuPont Kevlar filaments are added, then the resulting material will have a very low coefficient of thermal expansion (CTE). This is useful for mounting ceramic packages and for direct attachment of flip-chip integrated circuits. The structure can be as simple as a two-sided PCB or as complex as a many-layered PCB. The vias consist of a copper-epoxy paste that connects the various ALIVH layer pairs into a multilayer structure. This is not a sequential build-up process, but rather a parallel build-up process.

**23.3.2.9.2 Manufacturing Process.** The ALIVH process is shown in Fig. 23.22. The process starts with an epoxy-aramid B-stage prepreg. The laser cutting of holes can proceed very rapidly. The material is then printed with a conductive paste of copper and epoxy to fill these holes. Copper foil is applied and the structure is laminated to attach the foil and cure the prepreg and conductive pastes that serve as vias. The sheet of material is imaged and etched to provide the various circuits. Registration is less critical because the vias are now *under* the surface lands. Several of these two-sided layer pairs can be produced, inspected, and tested. The two-sided structures can then have additional single layers of B-stage/conductive paste layers with foil laminated to one or both sides, or the B-stage/conductive paste layer can be used to attach a number of layer pairs in one parallel lamination. The outside is imaged, etched, and completed as a normal PCB.

6. Fill prepreg with conductive paste 2

7. Co-Laminate with finished layer pairs 2

8. Coat solder mask & finish

FIGURE 23.22 The ALIVH manufacturing sequence for a multilayer substrate.

An advanced manufacturing process results in a product known as ALIVH-FB. This product has a fine-line, tight via structure suitable for wire-bonding and flip-chip substrates, as shown in Fig. 23.23. The manufacturing process for each microvia technology begins with a base core, which may be a simple double-sided board carrying power and ground planes or a multilayer board carrying some signal pattern in addition to power and ground planes. The core usually has PTHs, which become blind via holes (BVHs). Such a core is often called an *active core*.

In fabricating a base core with a pattern, manufacturers usually panel-plate the core panel and create the pattern through a dry-film tenting process. Some makers seem to prefer pattern plating, however. The choice depends on the fabricator's familiarity with these processes. After the pattern is formed, dielectric material is laminated over the core (in the case of prepreg, with copper foil) and the holes can be filled with resins, depending on the plated hole diameter and the thickness of the core. It is generally agreed that when the diameter of plated holes is equal to or less than 0.3 mm and the core thickness is equal to 0.6 mm or less, these holes can be filled effectively by the lamination process (although the resin thickness of 80 μm is preferred in the case of RCC).

When the diameter and thickness conditions are not met, it is necessary to fill the holes by a separate process. A screening process does this from one side of the panel with a polyester screen that has an oversized hole pattern. After filling the holes the resin is cured completely.

FIGURE 23.23 The ALIVH-FB manufacturing process for a multilayer substrate. (Illustration Courtesy of CircuiTree.)

**23.3.2.10 MSF** Shinko of Japan developed the MSF HDI technology. It utilizes laser-drilled RCC materials and vias filled with a conductive paste. After testing, these are laminated into the parallel build-up structure. Figure 23.24 shows the typical manufacturing sequence for this HDI technology.

**23.3.2.11 PALAP** PALAP (Patterned Prepreg Layup Process) is a process that was developed by a consortium consisting of the Japanese firms Denso, Wako Corporation, Airex, Kyosha, Noda Screen, and O.K. Print. Originally, the process started with copper-clad laminates (CCL), but now utilizes thermoplastics like PEEK resins (polyether-ether ketone) or a new plastic called PAL-CLAD. PAL-CLAD is characterized by the electrical properties and heat resistance of BIAC, a recyclable thermoplastic resin film produced by Japan Gore-Tex, Inc.

The single-lamination process compares favorably to conventional PCB processing, where lamination, curing, and wiring patterning are repeated layer after layer. PALUP boards can be multilayered by pressing together all thermoplastic resin layers, each having wiring patterns, as shown in Fig. 23.25. This significantly improves quality, lowers costs, and shortens delivery times. PALAP boards also offer high-interconnecting reliability by adopting metallic paste for filling vias, and have excellent high-frequency properties due to a low dielectric constant.

FIGURE 23.24 The MSF manufacturing sequence for a multilayer substrate.

2. Laminate thin plastic film to dielectric

3. Image and etch copper

4. Laser drill vias from resin side

5. Vias filled with conductive paste by screening

6. Remove thin plastic film

7. Repeat Steps 1–6 several times

8. Lay-up with finished layer (foil and unstructured cap layer)

9. Vacuum laminate with finished layers at 200-240C. Metal paste sinters, leaving only metal. Diffusion between paste and foil creates a strong metallurgical bond.

9. Circuitize outer layers and coat solder mask & finish

FIGURE 23.25 The PALAP manufacturing sequence for a multilayer substrate.

**FIGURE 23.26** The VIL manufacturing sequence for a multilayer substrate.

PALAP boards also give due consideration to the environment, one of the major issues requiring action in the area of electronics products, including those used in information technology and automobiles. Because PALAP boards use thermoplastic resin as their base material, they enable material recycling in which only the resin is separated and reused.

**23.3.2.12 VIL.** The VIL (Victor Interconnected Layers) HDI technology was developed by Victor of Japan. It utilizes FR-4 prepreg materials that are laser-drilled and sequentially laminated after the vias are filled with a conductive paste. Figure 23.26 shows the typical manufacturing sequence for this HDI technology.

### 23.3.3 Mechanical Drill-Via Technologies (See Fig. 23.6)

Hitachi HITAVIA is an example of the mechanical drill-via technologies available.

**23.3.3.1 HITAVIA.** The Hitachi HITAVIA technology is the only HDI process developed for use with conventional mechanical drilling. It utilizes RCC or prepreg materials that are mechanically drilled and sequentially laminated after the vias are filled with a conventional electroless copper and copper plating. The typical manufacturing sequence for this HDI technology is similar to that of previously described HDI processes such as CLLAVIS and PPBU.

### 23.3.4 Plasma-Via Technologies (See Fig. 23.7)

Plasma-via technologies include DYCOstrate, plasma micromilling, and plasma-etched redistribution layers (PERL).

**23.3.4.1 DYCOstrate.** Starting in 1989, Dr. Walter Schmidt of Contraves in Switzerland developed the plasma-etching process for microvias. Evolving from the traditional plasma desmear process, the plasma etcher for vias was jointly developed by Dyconex (successor to Contraves) and Technic Plasma of Germany. Dyconex trademarked and patented its via-generation process as DYCOstrate. Hewlett Packard licensed the technology in 1993 and developed it for mass, low-cost production. The low-cost production process of Hewlett Packard is called PERL (for plasma-etched redistribution layers).

**FIGURE 23.27** The DYCOstrate multilayer structure and cross-sections of through and blind vias.

DYCOstrate, along with SLC and Finstrate, is among the most enduring production processes for microvias generation. The DYCOstrate process was first employed for high-reliability military, aerospace, medical, and IC packaging starting in 1991. Since that time, Dyconex has used the process to produce hundreds of different printed boards both in polyimide film and with the new laminates called FR-4 RCC. This Dyconex called DYCOstrate-C.

**23.3.4.1.1 Structure.** Figure 23.27 shows the structure of DYCOstrate. The core material can be polyimide film with plasma-etched holes, drilled epoxy fiberglass, or other plasma-etchable materials such as liquid crystal polymers. Multiple layers can be built up to increase density with the resulting buried and blind vias, but two-sided DYCOstrate structures are also used in products because of the very high density that 0.075 mm through holes allow.

**23.3.4.1.2 Manufacturing Process.** The manufacturing process for a DYCOstrate substrate utilizes common printed circuit board techniques. Only the via-generation process is different. To produce a plasma-etched via hole, manufacturers use two or three process steps that replace the conventional mechanical drilling-debur-desmear steps:

1. Define photographically the location and geometry of the via holes.
2. Etch an opening in the copper foil that will serve as the resist mask.
3. For blind vias, reduce the copper-foil thickness to eliminate the copper overhang.

Figure 23.27 shows microsections of a plated through hole and a blind via in polyimide film. The plasma-etch procedure is basically an isotropic process, as indicated by the undercut seen on the through hole; considering the actual dimensions, however, this undercut is too small to cause any plating problems.

When the etching depth is increased, as in the case of a blind via, the resulting undercut is generally too big to allow reliable plating. To overcome this problem, the manufacturer can reduce copper use by etching the copper foil, eliminating the copper overhang, and providing a thinner copper foil for fine-line resolution.

Figure 23.28 shows two common products made with the Dycostate process (a four-layer flex-multilayer chip-on-board (COB) for a hearing aid) and the PERL process (a six-layer FR-4 COB for a networking module).

**FIGURE 23.28** DYCOstrate and PERL multilayer examples.

The manufacturing process for a DYCOstrate substrate with a standard four-layer build-up is shown in Fig. 23.29. Starting with a prefabricated double-sided DYCOstrate foil, the manufacturer bonds two single-sided copper clad foils to the center-core foil using standard lamination techniques of mass-lam-like process. The resulting four-layer structure is then processed and structured analog to the two-layer foil, producing blind vias instead of through holes.

Further refinements in magnetrons for IC manufacturing provide the opportunity for finer plasma-etched vias. Additionally, Dyconex has demonstrated landless vias to be simple and reliable, offering much higher densities at lower cost and simplifying fabrication registration.

**23.3.4.2 Plasma Micromilling.** The drilling of simple holes is not the only process in which plasma etching is used. Plasma can be also be used to sculpture the surface of the substrate or to fabricate slots, grooves, stepped windows, and more. Even angled vias or tubular systems can be formed. This is useful since cavities can be formed for wire bonding or recessed

**FIGURE 23.29** The DYCOstrate multilayer manufacturing sequence for a four-layer substrate.

mounting of components. A simple definition of the periphery outline by artwork can provide extremely accurate final fabrication, or windows in the final etch step can define areas that will flex.

**23.3.4.3 Plasma-Etched Redistribution Layers (PERL).** The PERL process was developed by Hewlett Packard to produce microblind and buried vias using the DYCOstrate plasma via process. The materials used are the FR-4 epoxy-coated copper foils (RCC) to replace epoxy-glass prepregs in normal multilayer production. These are copper foils coated with a B-stage epoxy or dual C-stage/B-stage epoxy films.

**23.3.4.3.1 Structure.** The structure of DYCOstrate PERL is shown in Fig. 23.28. The core material can be standard FR-4 multilayer innerlayers or a through-hole-plated two-sided or multilayer board. Multiple layers can be built up to increase density with the resulting buried and blind vias. Current production ranges from 4 layers to 12 layers with various buried board and buried via constructions. As with DYCOstrate, many materials are plasma-etchable and the resin butter-coated copper foils come in many thicknesses and resin types, such as BT, cyanate ester, and polyphenylene-ether (PPE).

**23.3.4.3.2 Manufacturing Process.** The manufacturing process for a DYCOstrate PERL substrate utilizes common printed circuit board techniques. Only the via-generation process is different. To produce a plasma-etched via hole requires only two or three process steps that replace the conventional mechanical drilling-debur-desmear steps:

1. Define photographically the location and geometry of the via holes.
2. Etch an opening in the copper foil that will serve as the resist mask.
3. For blind vias, reduce the copper-foil thickness to eliminate the copper overhang.

The manufacturing process for a DYCOstrate PERL substrate with a standard four-layer build-up starts with FR-4 innerlayers or a prefabricated double-sided or multilayer board. Two single-sided copper foils with resin coatings are bonded to the center-core foil using standard lamination techniques. This structure could also be procured through standard mass-lam channels. The resulting four-layer structure is then processed and structured analog to the two-layer DYCOstrate foil, producing blind vias. Through holes can be added or they can be in the preexisting buried board.

### 23.3.5 Screen-Printed Via Technologies<sup>[11]</sup>

Toshiba's new Buried Bump Interconnect Technology is a new screen-printed via process.

**23.3.5.1 Buried Bump Interconnect Technology (BBIT).** Toshiba has developed a new process referred to as BBIT (Buried Bump Interconnection Technology). With this process, a conductive paste is employed to replace via drilling, additive metallization, and via plating. The process has the advantage that hole-producing equipment is not required. Instead, a screened silver-epoxy paste is cured to be pointed like a thumbtack. This paste displaces the glass and epoxy during lamination to connect to the copper on the opposite side of the prepreg. The mass via-generation techniques, the simplification of metallization, and the fact that no drilling equipment is required make this new technique potentially very inexpensive. Currently, the design rules and features are for consumer products, but future uses are for simple plastic ball grid arrays (PBGAs).

**23.3.5.1.1 Structure.** The BBIT structure appears similar to that of other PCBs employing conductive paste vias. As shown in Fig. 23.30, the structure is similar to ALIVH. The difference is that the BBIT structure uses standard FR-4 materials and a novel way to produce a via.

FIGURE 23.30 Structure of the BBIT substrate.

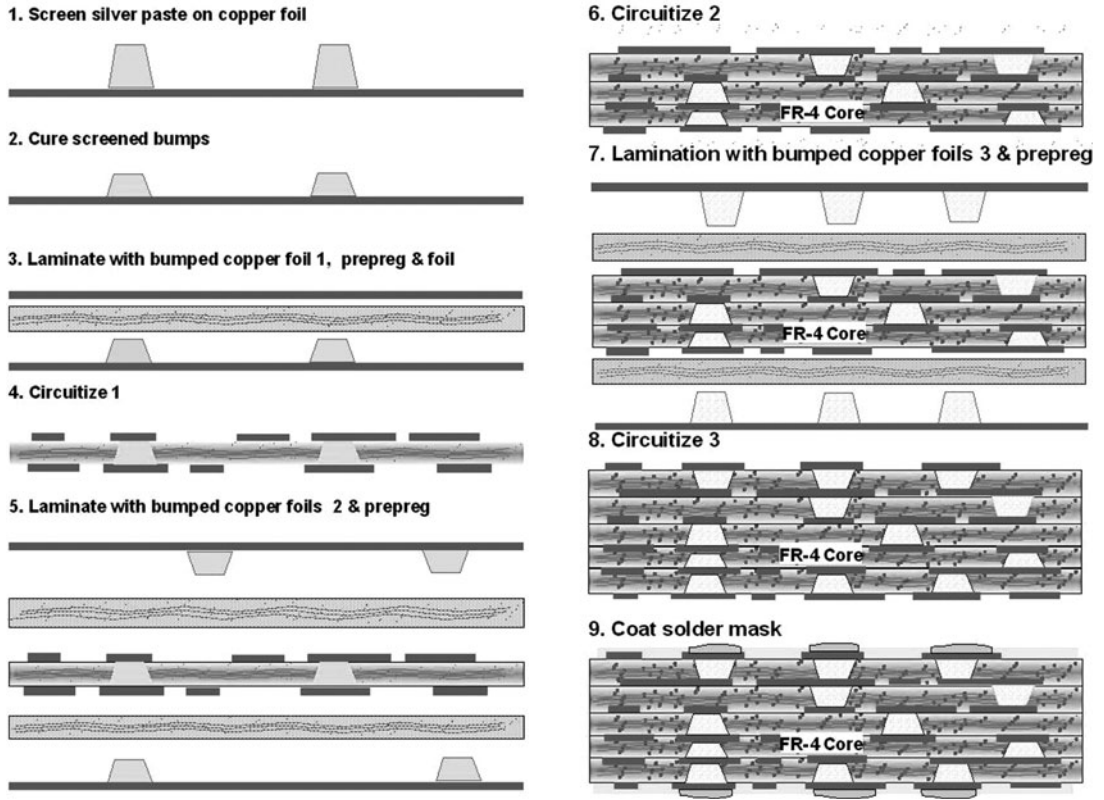

FIGURE 23.31 The manufacturing process for BBIT boards.

**23.3.5.1.2 Manufacturing Process.** A silver ink is screened on copper foil in the locations where vias are required. This copper is used in the manufacture of standard FR-4 laminate. The silver paste thumbtack-like obstruction forces itself through the glass cloth during lamination to connect itself to the copper foil on the other side of the laminate and to cure the prepreg. The sheet of material is imaged and etched to provide the various circuits. Registration is less critical because the vias are now under the surface lands. Several of these two-sided layer pairs can be produced, inspected, and tested. The two-sided structures can then have additional single layers of B-stage/conductive paste layers with foil laminated to one or both sides, or the B-stage/conductive paste layer can be used to attach a number of layer pairs in one parallel lamination. The outside is imaged, etched, and completed as a normal PCB. This process is seen in Fig. 23.31.

A newer BBIT process has been defined to manufacture wire-bonding and flip-chip substrates. In this BBIT process (shown in Fig. 23.32), the prepreg is laser-drilled so that smaller cream Ag solder can be used to bond to the copper.

### 23.3.6 Photo-Defined/Etched-Via Technologies

Neo-Manhattan Bump Interconnect is an example of the photo-defined and etched-via technologies available.

**23.3.6.1 Neo-Manhattan Bump Interconnect (NMBI).** The NMBI technology is one of the newest of the Japanese HDI technologies. It might be considered a “third-generation”

Source:IEEE Trans on Adv. Packaging, Aug.2000

FIGURE 23.32 The manufacturing process for the fine-pitch BBIT substrates.

HDI technology after technologies as ALIVH is considered a second-generation HDI technology. NMBI was pioneered by North Corporation of Japan.

**23.3.6.1.1 Structure.** Figure 23.33 shows the structure of an NMBI substrate. Also in this figure is an scanning electron microscope (SEM) of the etched-metal bumps that make up NMBI's via interconnects.

**23.3.6.1.2 Manufacturing Process.** The manufacturing process for NMBI is unusual in that it does not drill the via connections. Instead, a new material is employed that consists of two different coppers (one thicker than the other) that are bonded together. The thicker copper is imaged and etched to form the interconnect vias. This structure is then filled with a film or liquid dielectric. It is bonded to copper foil and both are cured. These copper foils are then imaged and etched to circuitize the layer pair. The layer pairs can be tested and later be stacked with uncured NMBI structures to form the final multilayer. Like the second-generation ALIVH HDI structure, an NMBI structure allows the connection of any layer to any other layer. This manufacturing process is shown in Fig. 23.34.

### 23.3.7 ToolFoil Technologies

Imprinted circuits are an example of a ToolFoil technology.

**23.3.7.1 Imprinted Circuits.** Imprint patterning is a similar technique used to manufacture compact discs (CDs). No photoresist, registration, or conventional techniques are employed.

FIGURE 23.33 The Neo-Manhattan Bump Interconnect structure.

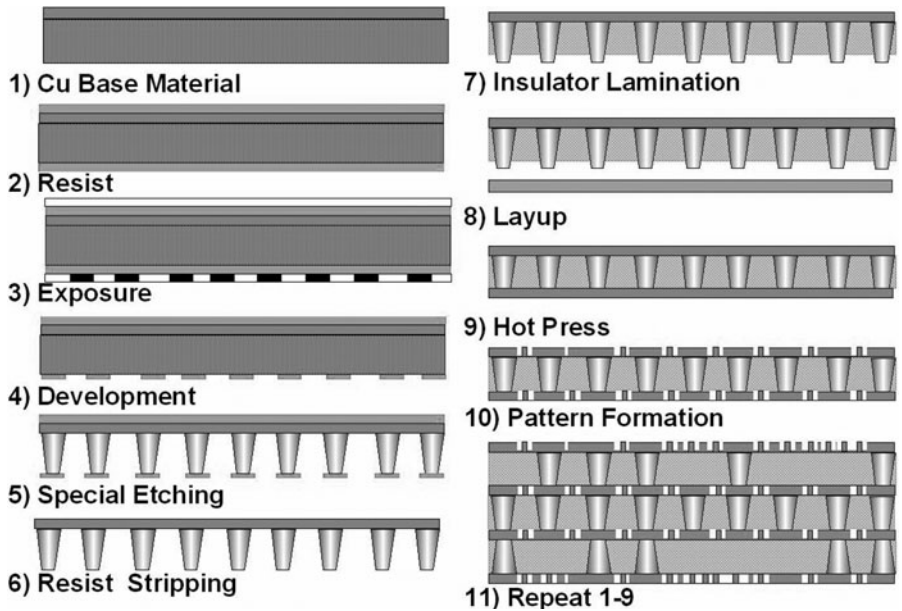

FIGURE 23.34 The manufacturing process for the NMBI substrates.

**FIGURE 23.35** A simplified diagram of the imprinted printed circuit structure.

Every substrate is a copy of the mold (or ToolFoil, in this case), and each can be done in sequence to make a build-up substrate. The unique characteristic of CDs and DVDs is the millions of 0.5 micron pits or vias. A typical CD includes over 3 km of these. The simple manufacturing process and perfect reproduction of the master tool creates inexpensive and accurate substrates. The patented process is a lab process; actual complexity is still under evaluation.

23.3.7.1.1 *Structure.* Figure 23.35 shows a diagram of the imprinted circuit structure, whereas Fig. 23.36 shows SEMs of an imprint-patterned circuit. The unique characteristic

12 mil SMT land with ~ 17 microns of copper

30 mil pitch SMT without the solder paste

25 mil pitch SMT lands with 4 mil traces

**FIGURE 23.36** Various views of SEMs of imprinted circuit liquids and traces. (Courtesy of Dimensional Circuits.)

Cross-section of Imprinted Dexter LF 69702.0 dielectric

**FIGURE 23.37** SEM examples of an imprinted circuit using Dexter LF69702 epoxy and showing how traces and vias are recessed. (Courtesy of Dimensional Circuits.)

of this structure is that all features are embedded in the substrate. The critical dielectric is the part that is imprinted or molded. A long fiber molding compound, such as that used on components' overmolding, is best suited for this task. Such a compound can be used with or without an FR-4 backing. The cross section of an imprint circuit shows the features similar to a CD or DVD, that is, the various impressions. All are metallized but the vias are deeper. This allows the vias to contact the next layer of imprinted circuits, as shown in Fig. 23.37.

**23.3.7.1.2 Manufacturing Process.** A master of the substrate is machined in copper by a UV laser or by photochemical machining. The vias are deep, and the circuits and pads are shallow. Since only one master tool, called a ToolFoil, is required, time can be taken to make sure the master is perfect. With a laser, it is possible to have perfect registration of lands to via holes or even landless vias. This master is electroformed with nickel and back-filled to make a master tool. A sample ToolFoil is shown in Fig. 23.38.

For production, the mold is filled with a thermoset or thermoplastic resin and then cured. The substrate is additive or semi-additive metallized, and plated thicker with copper. The recesses are filled with an etch resist, and the surface resist is removed to expose the copper surface by polishing or by using an abrasive agent. The exposed copper is etched away and the etch resist is dissolved. The entire manufacturing process does not employ photoresists, exposure, or registration. Because of this, the yield is expected to be very high. Figure 23.39 shows the process for tool generation and production substrate. The process for metallization is shown in Fig. 23.40.

**FIGURE 23.38** Example of a ToolFoil for imprinting. (Courtesy of Dimensional Circuits.)

**FIGURE 23.39** The manufacturing process for the ToolFoil and using the tool to make imprinted circuits.

### Metallization Method: *Full Build Copper*

## 23.4 NEXT-GENERATION HDI PROCESSES

HDI and microvias provide a big boost in density due to miniaturization. These technologies will continue to evolve and become smaller, following integrated circuit cell geometries. So the next revolution will be in optical wiring. Currently, optical networking ties together continents and cities, providing the backbone of modern worldwide networking. The fiercely competitive market is what technology will provide “the last mile” on connectivity? Optical wiring is competing for that market.

### 23.4.1 Printed Optical Waveguides

Although electrical signals can be multiplexed on a single 100 micron wire or trace, many individual laser wavelengths can each carry many multiplexed signals on a single 100 micron waveguide. This results in a 10,000× increase in information handling while not being influenced by magnetic and electrical fields such as electronic signals. These optical fibers can now be mass produced on a printed circuit as polymer optical waveguides, as shown in Fig. 23.41. Much like when the industry transitioned from single-point soldering by individual wires to printed circuits, single-point fiber-optical cabling can now have low-cost printed waveguides.

**23.4.1.1 Structures.** The optical waveguide structures are shown in Fig. 23.42. The transmitter package provides the multiplexed laser signal sources, through vertical cavity surface

FIGURE 23.41 Structure of a printed optical waveguide. (Courtesy of Siemens C-Lab.)

emitting laser (VCSEL) arrays into mirrors at the optical polymer waveguide level. At the receiver package, mirrors direct the laser signal up into photodiode arrays.

**23.4.1.2 Components.** Figure 23.43 shows what the transmitter and receiver BGA packages will look like, whereas Fig. 23.44 shows what the micro-mirrors, VCSEL, and photo-receptor sensors may look like.

**FIGURE 23.43** NTT chip-to-chip optical interconnection, Tx and Rx. (Courtesy of NTT-Lab.)

**23.4.1.3 Optical Waveguide Materials.** The optical materials being considered for integrated waveguides are currently polymers. Polymers have a number of advantages:

- **Stability** Such materials offer high thermal stability and long-term photostability. Bellcore Telecordia compliance (i.e., 1209, 1221) tested for less than 600 hr. at 85°C/85 relative humidity (RH), solder temperature >230°C, and degradation temperature >350°C.
- **Well established** A huge body of data has been gathered over the last 100 years on polymers including all the popular photoresists.
- **Useful** Polymers have unique properties (such as bend radius, modulators, and index tuning) that you cannot get anywhere else. These properties include unique processing options (photolithographic, reactive ion etching [RIE], direct laser writing, molding, and printing).

They also have a number of disadvantages:

- **Unstable** Many have low thermal stability (POF below 80°C) with photodegradation (laser dyes < days) and are sensitive to delamination, moisture, and chemicals.
- **Unknown** New materials require new processes, equipment, and experience.
- **Useless** Some polymers have losses of POF of 20 dB/km, whereas optical glass is <0.1 dB/km. The packaging cost of polymers is 80 percent of the cost in devices.

**FIGURE 23.44** Various components and mounting schemes for the VCSEL, mirrors, and photo-receptors. (Courtesy of Siemens C-Lab.)

Candidate materials are acrylates, halogenated acrylates, cyclobutenes, polyimides, and polysiloxane. Table 23.3 lists many of the most popular materials. The optical losses of the polymers (dB/cm) are in the lower wavelengths near 840 nm.

**23.4.1.4 Manufacturing Process.** The manufacturing process for polymer optical waveguides is much like using a liquid photoresist. Roller coating or meniscus coating of the liquid polymer is all that is required to apply the optical polymer on a standard multilayer innerlayer. After drying, the optical polymer is exposed through standard photo masks and developed. After a final curing, they are laminated into standard multilayers with prepreps. Figure 23.45 shows the lay-up of the TRUEMODE optical polymer from Terahertz Corporation.

**TABLE 23.3** Polymers for Optical Waveguides and Candidate Materials

Manufacturer	Polymer type	Patterning techniques	Waveguide optical loss (dB/cm)		
			840 nm	1300 nm	1550 nm
Allied Signal	Halogenated acrylate	Lithographic, RIE laser	0.01	0.03	0.07
	Acrylate	Lithographic, RIE laser	0.02	0.2	0.5

## 24.1 INTRODUCTION

---

The purpose of through-hole drilling printed circuit boards is twofold: (1) to produce an opening through the board that will permit a subsequent process to form an electrical connection between top, bottom, and internal conductor pathways, and (2) to permit through-the-board component mounting with structural integrity and precision of location.

The quality of a hole drilled through a printed circuit board is measured by its ability to interface with the following processes: plating, soldering, and forming a highly reliable, non-degrading electrical and mechanical connection.

As with any process, the elements of the drilling process are:

- Materials
- Machines
- Methods
- Workers

When workers are properly trained and educated so that they possess a sound understanding of the other three elements, it is possible to drill holes meeting the aforementioned requirements with high productivity, consistency, and yield.

The goals of this chapter are as follows:

- Understanding the drilling process thoroughly
- Recognizing what might go wrong
- Locating where problems could occur
- Detecting whether problems do occur
- Finding root causes of problems
- Correcting undesirable conditions
- Striving for zero discrepancies
- Making improvement a team effort

24.2 MATERIALS

Materials that affect the drilling process are as follows and as shown in the fishbone diagram of Fig. 24.1.

- Laminate material
- Drill bits
- Drill bit rings
- Entry material
- Backup material
- Tooling pins

24.2.1 Laminate Material

A typical circuit board laminate panel consists of three basic components:

- Supporting fibers
- Resin
- Copper layers

The laminate substrate material is constructed of supporting fibers (most commonly a glass fiber weave) and a resin (most commonly an epoxy compound). Finished board thickness may range from 0.010 to 0.300 in or thicker, with the most common panel thickness ranging around 1/16 (0.0625 in).

**24.2.1.1 Supporting Fibers.** Generally, the larger the glass fibers in the weave, the lower the cost of the base material. However, larger fibers are less desirable from a drilling point of view because they are more likely to cause the drill bit to deflect, resulting in decreased hole

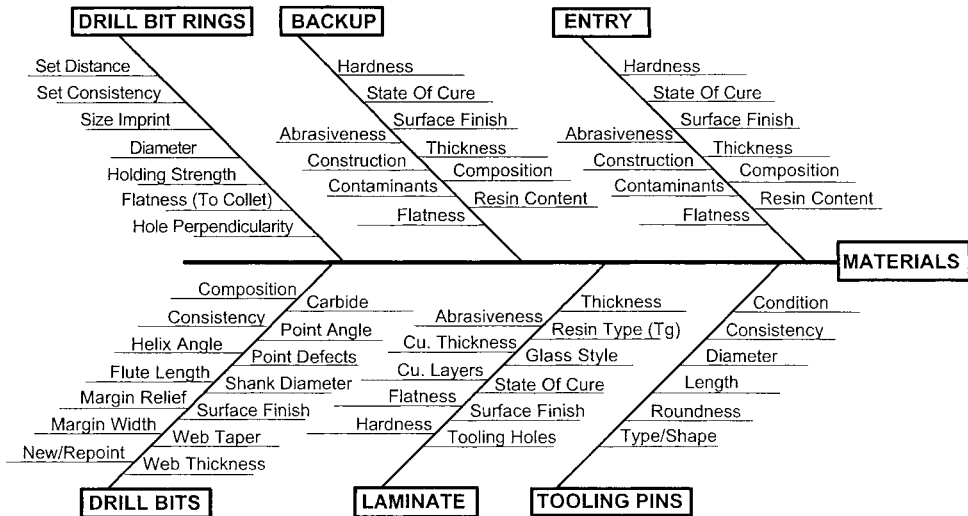

FIGURE 24.1 Materials used in the drilling process, with major variables and special considerations identified.

registration accuracy. In addition, larger fibers adversely affect drilled hole wall quality because they create larger (drilling) voids, defined as tear-out of supporting fibers. In simple terms: the larger the glass fibers, the larger the chunks torn out during drilling and thus the greater the hole wall roughness.

**24.2.1.2 Resin.** The most common resin system is FR-4 epoxy. However, general drilling considerations (see Fig. 24.1) are the same for all resin systems. The glass transition ( $T_g$ ) rating of a material is defined as the temperature at which fully cured resin starts to soften. The  $T_g$  of FR-4 is typically around 130°C or higher. Many materials have resin systems that include additives or that are different from FR-4 resins (e.g., polyimide) in order to raise the  $T_g$ . The reason higher  $T_g$  is desired is because it implies a more stable material with lowered  $z$ -axis expansion rates. Although higher- $T_g$  material may reduce the extent of hole wall resin smear, the compromise of a higher- $T_g$  product is that the material is more brittle and more abrasive to the drill, resulting in increased tool wear and hole wall roughness. This increased abrasiveness to the drill bit may be offset by reducing the surface speed to reduce the spindle speed, resulting in less frictional heat being generated. Lowering drilling heat reduces drill wear.

**24.2.1.3 Copper Layers.** Outer and inner copper layers may be of various thicknesses, the most common being what is referred to as  $1/2$ -oz and 1-oz copper. One-ounce copper equates to a thickness of approximately 1.4 mils (0.0014 in). The more copper layers within a laminate, the more balanced the panel from a drilling point of view, meaning reduced occurrences or extents of drilled hole defects such as voids (torn-out fiber bundles). However, in order to compensate for a greater number of copper layers, the chip load (advance per revolution) that determines the infeed rate usually needs to be adjusted to control nail-heading. Increasing the chip load reduces the amount of nail-heading. In addition, more copper layers wear the drill bit at a faster rate and may require lowering the maximum hit count per drill bit.

## 24.2.2 Drill Bits

**24.2.2.1 Materials.** Drill bits are made of tungsten carbide because its wear resistance (and relatively low cost) make it the most ideal material for cutting the very abrasive circuit board laminate materials. The compromise of this very hard (carbide) material is that it is also brittle and subject to damage in the form of chips if not handled carefully and correctly.

**24.2.2.2 Handling and Inspection.** When handling drill bits, do not permit the bits to come in contact with one another and be careful not to touch them to the sides of the tool pods. Modern drilling machines utilize drill cassettes to reduce time per load by eliminating manual tool changes. These cassettes may accommodate 120 or more drill bits and reduce drill bit handling damage. If drill bits are measured to verify diameter using a contact-type measuring device (such as a contact micrometer), take the measurement away from the point to prevent chipping of the cutting corners. Following diameter measurement, inspect the drill bit for damage using a microscope. After use, again use care when removing drill bits from the tool pods or cassettes and remember, if they are intended for repointing, to use the same careful handling practices as when they were new.

**24.2.2.3 Geometric Attributes.** The geometry of a drill bit very much affects the way it behaves during drilling. (See Fig. 24.2 for attribute nomenclatures.) The land is the area remaining after fluting. In order to reduce the amount of land that creates friction with the hole wall (thus generating heat), drill bits are margin relieved. The amount of land remaining in contact with the hole wall during drilling is referred to as the margin. The wider the margin, the greater the friction area and the higher the drilling temperature, resulting in higher extents of heat-related hole quality defects such as resin smear and plowing (defined as furrows in the resin).

FIGURE 24.2 Drill bit geometry.

The result of increasing the land mass and the web is a smaller flute area. Less flute space implies reduced amounts of available area to remove drilling debris, which again raises the drilling temperature. It is important to understand that some drill designs that are meant to increase strength (particularly in smaller-diameter drill bits, with the intent to reduce breakage) may include what are referred to as partial margin reliefs (see Fig. 24.3). What this means is that when the drill bit is viewed from the point, a relieved margin is seen. However, viewing

FIGURE 24.3 Drill tip attribute nomenclatures.

this type of design drill bit from the side reveals that the relief extends only part of the way, typically about one-fifth of the total flute length. The major drawback of this particular design is that it increases drilling temperatures (documented to be as much as 25 percent or more), resulting in increased heat-related drilled hole defects (such as smear) and drill breakage due to packed margins.

**24.2.2.4 Flute Length.** Minimum flute length must equal total drilled depth (total laminate thickness + entry thickness + backup penetration depth) plus at least 0.050 in of unused drill flute remaining above the stack at the bottom of the drill stroke to allow debris to be removed by the vacuum system. If debris cannot be removed from the drill flutes during and between drill strokes, the results are extensive hole quality defects and drill breakage.

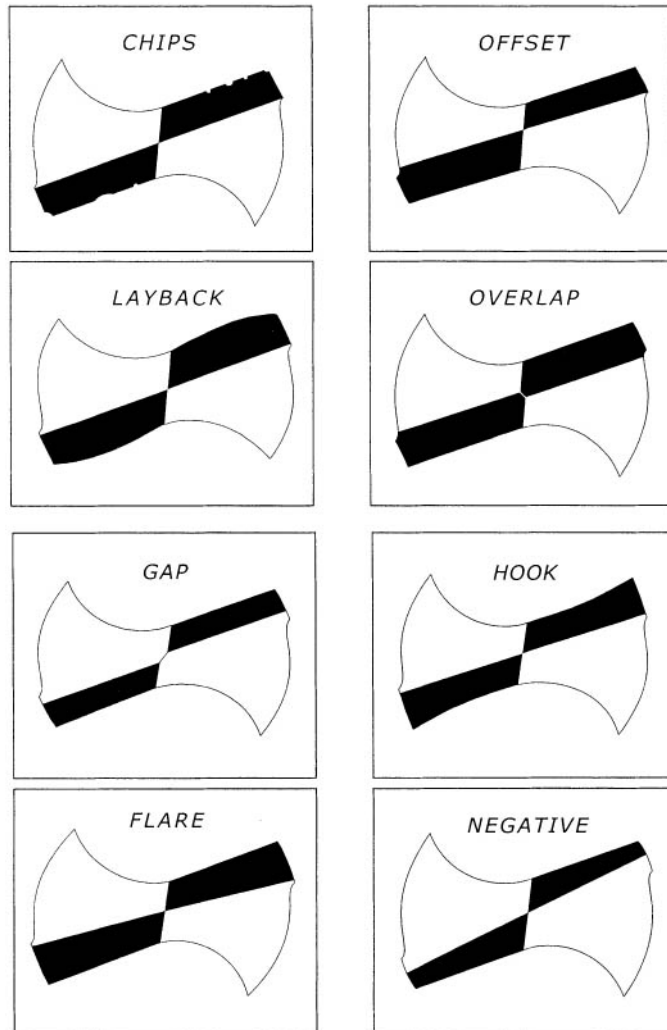

**24.2.2.5 New Drill Bits.** It is not necessary to inspect incoming orders of drill bits 100 percent. A procedure proved to be effective is to inspect drill bits according to an acceptable quality level (AQL) method (such as MIL-STD-105). This type of sampling plan allows the user to determine the percentage of drill bits that are inspected to judge an entire lot of drill bits to a predetermined quality level. Using this method, finding a defined quantity of drill bits that do not meet the specification is cause to return all received drill bits to the vendor; if the selected quantity of inspected drill bits meets specification, the entire lot of drill bits is accepted. Inspection criteria might include point geometry defects (refer to Fig. 24.4), damage (chips), diameter (drill and shank), and flute length, as well as correct ring set distance and size imprint (matching both the actual diameter and that labeled on the box).

**24.2.2.6 Repointed Drill Bits.** Drill bits are typically repointed for reasons of economics. The cost of repointing a tool may be as low as 15 percent of the cost of a new tool. The number of times a drill is repointed varies anywhere from 1 to as many as 10 times or more and typically depends on the drill diameter. The smaller the drill, the fewer times it is normally repointed. The reason is that smaller-diameter holes are more critical and require better hole quality.

There are two methods used to repoint tools.

1. The first is to specify a certain number of times the tool is to be repointed before being discarded. This number typically varies between one to three for smaller-diameter tools depending on hole quality experienced after repointing.
2. The second is to specify a minimum overall length of the tool at which it is discarded. Minimum overall length is determined by calculation based on minimum remaining flute length required to drill the required total drilling depth. This method does not allow determination of how many times a drill is actually repointed because stock removal during each regrind may vary from 0.002 to 0.005 in or more.

Repointed drill bits cannot be expected to perform as well as new drill bits because only the points are refurbished to a quality that may be as good as a new drill bit while the rest of the drill bit, including the critical margin, is not. The condition of the margin is very important because it is the part of the drill bit that finishes the hole wall. A rough margin results in a rough hole wall surface. When inspecting repointed drill bits, examine the sides of the drills for margin damage and/or fused or packed drilling debris remaining from previous use. These drill bits contaminate holes from the very first one drilled and may cause run-out due to an imbalanced condition of the drill bit resulting from the buildup. Drill bits must be repointed to the same point geometry specifications as those that apply to new drill bits. Point inspection criteria, therefore, is the same for repointed drill bits as for new drill bits.

**FIGURE 24.4** Drill point defect illustrations. (Courtesy of LCOA Technical Center.)

### 24.2.3 Drill Bit Rings

Drill bit rings are set to a common distance from the point to the back of the ring, thereby allowing a controlled drilling depth. The quality of these rings is as critical as the consistency of drill bit attributes because they can equally affect drill bit performance. Rings that fit loosely on the drill shank have been known to move during tool changes, resulting in insufficient drilling depth. Rings that fit too tightly may crack. Rings that have protruding material (“flash”) on the inside diameter may cause improper seating of the drill bit in the collet (of the spindle) or may prevent the drill bit from being properly inserted into the tool pod or cassette, resulting in destructive tool change problems.

Rings have specific color codes assigned to each size and are commonly imprinted with size, diameter, and design or series number. Rings may be either machined or mold-injected. While machined rings are superior because of their consistency and quality, their cost is prohibitive for many drill bit manufacturers. Some of the drawbacks of mold-injected rings that must be monitored are inside diameter, affecting how well the ring fits on the drill shank, and remaining flash.

## 24.2.4 Entry Material

**24.2.4.1 Purpose.** The purpose of the entry material is fivefold:

- Centers the drill
- Prevents drill breakage
- Prevents copper burrs
- Avoids contamination of the hole or drill bit
- Prevents pressure footmarks

**24.2.4.2 Types.** There are many different available types (constructions) of materials used as entry material for printed circuit board drilling, although few are specifically designed and engineered for this purpose. Engineered products are designed to improve hole registration accuracy and reduce drill breakage. The performance qualifications of the most popular materials are discussed in the next section.

Commonly available entry materials, listed in order of performance quality with respect to the five characteristics listed in the preceding section, are:

- Aluminum-clad cellulose core composite
- Solid aluminum (various alloys and thicknesses)
- Solid or melamine-clad phenolic
- Aluminum-clad phenolic

**24.2.4.3 Performance.** The right entry material will improve drilled hole registration and lower the risk of drill bit breakage by minimizing drill deflection upon contact with the stack. In order for the entry material to function properly, it must be flat and free of pits, dents, and scratches. Warped or twisted material will result in increased extents of entry burrs and drill bit breakage. Surface imperfections and materials that are too hard contribute to drill deflection, resulting in decreased hole registration accuracy and breakage of small-diameter drills.

Phenolic materials or phenolic composites (i.e., aluminum-clad phenolic) often warp and under most drilling conditions contaminate the hole wall, which results in problems with adherence of the plating because desmearing chemicals are not designed to remove phenolic resin. Solid aluminum materials of the correct composition and hardness that are not of an excessive thickness, yet are not too thin, may work satisfactorily with larger-diameter drill bits. However, drilling with solid aluminum materials (0.008 in and thicker) may increase the risk of breakage of smaller-diameter drills. Aluminum-clad cellulose core materials provide a hard surface to prevent burrs yet minimize drill deflection and breakage associated with solid aluminum.

## 24.2.5 Backup Material

**24.2.5.1 Purpose.** The purpose of backup material is defined by the following criteria. An ideal backup material will:

- Provide a safe medium for drill stroke termination
- Prevent copper burrs
- Not contaminate the hole or drill bit
- Minimize drilling temperatures
- Improve hole quality

**24.2.5.2 Types.** Numerous materials are available that are sold as backup material. Few of the materials used as backup materials are actually specifically engineered for circuit board drilling. Many of the popular backup products are composites with a variety of surface coatings or skins bonded to several different core materials. Available backup products include the following:

- Epoxy-paper-clad, wood-core composite utilizing a bonding agent with lubricating properties
- Aluminum-clad, wood-core composite
- Epoxy-paper-clad, wood-core composite
- Melamine-clad, wood-core composite
- Urethane-clad, wood-core composite
- Solid phenolic
- Aluminum-clad phenolic composite
- Plain wood
- Hardboard

**24.2.5.3 Performance.** Desired qualities in a backup material are minimal thickness variations, flatness (no bow, warp, or twist), no abrasives or contaminants, a smooth surface, low cutting energy (minimizing drilling temperatures), and a surface hardness that supports the laminate copper surface (to prevent burrs) yet does not cause damage or extensive wear to the drill bit.

Backup materials with lubricating properties have been proven to significantly reduce drilling temperatures by as much as 50 percent or more, often resulting in temperatures below the  $T_g$  of the laminate product being drilled. This advantage greatly reduces hole wall defects such as roughness, smear, and nail-heading and often allows increased drill stack heights and/or greatly increased drill bit maximum hit counts. The importance of these benefits is significant reduction in drilling cost per hole and improved productivity and yield.

Remember that drilled backup debris exits the stacks by passing through the holes in the laminate material and that therefore contamination (from the backup material) is of great concern. Materials containing phenolic, or composed of solid phenolic, are not suitable for circuit board drilling. Phenolic materials or phenolic composites (i.e., aluminum-clad phenolic) often warp and under most drilling conditions contaminate the hole wall, which results in problems with adherence of the plating because desmearing chemicals are not designed to remove phenolic resin. Hardboard types of materials cannot be maintained to thickness variation tolerances acceptable for circuit board drilling and are a source for a great variety of contaminants (e.g., oils crystallized on the surface for hardening purposes).

## 24.2.6 Tooling Pins

Seldom is any due attention given to the tooling pins. They come in many shapes and sizes and their cost, with respect to how much they add to the cost of fabricating a circuit board, is insignificant. Yet, quite often, tooling pins are found to be damaged or deformed (e.g., “mush-

roomed” from being hammered into the stack) or do not fit snugly. Tooling pins that do not hold the stack tightly in place or that allow the stack to move create a large variety of problems from burrs and other hole defects to poor registration or drill bit breakage. These unnecessary problems may be prevented by simply replacing tooling pins when they start to show signs of wear or damage. Use tooling pins that are hardened to minimize wear and deformation, and (ideally)  $\frac{3}{16}$  in in diameter. Pins that are less than  $\frac{3}{16}$  in in diameter (i.e.,  $\frac{1}{8}$  in) do not hold the stack firmly in place during drilling and may result in stack movement.

### 24.3 MACHINES

Machine variables that affect the drilling process are as follows and as shown in the fishbone diagram of Fig. 24.5.

FIGURE 24.5 Drilling machine elements, with major issues and special considerations identified.

#### 24.3.1 Air

**24.3.1.1 Quality.** Maintaining high levels of air quality is important. Air supplied to the machine and the spindle assemblies needs to be clean and dry. This is accomplished by filters that remove dirt and moisture from the air. In areas where the relative humidity is high, or when using air-bearing-type spindles, an inline air drying and filtering system may be necessary to control air moisture levels and dirt. Moist air causes corrosion of air surfaces (such as the spindle sleeve and other spindle components operating on air) and reduces the life of these components, resulting in increased repair costs. Dirty air affects operation of components relying on air by clogging the channels that supply the air (e.g., to the spindle sleeves and table air shoes). In addition, dirt serves as an abrasive that causes faster wear of machine components, resulting in reduced life cycles between repairs, again increasing downtime and repair costs. Cleaning the machine air filters and purging air compressors and lines on a routine basis may minimize problems resulting from dirt or moisture.

**24.3.1.2 Connections and Pressure.** Check connections, gauges, hoses, and switches for leaks and wear. Air hoses connected to the pressure foot pistons often crack near the piston connector; by simply bending the hoses in these areas it can be determined whether they are leaking. Other locations that commonly have poor connections and air leaks are the collet air connector on top of the spindle and the air manifold on the side of the spindle sleeve housing that supplies air to the collet and the spindle sleeve. Sufficient air pressure to both the collet and the spindle sleeve is critical and must be maintained adequately for proper operation. The tool table is designed to ride on a bearing of air supplied through the table air shoes. Verify proper operation of the air shoes by slightly rotating them back and forth; the shoes should move freely. If the shoes do not move with ease or do not move at all, the most likely reason is that the air channels are blocked due to trapped drilling debris, meaning the shoes need to be cleaned or replaced. Check the pressure foot air gauges for the correct air pressure; equal pressure must be supplied to each of the spindle stations. Insufficient or unequal air pressure results in burrs and increases the possibility of drill bit breakage.

### 24.3.2 Vacuum

Effective vacuum is absolutely essential because it greatly affects the resulting drilled hole quality. Heat (drilling temperature) seen by the hole walls depends on how effectively hot drilling chips are removed. Excessive temperature due to inefficient removal of drilling debris causes heat-related hole defects such as smearing and plowing, increases the opportunity for plugged holes, and is a major contributor to drill wear. Check hoses for proper connections, wear, and restrictions and examine the inside of the pressure foot for holes worn inside the connector attaching the vacuum hose.

### 24.3.3 Tooling

**24.3.3.1 Bushings and Slots.** Maintain tight tolerances on tool table bushings and slots and replace bushings that are sunken below the tool table surfaces or are worn. Bushings and slots that do not hold tooling pins snugly and allow stack movement during the drill stroke cause burrs, registration problems, and drill breakage.

**24.3.3.2 Subtooling.** Avoid subtooling plates that overlap across individual tool table stations and fasten the plates securely to the base plates with no separation or gaps. Ensure the subtooling is not warped, does not vary significantly in thickness, and has no surface protrusions (such as broken drill bits) to allow stacks to lay flat and to minimize variation in drill bit penetration depth into the backup material. If your subtooling is other than metal, watch for potential shrinkage or expansion problems indicated by difficulties in fitting the pinned stacks to the existing pinning holes in the plates. If this problem occurs, the results are the same as those caused by bushings and slots that allow stack movement.

### 24.3.4 Spindles

Spindle assemblies are one of the single most important components of the drilling machine. Proper operation is essential and requires maintenance (e.g., collet and collet seat cleaning) and verification on a regular basis.

**24.3.4.1 Collet Maintenance.** For mechanical (ball) bearing spindles, cleaning of the collet and the collet seat (inside the spindle) needs to be performed a minimum of once per shift; dirty collets increase drill run-out. When processing certain laminate materials that create greater amounts of drilling dust, and depending on your vacuum system efficiency, a higher

cleaning frequency may be necessary to maintain acceptable levels of drill run-out. It is recommended that after cleaning the collets be returned to the same spindle from which they were removed because collets tend to adjust to the respective collet seats. For air-bearing spindles, most manufacturers recommend cleaning the collets only when the run-out measures excessive.

**24.3.4.2 Run-Out Measurement.** Drill/collet concentricity, or total indicated run-out (TIR), is a measure that indicates how true the assembly rotates. It can be determined while the spindle is running at various speeds (rpm), which is referred to as a dynamic form of measurement. Another method is performed while the spindle is not running and is called a static measurement. Static TIR is determined by rotating a  $\frac{1}{8}$ -in (0.1250-in)-diameter pin installed into the collet by hand while reading movement on a dial indicator placed against the pin at a distance of approximately 0.800 in (simulating the distance of the drill point) from the collet nose (refer to Fig. 24.6). Of course, the pin used to measure TIR must itself be concentric.

**FIGURE 24.6** TIR measurement (static).

Maximum acceptable TIR for drills greater than 0.0200 in in diameter is 0.5 mils (0.0005 in). When using drills 0.0200 in or less in diameter, the maximum TIR needs to be maintained within 0.2 mils (0.0002 in) to prevent drill breakage. If excessive TIR is noted, it is wise to replace the pin and again measure the run-out. Drill bit blanks make ideal pins for measuring TIR and may be acquired from drill bit suppliers. Excessive spindle run-out results in drill breakage, causes burrs and other drilled hole defects, and adversely affects hole registration accuracy. Excessive TIR may often be corrected by simply cleaning the collet and the collet seat or by replacing a worn collet. Measure the run-out of spindles of each machine at a minimum frequency of once per week.

**24.3.4.3 Spindle Speed.** Maintaining correctly adjusted spindle speed is important because spindles running at speeds other than those displayed on the monitor imply that drill bits are rotating at surface speeds other than those that are desired. When actual rpm is higher than the displayed rpm, it implies higher surface speeds (refer to Sec. 24.4), and vice versa. Higher surface speeds cause greater frictional drill heat, resulting in faster drill wear and greater extents of heat-related hole defects such as smearing and plowing. Noncontact-type tachometers able to measure up to 150,000 rpm or more are available for around \$300 (a lot less than the cost of rebuilding just one spindle) and allow measurement of actual spindle rpm in a matter of minutes. Verifying spindle speeds once every 6 months is usually sufficient.

**24.3.4.4 Pressure Foot.** The pressure foot insert lead distance to the point of the drill bit is set at approximately 0.050 in to give the pressure foot sufficient time to hold the stack flat before the drill bit contacts and enters the stack. If the lead distance is significantly less than the specified distance or if the drill bit point protrudes from the pressure foot, drill bits will break. To ensure the pressure foot assemblies function properly, check pressure foot inserts for wear or damage daily and verify that the pistons and guide rods are not bent and move smoothly.

**24.3.4.5 Adjustment.** When adjusting the physical z-axis height of the spindle, for instance to accommodate a thicker subtooling plate, care must be taken to also adjust the pressure foot so its height remains identical relative to the spindle. The pressure foot adjustment is independent from the spindle and, if not performed correctly, may result in a gap between the bottom of the spindle casing and the top of the pressure foot window. This gap is noticed only while the spindle is engaged and will draw most of the vacuum air, effectively cutting off the vacuum from the pressure foot insert, resulting in a great variety of hole defects and drill bit breakage. If a gap is present, it is usually accompanied by great amounts of drilling debris spewed across the stacks and drilling machine.

### 24.3.5 Mechanical Factors

**24.3.5.1 Heat (Coolant) Exchanger.** Drill motor temperatures are reduced by exchanging a fluid through the spindles. The fluid is processed through a heat exchanger that works much like a car radiator. As with a car, it is important to maintain the recommended coolant mixture, proper fill level, and flow rate indicated by the flowmeter. Check the operation of the fan and minimize coolant flow restriction (due to algae buildup) by cleaning filters regularly. Algae growth is promoted through exposure to ultraviolet light and may be controlled by using black hoses instead of clear ones in addition to adding growth inhibitors to the coolant mixture.

**24.3.5.2 Hardware.** Although simple to perform, checking mechanical connections for loose or worn parts (i.e., causing travel slop of pressure foot assembly movement) is often neglected. It may be accomplished by observing the machine while it is running or checking by hand while the machine is idle.

**24.3.5.3 Lead Screws and Servos.** The environment and cleanliness of the drill room determine how often lead screws need to be cleaned and lubricated to ensure smooth operation and minimize wear. Most machine manufacturers recommend performing this type of maintenance every 6 months. When lubricating the lead screws, only a light coat of the appropriate grease needs to be applied. Excessive amounts of grease on the lead screws defeat the purpose, as this causes more dirt to be attracted, resulting in faster wear. Constant searching for programmed x-y locations indicates problems with the servo motors or lead screws. If this occurs, the displayed x or y (actual) location displayed on the controller will change continuously while the machine is stopped.

**24.3.5.4 z-Axis Stroke.** Because machines may have as many as six mechanical connections in the z axis, travel slop during the drill stroke or retraction may occur, causing chip loads to vary during the stroke, which results in burrs and other hole defects and drill breakage. Check connections by hand for slop while the machine is idle and observe and listen for improper operation while the machine is running.

### 24.3.6 Surfaces

A clean drilling room decreases repair costs and the possibility of improper operation of the drilling machines. Wipe surfaces clean using a lint-free cloth or use a vacuum to remove debris.

Never use compressed air to clean the drilling machine because debris will be blown into areas that need to be kept clean (e.g., lead screws).

**24.3.6.1 Granite.** Granite provides a stable platform that absorbs unwanted vibration. It also offers a smooth and level surface to support the movement of the table. Keep granite surfaces clean to prevent tool table air shoes from becoming clogged and to minimize collection of dirt on the lead screws.

**24.3.6.2 Working Surfaces.** Maintain clean working surfaces, such as the tool table, to minimize the possibility of dirt particles getting trapped between the stacked laminate, entry, and backup panels, causing stack separation that may result in burrs and possible drill bit breakage.

## 24.4 METHODS

Drilling parameter variables that affect the drilling process are as follows and as shown in the fishbone diagram of Fig. 24.7.

### 24.4.1 Surface Speed and Spindle Speed

As holes are getting smaller, higher spindle speeds are required to achieve the desired surface speed that determines throughput. However, higher surface speeds result in higher drilling temperatures that may increase heat-related hole defects such as smearing and plowing.

**24.4.1.1 Definition.** Surface speed is a measure of how much distance is covered by the drill's diameter while it is rotated by the spindle and is expressed in surface feet per minute (sfm). It is used to calculate spindle speed (rpm) for a given drill diameter. The formula to calculate spindle speed using the desired surface speed is shown in Eq. (24.1).

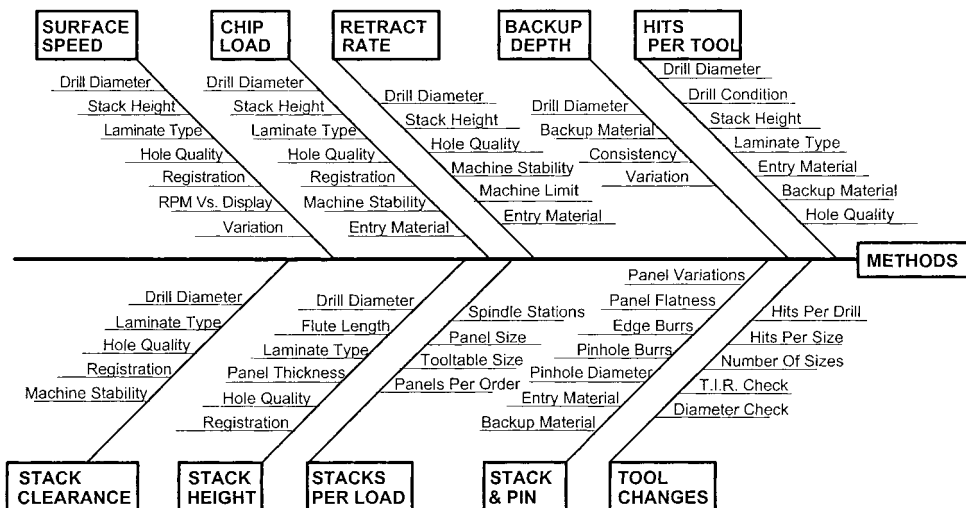

FIGURE 24.7 Methods used in the drilling process, with major variables and special considerations identified.

$$\text{spindle speed (rpm)} = \frac{\text{sfm} \times 12}{\pi \times \text{diam.}} \quad (24.1)$$

where diam. = drill diameter (in)  
 $\pi = 3.1415$

**24.4.1.2 Effects.** The higher the surface speed, the higher the spindle speed, and subsequently the higher the frictional heat that is generated, translating into greater extents of heat-related hole defects and drill wear. Conversely, lower surface speeds imply lower spindle speeds and less frictional heat. When more abrasive materials (e.g., materials with higher  $T_g$  such as multifunctional FR-4, polyimide, or cyanate ester) are processed or drilled stack height is increased, drilling temperatures increase. To offset the resulting increase in temperature under such conditions or when excessive extents of heat-related hole defects are apparent, decrease the surface speed to lower the spindle speed.

## 24.4.2 Chip Load and Infeed Rate

**24.4.2.1 Definition.** Chip load is defined as advance per revolution and is usually expressed in mils (1 mil equals  $1/1000$  of an inch [0.001 in]). It implies the distance the drill travels during the drill stroke per each full revolution of the drill bit. Chip load is used to calculate the infeed rate in inches per minute (ipm).

$$\text{infeed rate (ipm)} = \text{chip load (mils/revolution)} \times \text{rpm} \quad (24.2)$$

**24.4.2.2 Effects.** Higher chip loads result in greater throughput. However, chip load and infeed rate affect hole registration accuracy, drill breakage, burrs, and mechanical types of drilled hole defects such as voids (tear-out of the supporting fibers) and nail-heading. Faster infeed rates translate into higher (top laminate) entry burrs, lower extents of nail-heading defects and (bottom laminate) exit burrs, increased occurrences of drill bit breakage, and higher extents of drilling voids. Lower infeed rates result in exactly the opposite but lower throughput.

## 24.4.3 Retract Rate

**24.4.3.1 Definition.** Retract rate is the speed at which the drill bit exits the stack following the drill stroke and is expressed in inches per minute (ipm). Machine default (maximum) settings vary between manufacturers and may range anywhere from 500 to 1000 ipm.

**24.4.3.2 Effects.** Higher retract rates imply lower processing times per load. While the maximum retract rate setting may be fine for larger-diameter drill bits, when using drill bits in the diameter range of 0.0250 in (size #72) to 0.0135 in (size #80), retract rates may have to be reduced to 500 ipm or lower to prevent drill breakage. When drilling with sizes smaller than 0.0135 in in diameter, retract rates may have to be reduced even further. The maximum retract rate that may be used with any given drill diameter without causing drill breakage greatly depends on the stability and vacuum system efficiency of the drilling machine as well as the drilled stack height, laminate construction and thickness, type of entry material, use of proper stacking and pinning procedures, and the design characteristics of the drill bit such as flute length, web thickness, and web taper.

## 24.4.4 Backup Penetration Depth

**24.4.4.1 Definition.** Backup depth is the distance a drill bit penetrates the backup material at the bottom of the drill stroke. The minimum backup penetration depth setting varies

depending on drill diameter and is determined by calculating the drill bit point length (see Fig. 24.8) and adding approximately 0.010 in. As a rule of thumb, backup penetration depth may be set to a distance equal to the drill diameter or 0.040 in, whichever is less.

$$d(118) = \tan 31 \times \text{Radius} = \sim .600 \times \text{Radius} \text{ or } \sim .300 \times \text{Diameter}$$

$$d(130) = \tan 25 \times \text{Radius} = \sim .466 \times \text{Radius} \text{ or } \sim .233 \times \text{Diameter}$$

$$d(165) = \tan 7.5 \times \text{Radius} = \sim .132 \times \text{Radius} \text{ or } \sim .065 \times \text{Diameter}$$

**FIGURE 24.8** Point length calculation.

**24.4.4.2 Effects.** Excessive backup penetration depth increases drill wear and the occurrence of breakage of small-diameter drill bits, adversely affects hole quality, and increases process time per load. Insufficient backup penetration depth results in incompletely drilled holes. This implies that thickness variations of the backup material are very important, meaning that minimal variations are a much desired characteristic of the backup and need to be considered when choosing a material suitable for your application.

## 24.4.5 Hits Per Tool

**24.4.5.1 Definition.** The maximum hits per tool specified for any given drill size implies the number of drill strokes a drill bit is used for until its expected effective life is expired. Maximum hit count per tool is product and process specific and is affected by laminate material construction, panel thickness, drilled stack height, surface speed, and the type of entry and backup material used. Therefore, no specific number of hits per tool can be arbitrarily specified.

**24.4.5.2 Effects.** Excessive drill wear caused by excessive maximum hit count increases drilled hole defects and may prevent proper repointing. Conservative maximum hit counts greatly impact drilling cost per hole and increase time per load because of increased numbers of tool changes.

## 24.4.6 Stack Clearance Height

**24.4.6.1 Definition.** Stack clearance height is the distance between the point of the drill and the surface of the stack at the top of the drill stroke. Maintain a minimum stack clearance distance of  $\frac{1}{8}$  in (0.125 in), which implies a space between the bottom of the pressure foot and the top of the stack of 0.075 in, assuming the pressure foot lead distance to the point of the drill is correctly set at 0.050 in. Stack clearance may be adjusted for each load by simply sliding a 0.075-in shim between the pressure foot and the stack and adjusting the upper limit (“UP#”) until the pressure foot touches the shim.

**24.4.6.2 Effects.** The less the stack clearance distance between the drill point and the top of the stack, the shorter the drill stroke and therefore the shorter the processing time per load. Increasing the stack clearance distance allows more time between drill strokes and gives the tool table more time to settle, which may improve hole registration accuracy and prevent small-diameter drill bit breakage. In addition, the greater the time between drill strokes, the

more likely drilling debris will be removed from the drill flutes and, consequently, the lower the drilling temperatures, which results in reduced occurrences of drill breakage and lower extents of drilled hole quality defects.

#### 24.4.7 Drilled Stack Height

Material construction (panel thickness, number of copper layers, laminate type, etc.), drill bit diameter, and flute length, as well as hole quality and registration accuracy requirements, all are factors that need to be considered when deciding on appropriate drilled stack heights. A greater number of panels in the drilled stack means higher drilling temperatures, accelerated drill wear, and greater drill deflection, affecting the resulting hole quality and registration accuracy. When using smaller-diameter drill bits, stack heights need to be reduced to prevent drill breakage and to accommodate the shorter flute lengths. As a rule of thumb, the maximum total drilled depth (number of panels  $\times$  panel thickness + entry thickness + backup penetration depth) that can safely be handled by the drill bit without breakage is approximately 17 times its diameter.

#### 24.4.8 Stacking and Pinning

**24.4.8.1 Building the Stack.** Inspect all laminate panels and the entry and backup materials for surface damage and remove burrs from the panel edges as well as from the pinning holes. Even though the registration tooling holes on the laminate material may not be used to pin the stacked panels together, it is important to remove any resin buildup remaining around these holes after lamination (a common occurrence). Burrs and raised surface areas do not permit the panels to lay flat, causing gaps resulting in drilled hole registration problems, burrs, hole quality defects, and drill breakage. Reject entry and backup materials with excessive nicks, scratches, and other surface defects as well as those that are warped or twisted.

**24.4.8.2 Pinning Procedures.** Wipe the surfaces of all laminate panels and the backup material using a lint-free cloth to remove any debris before stacking the panels (allowing intimate contact between the stacked panels). Verify that the pinning holes and pin insertion are perpendicular to the stack and avoid using pins that are damaged or deformed.

**24.4.8.3 Installation.** Before placing the pinned stacks onto the drilling machine tool table, inspect the surface for burrs or broken drill bits protruding from the table that may prevent the stacks from lying flat. Do not continue if the pin bushings of the tool table are sunken or worn to the point that they do not hold the stack firmly in place. Loose or sunken tooling pin bushings cause movement of the stack during drilling and result in a variety of hole defects, registration problems, and drill breakage, yet are simple to replace at a minimum cost. After stacks are put in place, again wipe the surface of the top laminate material as well as the entry material. Place the entry material on top of the stack and tape it in place. The entry material size should be such that it clears the pins and does not extend beyond the stack edges. Pinning the entry material to the stack is not recommended because it tends to constrict the movement of the material, causing separation between it and the stack and resulting in entry burrs and possible drill breakage.

### 24.5 HOLE QUALITY

---

#### 24.5.1 Definition of Terms

The terms in Tables 24.1 and 24.2 are commonly used to describe drilled hole defects observed on copper and substrate surfaces. It is important to be able to identify these defects specifi-

**TABLE 24.1** Copper Defects

Defect	Definition	Type
Burr	Ridge left on external surface	Mechanical
Debris	Drilling residues	Mechanical
Delamination	Separation of the copper from the substrate	Mechanical/heat-related
Nail-heading	Burr on internal copper layer	Mechanical/heat-related
Smearing	Thermomechanically bonded resin deposit	Heat-related

**TABLE 24.2** Substrate Defects

Defect	Definition	Type
Debris pack	Drilling residues packed into voids	Mechanical
Delamination	Separation of the substrate layers	Mechanical/heat-related
Loose fibers	Unsupported fibers in the hole wall	Mechanical
Plowing	Furrows in the resin	Heat-related
Smear	Thermomechanically bonded resin deposit	Heat-related
Voids	Cavities due to torn-out supporting fibers	Mechanical

cally rather than in general terms. Using a general term such as *roughness* may imply voids or plowing. While voids are a mechanical type of defect, plowing is a heat-related type of defect. Therefore, excessive voids would lead one to examine the chip load (infeed rate) used; plowing would lead one to look at surface speed (spindle speed).

### 24.5.2 Examples of Drilled Hole Defects

Examples of typical drilled hole wall defects are shown in Figs. 24.9 and 24.10.

**FIGURE 24.9** Cross section of drilled hole showing examples of smearing and plowing.

**FIGURE 24.10** Cross section of drilled hole showing examples of nail-heading.

## 24.6 POSTDRILLING INSPECTION

---

A wealth of information is available by simply examining the materials from the drilled stack and the drill bits. For instance, inspecting the drill bits will allow one to determine if wear occurs at consistent rates (for drills of same diameter) or will reveal whether hit count maximums are excessive and the type of drilled hole wall defects to expect. Bonded debris and/or extensive wear to the drill corners imply high drilling temperatures (resulting in greater extents of defects such as smearing and plowing) or materials that are not fully cured and point to a problem with the materials (laminates, entry, or backup) or may suggest an excessive surface speed.

Extensive primary cutting edge wear indicates abrasive materials and may require lowering stack heights, reducing hit counts, or replacing entry or backup materials.

Burrs on the surfaces within the stack mean that there is a problem with the way panels are assembled and pinned or may be the result of warped panels. Entry or exit burrs on the outer laminates should cause one to question the entry and backup materials or the infeed rate.

The point of a postdrilling inspection process is that if one takes the time on a regular basis, to examine materials and drill bits after drilling, many drilling problems would be solved before they get out of hand.

## 24.7 DRILLING COST PER HOLE

---

Material and processing costs, as well as the resulting total drilling cost, may be determined by using an analysis matrix such as a cost model specifically designed for this purpose and generated with the use of a computer spreadsheet program. The advantage of using a spreadsheet is that it allows changes to be made in, for instance, specific material prices and processing times or parameters, and allows instantaneous viewing of the resulting effects on the total drilling costs, the cost per panel, and the average cost per hole. Knowing the cost per hole is important because it allows comparing different jobs or processing situations. Following is a step-by-step description of how to construct a drilling cost analysis matrix such as the one shown in Fig. 24.11.

### 24.7.1 Machine Time

Table A in the drilling cost analysis matrix is used to calculate the total time that is required to complete the job. First, the different drill sizes (a) and their respective total drilled holes per panel (b) as well as the total number of panels (c) to be drilled are determined and entered in the spreadsheet; this allows the spreadsheet to calculate the total number of holes for each size to complete the job (d).

Second, using the appropriate drilled stack height (e), the total number of drilled stacks (g) and the total number of drilled hits per drill size (f) can be calculated. The total number of drilled hits (drill strokes) is the total number of drilled holes per panel (b) divided by the number of panels per drilled stack (e).

Third, the number of total drilled stacks (g) is divided by the number of stations per machine (stacks per load [h]) to calculate the number of machine loads (i).

Fourth, the total drill time per load required per drill size (j) is entered to calculate the total machine time for each drill size (k).

Fifth, the total times of each of the drill sizes are simply added up to arrive at the total time required to finish the job.

An option is to enter the total drill time per load instead of entering the time for each of the drill sizes and multiplying the total drill time per load by the number of machine loads to determine total machine time.

**TABLE A** Machine Time

a	b	c	d	e	f	g	h	i	j	k
Drill bit size	Number of holes per panel	Number of drilled panels	Total number of drilled holes	Panels per drilled stack	Total number of drilled hits	Total number of drilled stacks	Stacks per machine load	Number of machine loads	Drill time per load (h)	Total machine time
0.0135	7,000	120	840,000	2	420,000	60	4	15.0	1.12	16.80
0.0160	5,000	120	600,000	2	300,000	60	4	15.0	0.80	12.00
0.0225	3,125	120	375,000	2	187,500	60	4	15.0	0.48	7.20
0.0350	1,500	120	180,000	2	90,000	60	4	15.0	0.19	2.85
0.0520	800	120	96,000	2	48,000	60	4	15.0	0.10	1.50
0.0700	250	120	30,000	2	15,000	60	4	15.0	0.04	0.60
	17,675		2,121,000						2.73	40.95

**TABLE B** Drill Bits

l	m	n	o	p	q	r	s	t	u	v

0.0520	\$1.15	\$0.25	4	\$2.15	5	\$0.43	48,000	2,000	24.0	\$10.32
0.0700	\$1.30	\$0.25	4	\$2.30	5	\$0.46	15,000	2,500	6.0	\$2.76
										\$527.83

**TABLE C** Entry and Backup Material

	w	x	y	z	aa
Material type	Cost per ft <sup>2</sup>	Stack size ft <sup>2</sup>	Cost per stack*	Total number of drilled stacks	Total material cost
Entry material	\$0.53	3.00	\$1.59	60	\$95.40
Backup material	\$0.65	3.00	\$0.98	60	\$58.50
					\$153.90

\* Backup material = cost/2 (uses per panel)

**TABLE D** Labor and Burden

	ab	ac
	Cost per hour	Cost total
Labor	\$15.00	\$614.25
Burden	\$10.00	\$409.50
		\$1,023.75

**TABLE E** Total Costs

Cost variable	Cost per panel	Total cost	% of total
Drill bits	\$4.40	\$527.83	30.9%
Entry material	\$0.80	\$95.40	5.6%
Backup material	\$0.49	\$58.50	3.4%
Labor	\$5.12	\$614.25	36.0%
Burden	\$3.41	\$409.50	24.0%
Total drilling cost	\$14.21	\$1,705.48	100.0%

**TABLE F** Drilling Costs

Drilling cost per panel	\$14.21
Average cost per 1000 holes	\$0.804

**FIGURE 24.11** Drilling cost analysis matrix. (Courtesy of LCOA Technical Center.)

### 24.7.2 Drill Bits

The cost of the drill bits needed to complete the job may be determined after the average cost per drill bit use has been calculated. To find the average cost per drill bit use, the typical number of repoints for the particular size (o) is multiplied by the cost of each repointing (n). The resulting cost, added to the new drill bit price (m), is the cost per drill bit life (p). By dividing the cost per life by the number of uses (q) per life (the number of times the bit is repointed + 1), you arrive at the average cost per drill bit use (r). Next, by dividing the total number of hits per drill size (s) by the number of maximum hits per drill bit use (t), the number of required drill bit uses (u) for each size may be determined. Then calculate the total cost per drill bit size (v) by multiplying the number of uses (u) by the average cost per use (r). The sum of the total costs of each of the drill bit sizes (v) brings you to the total cost of drill bits needed for the job. This cost, of course, is true only with the assumption of no drill bit breakage.

### 24.7.3 Entry and Backup Materials

Entry and backup material cost per stack (y) is determined by multiplying the stack size (square foot per panel [x]) by the cost per square foot. Remember to divide the backup cost by 2 since each backup panel may be used twice. Total material cost (aa) is calculated by multiplying cost per stack (y) by total number of drilled stacks (z).

### 24.7.4 Burden and Labor

Using typical burden and labor rates per hour (ab), these values are multiplied by the number of hours to complete the job (determined in Table A) in order to calculate the total burden and labor costs (ac).

### 24.7.5 Total Drilling Cost and Cost per Hole

After entering the required data in Tables A through D of Fig. 24.11, the total drilling cost and the cost distribution (see Table E) as well as the drilling cost per panel and the cost per hole (see Table F) can be calculated. Because the cost per hole typically ranges around  $\frac{1}{10}$  of a cent, a more accurate and easier way to comprehend this value is by showing the average cost per 1000 holes, as is done in the cost model.

---

## CHAPTER 25

---

# PRECISION INTERCONNECT DRILLING

---

**Terry Haney**

*Excellon Automation Co., Rancho Dominguez, California*

---

### 25.1 INTRODUCTION

---

As circuit density continues to increase along with the demand for higher and higher accuracy in hole location, the drilling machines and the environment in which the machines operate must be tightly controlled to achieve success in the drilling operation.

High-density interconnect (HDI) has been defined as referring to holes with diameters of 0.006 in. or less. HDI holes were generally expected to be made by nonmechanical means, such as lasers, plasma, or photoimaging. However, most holes continue to be created by mechanical means, and as the hole size approaches or in some cases decreases to less than 0.004 in., special challenges face the mechanical drilling process. With the density increase, innerlayer registration is of utmost importance. Artwork generation and fabrication processes can introduce layer shift. This shift is particularly troublesome in high-layer-count printed circuit boards (PCBs). This chapter addresses these issues of small-hole drilling as well as layer-to-layer registration.

In this chapter, holes created by traditional mechanical drilling methods are referred to as “drilled,” and the process is referred to as “drilling.” Holes created by laser, plasma, or photoimaging are not really drilled, even though the term is often used to describe them. When this chapter references nonmechanical via-hole creation processes, these are referred to by their specific type.

---

### 25.2 FACTORS AFFECTING HIGH-DENSITY DRILLING

---

PCB technology requires holes as small as 0.002 in. (0.05 mm) to be drilled with extremely high accuracy, particularly when drilling dense hole patterns. The processes and machines used to drill these holes now constitute a highly developed science.

As the drilling process approaches these HDI dimensions, numerous factors become increasingly critical, such as:

- Hole location
- Predrilling process issues
- Drill room temperature/relative humidity

- Vacuum
- Drill bit condition
- Dynamic spindle run-out
- Backup and entry material (type and thickness)
- Maximum spindle speed
- Depth control

### 25.3 LASER VERSUS MECHANICAL

Although it is somewhat subjective, the decision to drill with mechanical or laser systems can be influenced by the following considerations:

- **Aspect ratio determination** If the via to be formed is more than 0.016 in. (6.3 mm) deep, it is better to use a mechanical drilling process.
- **Material type** Materials that tend to have excess smearing that clogs the flutes in a mechanical system are usually better on a hybrid laser system.
- **Size of holes** If the hole to be drilled is larger than 0.008 in., then use a mechanical system for speed and hole wall quality.

#### 25.3.1 Lasers for PCB Processing

Several types of lasers can be used to fabricate PCBs, including:

- Infrared (IR) (CO<sub>2</sub>) lasers (9.4 μm to 10.6 μm)
- Ultraviolet (UV) lasers for PCB
- YAG (yttrium-aluminum-garnet)
- YVO<sub>4</sub> (yttrium-lithium-floride)

See Fig. 25.1 for diagram of laser wavelengths by type.

**FIGURE 25.1** Laser wavelength by type.

FIGURE 25.2 Laser beam delivery.

### 25.3.2 Beam Delivery

Laser source outputs a collimated beam. Turning mirrors (see Fig. 25.2) guide the beam to the scanners. The attenuator is used to control UV beam power. Scanners move the beam on the worktable. The lens focuses the beam to the worktable.

### 25.3.3 IR (CO<sub>2</sub>) Drilling

IR drilling requires the following:

- **Thermal ablation** This ablation requires heating, melting, and vaporizing. CO<sub>2</sub> IR wavelengths are reflected by copper.
- **Large focus diameter** The focus should be  $\sim 200 \mu\text{m}$ .
- **Larger beam size** The beam is adjustable through defocusing or apertures.
- **Percussion drilling** Each pulse removes a portion of dielectric material.
- **High dielectric removal rate** Scanner speed limits throughput.
- **Postprocess clean** A desmear process is required.

See Fig. 25.3 for an overview of the CO<sub>2</sub> process.

### 25.3.4 UV Drilling

UV drilling requires the following:

- **Photo ablation** This process breaks molecular bonds. Minimal heat damage is inflicted on the surrounding area.
- **Precise cutting** The small focus diameter should be  $\sim 20 \mu\text{m}$ .
- **Percussion drilling** The hole diameter must be the same as the focus diameter.
- **Trepanned drilling** The hole diameter must be greater than the focus diameter.

UV light is absorbed well by most PCB materials, but each material absorbs at a different rate.

**Conformal Mask Processing**

A mask of holes made by drilling, etching, or laser-ablating the top layer of copper. CO<sub>2</sub> is used for dielectric removal and a high ablation rate.

**Direct Dielectric Drilling**

No copper layer is required. The mask in the laser beam defines the via diameter.

**Via Formation with CO<sub>2</sub> Only**

The copper layer is etched and oxidized. CO<sub>2</sub> is used for copper and dielectric.

**FIGURE 25.3** CO<sub>2</sub> process overview.

**25.3.5 Creating Board Elements with Lasers**

Vias are created by having the laser beam make concentric circles or spiraled cuts. Laser pulse trains can be used to create vias or lines. Hole desmear can also be done by laser.

**25.3.6 UV Lasers**

*25.3.6.1 Yttrium-Aluminum-Garnet (YAG).*

- The output pulse is ~120 nanoseconds.
- YAG was first used for laser PCB drilling.
- It provides high pulse energy.

*25.3.6.2 Yttrium-Vanadate (YVO4).*

- YVO<sub>4</sub>'s output pulse is ~20 nanoseconds.
- Its repetition rate is ~100 KHz.
- Currently YVO<sub>4</sub> is most commonly used for PCB drilling.

**FIGURE 25.4** Hybrid laser via formation using UV and CO<sub>2</sub> lasers.

#### 25.3.6.3 Yttrium-Lithium-Fluoride (YFL).

- The output pulse is ~50 nanoseconds.
- YFL is more efficient, providing five times the absorption coefficient of YAG at the pump wavelength.

#### 25.3.7 Hybrid Lasers (UV and CO<sub>2</sub>)

Figure 25.4 shows a flow of the use of hybrid lasers for via formation. This hybrid is the combined use of CO<sub>2</sub> and UV laser technology.

### 25.4 FACTORS AFFECTING HIGH-DENSITY DRILLING

The following are factors to be considered regarding mechanical drilling.

#### 25.4.1 Positioning/Hole Location

The positioning system for conventional drilling machines consists of x-, y-, and z-axes. The x- and y-axes refer to the position of the circuit board under the drill spindle, and the z-axis to the plunging and retracting motions that allow the drill spindle to feed the drill bit into the substrate material. Machine accuracy is defined by the machine's ability to position the table under the spindles to the desired programmed x and y values. All process variables, such as tool design, stack height, feeds and speeds, and tooling methods, must be eliminated to evaluate machine accuracy.

The stability of the machine is critical when microdrilling dense drill patterns. When the drilling system is designed, stability is one of the most important factors taken into consideration. The foundation or base of the machine is usually constructed of granite or similar material. Granite is typically used because of its mass and low coefficient of thermal expansion (CTE) to temperature fluctuation. The upper structure of the machine is designed with a high natural frequency, which allows the structure to stabilize quickly, reducing the time the machine must pause before making a rapid movement to the next hole location.

Vibration caused by forces such as punch presses, drilling machines operating in close proximity, or any other type of equipment capable of causing severe vibration can have a

detrimental effect on HDI drilling, such as drill bit breakage and hole mislocation. Each drilling machine should be isolated from these forces as thoroughly as possible. The ideal solution is to have each drill machine placed on its own isolated pad made of reinforced concrete. This setup serves to isolate the drill machine from a large percentage of the vibration transmitted through the shop floor.

#### 25.4.2 Drill Room Temperature and Relative Humidity

All materials have coefficients that, because of the precision required, are critically important to the operation of drilling machines. Temperature has a profound impact on the accuracy of the drilling machines. With changes in ambient temperature, the materials used to build the machines may expand or contract, changing the position of the drilled hole in the printed circuit board.

Keeping a consistent room temperature is essential for maintaining accurate positioning of the machine. A stable temperature throughout the PCB process assists in decreasing the amount of potential growth and contraction of the substrate materials. The drill room should be kept at a constant temperature and humidity, typically  $72 \pm 2^\circ\text{F}$  ( $22 \pm 1.1^\circ\text{C}$ ) and 45 to 60 percent humidity.

#### 25.4.3 Vacuum

Sufficient vacuum flow is imperative when drilling high-aspect-ratio holes in tightly drilled grids. The vacuum system serves two main purposes:

- To extract debris from the drilling surface
- To keep the tool cool by removing the debris, thus decreasing the amount of friction in the hole wall

Insufficient vacuum flow leads to hole wall quality problems such as gouging, nail heading, and excessive smearing. Table 25.1 provides a hole-quality troubleshooting matrix that addresses these problems. The minimum industry standard for vacuum strength is approximately 20 in. of water measured at the pressure foot.

There are numerous applications such as high-aspect-ratio drilling that require an increased amount of vacuum pressure to remove debris sufficiently, and the equipment manufacturer can provide specific guidelines for special situations. Increasing the z-stroke distance between the pressure foot insert and the top of the drilled stack also assists in cooling the drill bit.

#### 25.4.4 Drill Bit

Drill bits (called *tools*) are critical in the drilling process. A wide variety of tools are available and your tool vendor can be very helpful with selecting feeds and speeds. Be sure to try several vendors to find the best tools for your particular process.

#### 25.4.5 Drill Bit Condition

The condition of the used drill bit is a key indicator of the control and capability of the drilling process and provides an indication of the condition of the drilled hole wall. A wealth of process information can be extracted from the used drill bit. Examining drills before the

**TABLE 25.1** Hole Quality Troubleshooting Matrix

Problem	Common causes	Parameter solutions	Process solutions	Possible equipment issues
Entry burrs	Excessive infeed rates	Lower infeed Decrease chip load Increase SFM	Change entry material type and/or thickness	Pressure foot lead set incorrectly; pressure foot insert damaged
Exit burrs	Warped panels Excessive infeed rate/SFM rate	Increase pressure foot, pressure value	Correct warpage issue in lamination; clean area between panel and backer	Verify pressure foot pressure is correct (45 psi)
Nailheading	Chipped/damaged tools Insufficient flute volume Poor drilling parameters	Modify feeds and speeds Decrease SFM	Remove defective drill bits Redefine minimum flute volume values	Machine not running at specified feeds and speeds
Rough holes	Chipped drill bits Poor drill concentricity Poorly cured laminate	Modify feeds and speeds	Inspect used tools for excessive wear patterns Replace worn drill bits Check laminate cure	Machine not running at specified feeds and speeds
Drill bit breakage	Poor drill concentricity Manufacturing defects Excessive drill depth Poor parameters	Check feeds and speeds Correct excessive runout Check z-axis offset values Clean and adjust collets	Check depth into backup Reset pecking depth values Replace drill bits Check program for double hits	Slop in lead screw Machine configured incorrectly Excessive spindle runout Poor machine maintenance
Excessive smear	Undercured laminate Excessive SFM Worn drill bits	Increase infeed rate Decrease SFM	Verify correct laminate cure	Machine not running at specified feeds and speeds

repointing process can be a warning indicator of drilling problems in a real-time mode soon after the process has been affected.

Drill machine operators and drill bit resharpeners should regularly evaluate the condition of used drill bits and report the findings to the process engineers. The areas of greatest concern when evaluating the condition of used drill bits are:

- Excessive margin wear
- Large amounts of burned substrate material attached to the relief areas
- Chips in the primary cutting edges of the tools

When tracked over time, this information can help alert the engineering team of any sudden changes in the drilling process. Although the used drill bit condition information is subjective, with properly trained personnel it can serve as a key indicator of the level of hole wall quality.

### 25.4.6 Dynamic Spindle Run-Out

The spindle houses the collet, which holds the drill bit that produces the hole in the printed circuit board. Modern spindles are capable of running at a wide range of rpm (15,000 to 200,000) with a power rating near one horsepower (1 hp). Due to the accuracy required when drilling with small drill bits, the drill bit must run true in the spindle. Excessive spindle run-out causes the drill bit to rotate eccentrically, which leads to inaccurate hole location, drill bit breakage, and hole wall quality problems.

The spindle run-out must not exceed 0.002 in. (0.005 mm) total indicated run-out (TIR) in a static situation. This trueness is achieved by using electrically powered spindles that rotate by the means of air bearings rather than mechanical ball bearings.

Other factors, such as poor collet condition and adjustment, can also lead to excessive run-out. Frequent collet cleaning and adjustment are necessary to ensure accurate mechanical hole location. Some modern drill machines are equipped with a tool metrology gauge (TMG). This feature measures the run-out for each drill bit during the tool change process, and if the run-out value measures over the predefined range, the tool is rejected. TMGs can help increase productivity and quality by identifying potential problems before they occur.

### 25.4.7 Spindle Speed

As via holes get smaller and smaller, maintaining an adequate cutting speed is essential, particularly with chip loads exceeding 0.001 in. per revolution. Increased spindle speed also allows for higher productivity because it corresponds to maintaining consistent chip load values while increasing z-axis feed rates. Spindle speed settings control the rotation of the drill bit during the drilling cycle. Measured in revolutions per minute, speed impacts hole wall quality as well as the condition of the drill bit's cutting edge. Excessive spindle speeds can result in premature wear on the cutting edges of the drill bit and may clog the margin relief area of the tool with burnt substrate (see Table 25.2). Spindle speeds are dependent on the process and the application. The maximum spindle speed capability is a factor when microdrilling, particularly when the desired surface foot per minute (sfm) values are above 300. Note the maximum achievable sfm for the microdrilling diameter range when utilizing the 180,000 rpm parameters for FR-4 material listed in Table 25.2. When the maximum allowable spindle speed is increased to 180,000 rpm, the 300 sfm value can be achieved when microdrilling, as shown in Table 25.2. As the table indicates, the upper spindle speed range accommodates microdiameter drill bits. Table 25.3 shows spindle parameters for FR-4 materials at various spindle speeds.

**TABLE 25.2** Spindle Parameters for FR-4 Materials at 180,000 rpm

Spindle Speed 180,000 RPM				
Desired Cutting Speed: 500 SFM				
Tool size (inch)	Infeed rate (in/min)	Spindle speed (rpm)	Chip load	SFM
.0071	077	180,000	.00043	334
.0080	094	180,000	.00052	377
.0100	130	180,000	.00072	471
.0120	134	159,200	.00084	500
.0145	137	131,700	.00104	500

**TABLE 25.3** Spindle Parameters for FR-4 Materials at Various Spindle Speeds

Spindle Speed 125,000 RPM				
Desired Cutting Speed: 500 SFM				
Tool size (inch)	Infeed rate (in/min)	Spindle speed (rpm)	Chip load	SFM
.0071	054	125,000.0	.00043	232
.0080	065	125,000.0	.00052	262
.0100	090	125,000.0	.00072	327
.0120	105	125,000.0	.00084	393
.0145	130	125,000.0	.00104	474

### 25.4.8 Chip Load

Chip load is calculated by dividing the feed rate by the spindle speed. The term identifies the amount of penetration the drill bit completes per revolution. As commonly used, the chip load accurately describes the proper cutting action needed to drill certain applications successfully.

### 25.4.9 Surface Speed

The surface speed in sfm is described as the distance that the drill bit's outermost cutting edge travels in 1 min. Cutting speed is frequently used in the metal-cutting industry, and the meaning is the same in the PCB drilling process. Particular substrate materials drill and fabricate favorably at certain cutting speeds. Cutting speed should remain consistent throughout the drill range (except when limited by spindle speed capability). For general guidelines, see Table 25.4.

**TABLE 25.4** General Guidelines for Cutting Speed

Cutting speed (sfm)	Material type
200	Plastics, acrylics, soft materials
300	Teflon, Kapton
400	Polyimide, cyanate ester, BT epoxy, high- $T_g$ laminates
500	FR-4, tetrafunctional, multifunctional multilayers
600	FR-4, difunctional rigid, double-sided

### 25.4.10 Retraction Rate

The z-axis return stroke can be programmed as well. This rate, known as *retraction*, should be set to the value that will minimize the time that the drill bit spends inside the drilled hole. The z-axis stability and drill bit diameter often influence the optimum retract values. An unstable or worn z-axis can lead to poor depth control, poor hole wall quality, and high levels of drill bit breakage. Another advantage of high retraction rates is the speed of the drill stroke.

Increasing production in this case through faster drill stroking is a high priority for the PCB manufacturer. Machine technology allows the user to set retraction rates upward to 1,400 in./min (35,560 mm/min).

## 25.5 DEPTH-CONTROLLED DRILLING METHODS

---

There are three common methods of depth control used in the drilling process:

- Manual through-hole drilling
- Machine depth-controlled drilling
- Controlled-penetration drilling

### 25.5.1 Manual Through-Hole Drilling

Manual through-hole drilling utilizes a down limit value to determine the bottom of the z-axis stroke. This method does not utilize the top of the stack or the top of the backing material as a reference point. Careful consideration should be given when a down limit is set. The operator needs to ensure that the drill bit is penetrating all the way through the stack of laminated panels. Shallow penetration or incomplete holes can result in drilling scrap. Excessively deep penetration leads to increased drill bit cutting edge wear, excess debris to be removed, higher drilling temperatures, and drill bit breakage. The down limit should be set at a value that enables the drill bit to clear the point and also avoids drilling too deeply into the backing material.

### 25.5.2 Machine Depth-Controlled Drilling

Depth-controlled drilling utilizes the top of the drilled stack as its reference point. Before this depth-control method can be utilized mechanically, the machine needs to know what the distance is from the pressure foot insert to the tip of the drill bit.

To determine this distance, the manufacturer performs a TMG check using standard measuring devices. Once this distance is established, any negative (–) values entered into the depth box will cause the z-axis to stop at the desired depth measured from the top of the stack.

### 25.5.3 Controlled-Penetration Drilling

Controlled-penetration drilling is utilized for drilling applications where the depth is referenced from the top of the backing material. This mode of depth control is not affected by stack height. The specified depth value or z-axis offset is treated as the desired amount of penetration relative to the top of the backing material. For the machine to be run in mode 3 depth control, a process called *mapping* must be performed prior to drilling any panels. During the mapping cycle, the machine touches down on the surface of the backing in 2 in. increments.

At each touchdown point, the thickness value of the backing is recorded. Once the mapping procedure is complete, the z-axis zero is established. Any negative values entered into the offset box represent the drill depth into the backing material. Controlling the penetration of the drill bit into the backing material assists in decreasing heat generation, improving hole wall quality by limiting the amount of debris, and decreasing drill bit breakage due to excessive depth.

## 25.6 HIGH-ASPECT-RATIO DRILLING

---

As circuits have gotten denser, not only have the traces gotten smaller, but the number of layers in a board has increased. The result is smaller holes penetrating thicker boards. To accommodate this increase in hole aspect ratio, two processes have been developed:

- Peck drilling
- Pulse drilling

### 25.6.1 Peck Drilling

Peck drilling is accomplished by dividing the total z-stroke into separate increments rather than completing the drill stroke in one action (see the example shown in Fig. 25.5).

**25.6.1.1 Advantages.** The advantages of peck drilling are as follows:

- Decreased drill bit breakage
- Lower aspect-ratio values
- Improved positional accuracy
- Decreased bottom-panel burring

**FIGURE 25.5** An example of through-hole peck drilling, showing a stack of three boards with entry and backup material creating a stack height of .285 in. and a total z-axis drill stroke of .206 in. The effective aspect ratio of 15.3 is reduced to 3.8 per peck when four pecks are made to complete the hole.

**25.6.1.2 Effective Aspect-Ratio Reduction.** The primary accomplishment of peck drilling is the decrease in effective aspect ratio value. Whereas aspect ratio is defined as the thickness of the board divided by the hole diameter, effective aspect ratio is defined as the total z-stroke divided by the smallest drill bit diameter. For example, if the total z-stroke equals 0.209 in. (the total thickness of the board) and the smallest diameter is 0.025 in., the aspect ratio and the effective aspect ratio would have the same value of 8.36. By taking a total z-stroke of 0.209 in. and dividing it into four pecks, the aspect ratio is decreased from 8.36 to 2.08. In general terms, an aspect ratio scale of 1 through 15 is commonly used, 1 being conservative and 15 being on the aggressive side of the scale.

**25.6.1.3 Decision to Use Peck Drilling.** The decision as to when to use peck drilling is very subjective.

Drill bit breakage and bottom-panel burring are ordinarily the main factors considered when electing to peck drill:

- **Decreased drill bit breakage** Decreased drill bit breakage is the primary benefit of peck drilling. If the z-stroke is reduced, the drill bit has less debris to extract per revolution, decreasing the chances of clogged flutes, which can cause the drill bit to seize in the hole and break. Setting pecking parameters is a very subjective science; at best, it is an approximation.
- **Hole wall quality** Analysis of the hole wall quality results should be completed before implementing any pecking procedures.
- **Hole location improvement** Another benefit of peck drilling is an improvement in hole location. Once a drill bit is deflected, it will continue at that deflection angle as it drills through the stack. Essentially, hole location is worse at the exit point than at the entrance point, particularly when drilling through thick panels with small-diameter tools (high-aspect-ratio drilling). Peck drilling can assist in achieving better hole location by lessening the effects of deflection by dividing up the total drill stroke, therefore decreasing the effective aspect ratio value.
- **Bottom-panel burring** Peck drilling can assist in decreasing the amount of bottom-panel burring by reducing the drilling temperatures resulting from drilling thick panels with small drill bits. Plowing, voids, and debris pack are reduced by peck drilling due to the decrease in the amount of debris the tool must extract per z-axis stroke.
- **Drill bit cooling** When peck drilling, each individual stroke increment returns to the upper limit value. For the example in Fig. 25.5, a value of 0.015 in. above the stack was used.

Figure 25.5 is an example of through-hole peck drilling, showing a stack of three boards with entry and exit material creating a total stack height (or z-axis stroke) of 0.285 in. The effective aspect ratio is reduced when four pecks of the drill are made to complete the hole. Increasing the distance above the stack (sometimes referred to as the second upper limit value) assists in cooling the drill bit before completing the next z-stroke. By cooling the drill bit, the manufacturer can substantially reduce nail-heading values and smearing.

**25.6.1.4 Disadvantages.** Peck drilling has some disadvantages. For example, it can cause the following:

- Increased nail heading
- Increased smearing
- Hole wall roughness
- Increased cycle times

**25.6.1.4.1 Hole Wall Quality.** Peck drilling increases the overall cycle time due to the greater number of z-strokes necessary to complete one drilled hole. Nail-heading values tend to be worse for peck drilling due to the certainty that some copper pads will make contact

with the drill bit several times as opposed to making only one contact when using a single drill stroke.

Hole wall smearing can also be a problem when peck drilling. The increase in heat caused by drilling the same hole several times can cause the substrate material to become heated to its melting point, which can lead to deposits of resin along the hole wall. A similar effect on hole wall roughness can also be seen.

**25.6.1.4.2 Reducing the Effect of Disadvantages.** Methods for reducing the negative effects on the hole wall caused by peck drilling include the following:

- Increasing the feed rate decreases the amount of time the drill bit spends in the hole.
- Minimizing the number of pecks also decreases heat generation and reduces overall drilling cycle time.

The design of the tool has a major effect on hole wall quality when peck drilling. To decrease heat generation in the hole wall, the manufacturer must reduce the amount of friction caused by the drill bit making contact with the hole wall. To accomplish this reduced friction, the manufacturer can use an undercut tool design, sometimes referred to as a headed drill bit. The undercut tool design decreases the amount of contact by reducing the diameter of the tool, which creates a larger clearance area, consequently decreasing the amount of flute making contact with the hole wall. The undercut tool design reduces the amount of nail heading and smearing caused by peck drilling.

## 25.6.2 Pulse Drilling

Pulse drilling is designed primarily as a method to reduce problems related to “bird nesting,” where excess debris builds up and remains attached to the flutes and shanks of the drill bit after it is retracted from the drilled hole. This condition also occurs in specialized drilling processes such as high-aspect-ratio drilling, drilling of test fixture materials, and drilling of abrasive materials used in high-temperature applications.

Pulse drilling acts as a chip breaker by driving the z-axis into the material using a short series of steps or pulses.

**25.6.2.1 Advantages.** Unlike peck drilling, where the tool is retracted completely out of the drilled hole, in pulse drilling the z-axis pauses for milliseconds between each drill stroke while remaining in the drilled hole. This action allows the drill bit to extract debris up the flute before continuing the next stroke. Due to the rapid rate at which debris accumulates, the duration of each pulse must be kept to a minimum, resulting in a decreased infeed rate. To reduce this effect, pulse drilling uses a depth sensor on the drilling machine to detect the top of the stack. Once the top of the stack is detected, the spindle begins the pulse-drilling process.

**25.6.2.2 Disadvantages.** Pulse drilling increases the amount of heat generated in the hole wall. It should be used only when hole wall quality is not the most significant aspect of the drilling operation.

## 25.7 INNERLAYER INSPECTION OF MULTILAYER BOARDS

---

Innerlayers of multilayer boards can shift during fabrication processes and create poor layer-to-layer alignment. During the artwork exposure or fabrication of the multilayer boards, the position of the copper shifts relative to the nominal stacked position. This can create breakout or missing of the copper pads when drilling the interconnection holes.

Two methods of inspecting the innerlayers of multilayer panels exist. One that has been used for several years is x-ray. This technology has progressed significantly and is widely used.

### 25.7.1 X-Ray

X-ray technology is used to inspect the innerlayers of multilayer PCBs and to verify that the drill pads are located properly. Innerlayer shift is identified easily in an x-ray image, and a simple technique can be used to measure the misalignment accurately. In developing the PCB artwork, a set of stacked pads are located in the coupon area. These are inspected and a “best-fit” centering is calculated.

X-ray inspection also is used to determine movement of each individual layer. In this case, a locating pad with a corresponding layer pad is on each individual layer. The system can measure the distance from the locating to layer pad and determine movement of each layer due to the location of the layer pads. PCBs can be inspected after tooling holes are drilled to verify that they are in the proper locations. In addition, x-ray inspection can be performed after final drilling to verify that the holes are centered within the pads.

### 25.7.2 Direct Vision

Using direct vision technology, the drilling machine opens a conical hole in the board’s outer coupon area (or interior if space is available) and physically examines it with the help of an autofocus/autozoom camera at the copper traces exposed by the cut. These traces represent the various layers and can be measured to indicate their x and y variance from nominal. This is done for each internal layer, and algorithms are applied to generate a new drilling program that will provide for a best-fit drilling scenario.

**25.7.2.1 Overview.** The autofocus/autozoom camera looks at fiducial targets that are a cross pattern of traces spaced larger than the diameter of the tool used to drill the targets. The cross target should be repeated as a pattern shown in Fig. 25.6 to enable multiple depth cuts for thick panels.

**25.7.2.2 Process.** This pattern should be stacked on each internal layer and placed outside the circuitry. It is recommended that the patterns be as close to the circuitry as possible without interference to gather the best possible layer movement data.

FIGURE 25.6 Fiducial target.

**FIGURE 25.7** Multiple entries exposing all layers.

It is also recommended that this pattern be repeated around the circuitry in four places around the corners to enable the most flexible selection of analysis algorithms as described in the discussion of analysis later in this section.

With thick boards, all of the layers may not be visible with one countersink hole. The conical part of the drill bit is the only part where layers are exposed. The tip of the drill does not expose the layer adjacent due to alcohol residue during the cleaning process. Repeat entries at progressive depths expose all of the internal layers, as shown in Fig. 25.7.

After the conical holes are drilled, an automatic alcohol sprayer is activated to clean debris caused by the drilling process. The camera then activates its autofocus/autozoom mode to close in on the subject area.

Figure 25.8 shows the image created by the camera on the first conical hole. You can see the copper layers and some of the movement in the innerlayers.

\* Note: Each layer  
being displayed

Drilled hole is being viewed  
prior to having gained the  
offset information.

**FIGURE 25.8** Camera-generated conical hole image.

The operator sets the area in which the analysis software should attempt to locate the edges of the traces (see Fig. 25.9). These bounding boxes are mouse-controlled and should be wide enough to enclose all traces.

Gray circles represent the layer for the system to search. The area inside a boundary where the gray circle crosses a trace is searched for trace edges.

The analysis software then locates the trace edges and indicates them with hash marks (see Fig. 25.10). If any of these are incorrect, the operator can easily move the marks with the mouse.

FIGURE 25.9 Selecting the inspection areas.

FIGURE 25.10 Trace edges located.

### 25.7.3 Correction for Registration Alignment (Direct or X-Ray)

After the data have been recorded by the x-ray or direct image system, the operator can select from several algorithms to perform several functions.

If there were only two corner fiducials inspected, the software can perform the following function:

- **Two-point offset and rotation** Two alignment fiducials are inspected (see Fig. 25.11) to calculate the offset and rotation values. The pattern is rotated to a point located about halfway between the two fiducials. The offset is calculated based on the average distance of the fiducials from their programmed location after the rotation is applied.

If three or four cornered fiducials are inspected, the analysis software can perform the following:

- **Three- or four-point offset, rotation, and scaling** Three or four alignment fiducials are inspected (see Fig. 25.12) to calculate the vision corrections. If only three alignment points are used, they may be located on any three corners. The offset is calculated based on the average distance of the fiducials from their programmed location after the rotation is applied.
- **Three- or four-point best-fit** This function is the same as the three- or four-point offset, rotation, and scaling algorithm, except scaling is not applied (see Fig. 25.13).
- **Three- or four-point alignment** The pattern is linearly adjusted in both axes to match the alignment fiducials. This generally transforms the pattern into a trapezoidal shape. Four-point alignment is used to adjust the pattern to match the visible landmarks precisely.

When the selected algorithm is applied, the operator has some choices. One is to elect to go ahead and drill the board on the same machine if it happens also to be an x-ray drilling machine or the Intelli-Drill, since such machines are also high-precision single spindle drillers with a 180,000 rpm spindle. This is the best choice because it does not require the operator to remove the panel from its tooling and all reference points are still aligned.

The operator can, however, elect to remove the panel and output the modified drill program for drilling on another machine, thereby freeing the Intelli-Drill or x-ray system to inspect another panel.

A third option is for the operator to inspect a number of panels and have the algorithms averaged to produce the best-fit program for the entire lot.

FIGURE 25.11 Two-point offset and rotation.

FIGURE 25.12 Three- or four-point offset rotation and scaling.

FIGURE 25.13 Four-point best-fit.

### 25.7.4 Saving Data

The data that are generated can also be stored in an optional database that allows searches to determine, by board type or part number, what is changing over time so that predrill processes can be modified to eliminate error as much as possible. Material types and vendors can also be tracked to verify performance. A utility for basic searches is included with the database option. For more detailed searches, any standard database acquisition program may be used.

25.7.5 Examples of Database Output

Examples of database output include the following:

- Artwork scaling data for each layer on each panel with an average and standard deviation for the order
- Shift data for each panel with an average and standard deviation for the order
- Front-to-back registration error for each layer with average and standard deviation for the order
- Layer-to-layer registration for each panel
- Optimized offset for each panel and average per order or a grouping of similar panels
- A part number history database for trend analysis
- Skew analysis by panel

Figures 25.14 and 25.15 show examples of analysis data provided by the utility.

25.7.6 Process Improvement for the Future

This method is a good tool to increase yields of complex multilayer panels as well as multilayer flex material. The actual layers are exposed and inspected to determine their position with

The screenshot shows a software window titled "Drill Layer Measurements: 1". The main area contains a table with the following data:

Drill Layer Measurement										
Date/Time	Drill Program	Zone	Group	Layer	Target	X Nominal	Y Nominal	X Offset	Y Offset	TPR

## 26.1 INTRODUCTION

---

Imaging is the process that patterns the metal conductor to form the circuit. This process involves a multistep integration of imaging materials, imaging equipment, and processing conditions with the metallization process to reproduce the master pattern on a substrate. Large features (200  $\mu\text{m}$  and greater) can be very economically formed by screen printing. Feature sizes smaller than 200  $\mu\text{m}$ , however, are formed using a photolithographic process, which is the main discussion of this chapter. As circuit densities have increased over the years, the imaging process has continually evolved to enable commercial production of finer features. This need for high-density interconnect (HDI) is driving the industry to feature sizes of 10  $\mu\text{m}$  or lower. Imaging equipment and materials have been developed to meet this challenge.

To achieve a reproducible high-yield/low-cost imaging process for a given feature size, various factors must be carefully balanced. This chapter outlines the chemistry and equipment options for the photolithographic imaging process, highlighting trade-offs that must be considered so that process engineers, designers, and procurers of printed wiring boards (PWBs) and HDI structures have an overview of the process considerations that can enable a manufacturable product.

Printing is an alternate process for imaging. Screen printing is used to print resist on foil and silver inks on polyester. Ink jet printing has been used to pattern resist, legend, and silver conductors. Recently an ink jet system has been introduced that prints a UV-curable catalyst layer to electroless plate copper at thicknesses of 0.05 to 5 microns.<sup>1</sup> Significant development work is underway on organic transistors patterned by ink jet and other printing methods. These techniques are beyond the scope of this chapter.

The photolithographic process sequence for imaging is given in Fig. 26.1. Basically the process

**FIGURE 26.1** The photolithographic process sequence.

involves applying a light-sensitive polymeric material (photoresist) onto the substrate of interest, exposing this photoresist to light with the desired pattern, and developing the exposed pattern. This developed pattern is used for either subtractive (etching) or additive (plating) metal pattern transfer. Details of these metallization processes are given in subsequent chapters. After metallization, the photoresist is stripped from the surface and the panel is ready for further processing.

## 26.2 PHOTSENSITIVE MATERIALS

The photosensitive polymeric systems used as photoresists in the interconnect industry are either liquids or dry films formed from a liquid solution. Dry-film photoresists are the industry standard, but liquid photoresists have become widely used, particularly for fine-feature circuits. Both types of photoresist can be used for a variety of processing requirements.

### 26.2.1 Positive- and Negative-Acting Systems

Photoresists may function in a photographic sense in either a positive or negative tone. The difference, illustrated in Fig. 26.2, is a result of the specific chemical reactions that occur on exposure to light. For the common negative-acting systems, exposure initiates cross-linking

**FIGURE 26.2** The photolithographic process sequence for positive and negative tone photoresists. (Reprinted by permission of C.G. Willson, *Introduction to Microlithography, Theory, Materials and Processing*, ACS Symposium Series 219, Washington, D.C., 1983, p. 89.)

between one or more of the components in the polymeric matrix, reducing the photoresist's solubility in the developing solution. The exposed regions remain after development of the image. For positive-acting photoresists, the chemistry is often the novalac resin-based materials utilized by the semiconductor industry. Upon exposure, an acid-catalyzed reaction occurs that increases the solubility of the photoresist in the developer solution. In this case, it is these exposed regions that are removed in the developer solution.

Photographic tone can have an effect on product yield caused by contamination between the phototool with the master image and the photoresist. For a negative-acting photoresist, contamination blocks the light and prevents cross-linking, leading to a mousebite (partial reduction in line width) or an open circuit in the conductor after etching. For a positive-acting photoresist, contamination blocks the light and prevents the acid-catalyzed solubilization, leaving excess metal and a possible short after etching. Since circuit patterns often have a greater area of spaces than lines, there is a lower probability of a contaminant causing an actual defect with the positive-acting photoresist. However, negative-acting photoresists are the most widely used since many other factors impact yield and contamination must be minimized in any photolithographic process..

### 26.2.2 Decision Factors

The large variety of commercially available photoresists makes it a challenge to determine which one is likely to perform best for a given application. Key technical and economic factors that must be considered are summarized in Fig. 26.3. The primary consideration is the end use of the pattern.

- The photoresist must be chemically compatible with the subsequent pattern transfer steps (i.e., can withstand the chemical environment such as the solution pH) for it to function as an accurate mask for pattern transfer.

**FIGURE 26.3** Criteria for selection of photoresist materials.

- The nature of the substrate itself in terms of topography and surface features must also be considered. Is the photoresist required to cover or tent plated through holes or tooling features, and must it conform to existing circuitry? This consideration will dictate if dry-film or liquid photoresists are appropriate and, in some instances, the required tone.
- The required product feature dimensions are equally important. They are usually specified in terms of line width and spacing with a given allowable variation. Since these product specifications are for the final conductor features, the impact of photoresist processing on the critical dimensions must be established. Each photoresist has an inherent contrast (i.e., the rate of change of solubility on exposure to light). This contrast, combined with the resist thickness, phototool, light source used for exposure, and developing conditions, determines the finest feature that can be imaged. For photoresists used in the PWB industry, the minimum line width achievable in production is usually 10 to 25  $\mu\text{m}$  greater than the photoresist thickness. Novel process sequences have demonstrated it is possible to overcome this traditional barrier.<sup>2</sup>
- The adhesion of the photoresist is another key attribute. The chosen photoresist must have good adhesion to the underlying substrate during pattern transfer but must also be able to release cleanly from the substrate during stripping.

### 26.3 DRY-FILM RESISTS

Dry-film photoresists are generally used for pattern formation prior to both plating and etching.

These films have a three-layer structure, with the photosensitive material sandwiched between a polyester coversheet and a polyethylene separator sheet (see Fig. 26.4). The photoresist thickness is typically 25 to 50  $\mu\text{m}$ , but thinner and thicker films are used for special applications. The photoresist is applied to the printed wiring board (PWB) substrate using lamination: The polyethylene separator is removed, and the photoresist flows under the heat and pressure from the laminating rolls to adhere to the substrate. The polyester coversheet

**FIGURE 26.4** Dry-film photoresist components. (Reprinted with permission of DuPont Electronics, DuPont Technical Literature.)

performs several key functions. It protects the photoresist during handling, prevents sticking to the phototool during contact printing, and acts as an oxygen barrier during exposure. The optical properties of this polyester coversheet are important, especially for producing features less than 100  $\mu\text{m}$ .

Dry-film manufacturers have increased the optical clarity and reduced the thickness of the polyester sheet to achieve the required image quality. Thin dry films of 25  $\mu\text{m}$  thickness and less generally use this high-quality coversheet.

The chemical and mechanical properties of dry-film photoresists have been tailored to withstand various plating solutions and acid or ammoniacal-etching solutions. They can be grouped in terms of the processing chemistry used to develop the image:

- **Aqueous-developable** This group is the industry standard.
- **Semiaqueous-developable** These are used in special applications.
- **Solvent-developable** This is the original system (see Table 26.1). Since solvent development used chlorinated hydrocarbons, use of the solvent-developable photoresists has generally been abandoned.

**TABLE 26.1** Summary for Dry-Film Photoresist Types and Chemistries

Photoresist type	Develop solution	Strip solution	Application
Aqueous-processable	Sodium/potassium carbonate	Sodium/potassium hydroxide	Acidic solution: etching, plating Limited alkaline solutions: alkaline etch
Semiaqueous-processable	Sodium tetraborate/ Butyl cellusolve	Ethanolamine or Butyl carbitol/Butyl cellusolve	Alkaline solutions: etching, precious metal plating
Solvent-processable	(Methyl chloroform) Alternate to CFCs	(Methylene chloride) Alternate to CFCs	Strong alkaline: full-build electroless Cu plating

### 26.3.1 Chemical Composition Overview

Dry-film photoresists vary in their exact chemical compositions, but all contain the following components:<sup>3</sup>

- **Polymer backbone**
- **Photoactive compound**
- **Monomer**
- **Dye**
- **Additives** The polymer backbone sets the fundamental solubility and chemical resistance of the system.

On exposure, the photoactive compound absorbs light of the appropriate wavelength and subsequently reacts with the monomer to alter the solubility of the film in exposed areas. The dye changes color on exposure to provide a visible latent image of the master pattern in the film, referred to as the printout image. Although the printout image decreases the efficiency of the desired photoreaction by consuming a portion of the exposed photoactive compound, it has proven to be a valuable manufacturing aid and is used in almost all dry-film photoresists.

Additives include adhesion promoters, flexibilizers, and other compounds that can improve a desirable property. All the ingredients function together to provide the process latitude needed for the photoresist's specific range of applications.

### 26.3.2 Aqueous-Processable Dry Films

The majority of materials used are based on an acrylic polymer with various forms of photoreaction initiation. The initiator's absorption is designed to coincide with the major emission wavelength of the mercury arc lamps in the ultraviolet region of the spectrum at 365 nm.

Many are based on the use of Michler's ketone and its subsequent sensitization of a triplet state promoted radical chain polymerization. This also explains the material's sensitivity to oxygen, an efficient triplet quencher. These materials are also very efficient at converting light energy into a chemical reaction due to the radical chain reactions; absorption of one photon of light results in many cross-links in the polymer matrix. Usual exposure doses measured as the irradiance from 330 to 405 nm to cross-link these materials functionally vary from 25 to 90 mJ/cm<sup>2</sup> depending on the exact chemistry used and the thickness of the materials, which compares favorably to positive-acting materials used for optical lithography in semiconductor integrated circuit (IC) production, where doses of 200 to 500 mJ/cm<sup>2</sup> are common.

The images in these materials are developed in alkaline solutions of 1 percent or less by weight of sodium or potassium carbonate. The complete removal of the photoresist after pattern transfer is accomplished in 1M or greater solutions of sodium or potassium hydroxide at elevated temperatures, often with an antitarnishing additive to limit oxidation of the copper.

Thus, in general, these materials exhibit excellent stability in acidic solution, but they do have varying stability to more strongly acid and alkaline solutions. In fact, there are three subclasses of materials: for acid etching of copper, for acid plating of copper, and for alkaline (ammoniacal usual) etching of copper. Increased acid stability is required for use in acid copper plating, in which the pHs of the solutions often are below 1. For ammoniacal copper etching at pH 8 to 9, increased alkaline stability is required. This latter capability illustrates the flexibility in tailoring these materials to their end use since these materials are imaged using similar alkaline chemicals: develop at pH 10.3 and strip at pH 13. Often these alkaline-stable materials are developed at high temperatures.

In the past, several photoresists were formulated for exposure at a visible wavelength, 450 nm, using specialized exposure equipment—either visible lasers or magnified projection printing. More recently, laser direct imaging (LDI) based on the Ar<sup>+</sup> laser output clustered around 360 nm has been commercialized. Conventional photoresists can be exposed on LDI equipment, but higher photospeed has been key to the productivity and economics of LDI.

Photoresists requiring only 10 mJ/cm<sup>2</sup> are now commercially available for the major applications. In general, these high-speed photoresist processes are similar to conventional ones, but improvements include photospeed, sensitivity to yellow safelights, and postlamination hold.<sup>4</sup>

Novel aqueous-developable photoresists have been formulated to process in dilute acidic media. A dry film based on electrophoretic depositable (ED) materials was shown to have excellent stability in strong alkaline solutions, potentially useful for etching polyimides or for full-build electroless copper plating.<sup>5</sup>

### 26.3.3 Semiaqueous- and Solvent-Developable Dry Films

Semiaqueous-developable photoresists are used when increased resistance to chemical attack is required, such as the highly alkaline solutions used in polyimide etching or gold and precious metal plating applications. Their composition is similar to the aqueous-developable photoresists, but the polymer backbone is less alkaline-soluble. This increased chemical stability provides accurate image transfer by maintaining the integrity of the surface and sidewalls and minimizing underplating. Semiaqueous-developer chemistry is slightly alkaline (sodium

tetraborate) and contains an organic assist, typically butyl cellulose. Process control for this mixture is more complicated than that used for aqueous development.

Solvent-developable dry-film photoresists were the first to be commercially produced. Since they are the only materials that can withstand the harsh conditions in some chemical processing sequences, they still have some interest. They are based on methyl methacrylate polymers and a Michler's ketone initiation system similar to that used for aqueous-developable photoresists. Although they can have very high contrast, they are prone to scumming, leaving residue in the spaces between exposed photoresist features after development. Slight etching of the underlying substrate is often required to have a clean image-transfer step, especially for pattern-plating applications. Traditionally these materials were developed in trichloroethane and stripped in methylene chloride. However, as the hazards associated with chlorinated hydrocarbons were recognized, use of these solvents has been practically eliminated. This has forced the use of alternative develop and strip chemistries for solvent development.<sup>6</sup>

## 26.4 LIQUID PHOTORESISTS

---

Liquid photoresists come in a variety of chemistries.<sup>7</sup> Many are simply coatable forms of the dry-film materials. They have been used primarily for patterning innerlayers and are applied to the substrate by roller, spray, curtain, or electrostatic coating techniques. These methods are discussed later in the chapter (with equipment). Applied thickness is typically 6 to 15  $\mu\text{m}$ , giving superior resolution compared to dry-film resists that are generally thicker. Since resolution is approximated by the thickness, they have the ability to resolve features less than 25  $\mu\text{m}$ . Conformation of liquid photoresist to the copper substrate is generally very good, and it is possible to achieve high yield at 50  $\mu\text{m}$  features and less.<sup>8</sup> However, cleanliness of the substrate and the coating and drying operation is critical. Liquid photoresists are dried to allow for hard contact with the phototool during exposure, maximizing resolution. If soft or off contact is used, resolution and yield decrease, especially for features 100  $\mu\text{m}$  or less. For the majority of liquid photoresists, the developing and stripping conditions are similar to those for aqueous-developable dry films: mild alkaline sodium carbonate and strong alkaline sodium hydroxide. Exceptions are positive-acting novolac-based photoresists, thermal photoresists,<sup>9</sup> and negative-acting acid-developable photoresists.

### 26.4.1 Negative-Acting Liquid Photoresists

The chemistry of the typical materials is similar to that of the aqueous-developable dry films. They depend on a radical chain reaction to promote cross-linking in the acrylic polymer. Their sensitivities differ depending on the initiator system chosen. Materials are available with minimal solvent content, and a few are diluted with water.<sup>10,11</sup> This reduces the emissions from coating and drying that must be contained and treated.

Acid-developable photoresists mentioned in the dry-film aqueous section can also be formulated as electrophoretic-depositable liquids. These materials have high contrast, good resolution, and chemical stability in strongly alkaline solutions since they are developed in aqueous acid solutions.

### 26.4.2 Positive-Acting Liquid Photoresists

The other alternative is a positive tone novolac resin-based system that finds its application most usually in the semiconductor industry for imaging integrated circuits. It has excellent resolution and chemical stability in acid and a large number of basic solutions (precious metal

**FIGURE 26.5** Chemistry mechanism of positive-acting liquid photoresists.

plating). The chemistry involves the conversion of a base-insoluble diazonaphthalquinone to the base-soluble indene acid. Thus, this photo-driven conversion alters the solubility of the base material in alkaline solutions, allowing for image formation (see Fig. 26.5).

## 26.5 ELECTROPHORETIC DEPOSITABLE PHOTORESISTS

Electrophoretic depositable (ED) photoresists<sup>12,13</sup> were introduced in the late 1980s with expectations of broad adoption by the interconnect industry. The early materials were modifications of those used for coating automobiles and appliances. These fast-coating processes provide a defect-free film of high durability on conductive substrates and are well suited to large-volume production. Anodically and cathodically deposited materials that are both positive and negative acting have been introduced but have achieved limited market penetration in the interconnect industry. Advances in dry-film photoresists and liquid photoresists reduced the interest in implementing a new photoresist process. (A detailed discussion of electrophoretic depositable photoresists is included in Sec. 17.1.6 of the fourth edition of this handbook.)

## 26.6 RESIST PROCESSING

Imaging is a sequential process, and the various steps are very interdependent. Equipment and processing conditions play a large role in the image quality, yield, and productivity that can be achieved. The choice among the numerous options for each step depends on the type of substrate to be imaged, the feature sizes to be produced, the existing equipment, the type of photoresist, and the productivity and economics of the production line. Alternatives for each process step are described and compared.

### 26.6.1 Cleanliness Considerations

Cleanliness is an issue throughout the entire photolithography process, including yellow room contamination level (cleanliness class), solution filtration, equipment cleanliness class, and product handling. Its importance increases as feature size decreases. The level of cleanliness needed to give acceptable yield for the finest features must be established and maintained.

Sticky rollers, either as free-standing equipment or as handheld items, are one type of equipment used to remove contamination from flat surfaces, either panels or equipment.

### 26.6.2 Surface Preparation

Good adhesion between the photoresist and the substrate is essential for the remainder of the process to be successful. All laminates arrive at the imaging area, dirty, and the exact process sequence for surface preparation is chosen based on the nature of the contamination. Epoxy dust generated during trimming and processing of the laminate is removed by mechanical cleaning. The copper surface is either foil or foil with electroless or electroplated copper. Foil typically has an antitarnishing agent of chromium and zinc that must be removed for reproducible imaging results. During cleaning, the texture or surface roughness of the copper is altered, promoting mechanical adhesion between the copper and the photoresist. The extent of this texturing is measured by the usual parameters for surface roughness, the height and spacing of the topography measured by profilometry (see Fig. 26.6).

$R_a$  Arithmetic mean of all departures from the mean line

$R_{max}$  Maximum peak to valley height within sampling area

$S_m$  Mean spacing between peak measured at the mean line

**FIGURE 26.6** Surface roughness parameters.

**TABLE 26.2** Copper Surface Chemical Composition as Measured by X-Ray Photoelectron Spectroscopy (XPS)

Sample	% Cu	% O	% C	% N	% Zn	% Cr
Initial		46	24		16	12
Preclean 1	12	19	68			
Preclean 2	6	10	70	14		

Chemical cleanliness can be determined in a variety of ways. Wetting is often tested using a *water break test* or more analytically in terms of contact angle, with a low value being desirable.

In addition, analytical techniques (Auger and x-ray photoelectron spectroscopies) can be used to evaluate the chemical composition of the surface (see Table 26.2).<sup>14</sup>

**26.6.2.1 Mechanical Cleaning.** Most mechanical cleaning equipment physically abrades the copper surface using a pumice or aluminum oxide slurry either directly (scrubbing or vapor blasting) or impregnated into brushes. Scrubbing provides an even final surface texture, whereas brushing creates grooves (see Fig. 26.7). The copper thickness must be sufficient to provide the desired final conductor height after cleaning. Mechanical cleaning is more difficult for very thin flexible panels.

**FIGURE 26.7** Comparison of the pumice cleaned (a) and mechanically abraded copper surfaces (b), 1200 $\times$ . (Reprinted with permission of D. P. Seraphim, R. C. Lasky, and C-Y Li, *Principles of Electronic Packaging*, McGraw-Hill, 1989, p. 383.)

The texture of the mechanically cleaned surface affects the adhesion between the photoresist and the copper. The resist should conform to the topography, and thus, the extent and type of texture must be tailored to the type of photoresist. If the gouges are too deep, a dry film applied with traditional lamination will have difficulty conforming to the surface and create defects: near or full opens after etching, and underplating or shorts after pattern plating. Thus, the cleaning process, photoresist type, and application method must be matched to image at high yields.

Conveyorized equipment is used that passes the panels through the brushes or slurry and then to rinse chambers before exiting through a dryer section. If rinsing is insufficient, residual

**TABLE 26.3** Cleaning Solutions Used to Remove Various Contaminants

Cleaning technique	Process chemistry	Contaminant removed
Abrasion	Pumice, Al oxide	All
Plasma	CF <sub>4</sub> /O <sub>2</sub> , O <sub>2</sub> /H <sub>2</sub> O	Organic
Chemical solutions (aqueous etchants)	H <sub>2</sub> SO <sub>4</sub> , HCl, etc.	Inorganic
Chemical solutions (nonaqueous)	Alcohols, etc.	Organic
Thermal	N <sub>2</sub>	H <sub>2</sub> O

*Source:* Adapted from *Introduction to Microlithography*, 1st ed., L. F. Thompson and M. J. Bowden, American Chemical Society Symposium Series 219, Washington, D.C., 1983, p. 184.

pumice can remain on the copper surface. Maintaining proper functioning of the mechanical parts that contact the product is essential since brushes and slurry deteriorate with use. Equipment designs that isolate the abrasive from the majority of the tool are more durable.

**26.6.2.2 Chemical Cleaning.** Chemical cleaning includes a variety of solutions since the solubility of contaminants can be quite different (see Table 26.3). Grease and fingerprints require a soap solution or solvent to dissolve them. Antitarnish treatment removal and copper roughening is done with mild etchants for the copper, such as ammonium persulfate, sodium persulfate, or peroxide/sulfuric acid. Depending on the oxidation level and the amount of antitarnish treatment, there is often an induction time for copper removal. Solutions used can be common chemicals or proprietary mixtures in which surfactants and other additives have been included. Alternatively, the oxide and antitarnish treatment can be removed initially, followed by a surface roughening. In this case, the oxide removal is accomplished with mild acidic cleaning solutions such as sulfuric acid.

The selection of the cleaning solution also depends on the copper thickness. Thin “seed” layers used for electrolytic pattern plating can tolerate very little etching, and extremely dilute solutions or dry methods are used. Thus, chemical adhesion can be more important than mechanical.<sup>15</sup> Selection of the proper process chemicals and sequence depends on the overall conductor formation process and the photoresist to be used.

Chemical cleaning sequences are often contained in conveyORIZED spray equipment with rinsing between each step. Batch processing in a tank system is also used, with a hoist for basket movement between solutions. Uniformity of the etching of panels within a basket must be measured, but is generally quite good and reproducible as long as the immersion time is short and the bath’s chemical composition is consistent.

**26.6.2.3 Electrolytic Cleaning.** A unique inline conveyORIZED tool built by Atotech uses electrolytic cleaning.<sup>16,17</sup> The antitarnish is removed electrolytically along with oils and fingerprints in a uniform process with very little copper removal. The surface texture is then altered by microetching and passivated prior to dry-film photoresist lamination or other coatings.

### 26.6.3 Photoresist Application

The technique used to apply the photoresist to the substrate depends on the type of photoresist selected. The various techniques used with dry-film and liquid photoresists are discussed.

For any of these techniques, the cleanliness of the operation—both the equipment and the room—and the handling of the product are critically important, especially for high density. It is also advisable to minimize handling at this stage by using automated inline equipment for the preclean step and automatic loading and unloading.

**26.6.3.1 Dry-Film Hot Roll Lamination.** In this process, both temperature and pressure are used to laminate the dry-film photoresist to the panels. After stripping off the polyethylene

separator sheet, the photoresist is contacted to the substrate in a nip between two heated rolls. Heat reduces the viscosity of the photoresist and pressure causes it to flow, conforming to the irregularities of the copper surface.

The weave of the laminate affects the topography of the substrate and how much flow is required to achieve good conformation, an essential condition for high yield. Dry-film photoresists are tailored to have rheology that maximizes flow during lamination while preventing flow in the roll prior to lamination, which could cause edge fusion. Panels are often heated with heated rolls and infrared heaters prior to lamination to improve photoresist conformation. The key process parameters affecting conformation are laminator speed, laminating roll temperature, and rigidity of the rolls with respect to the core material and rubber durometer. For aqueous-developable materials, wet lamination has proven to be effective in improving conformation and yield for innerlayers. By using a water-alcohol mixture, wet lamination can also be applied to tent and etch inner via holes to minimize the land diameter.<sup>18</sup>

Both automatic and manual tools are available for film lamination (see Fig. 26.8). With manual tools, the panel is placed in the nip and pulled through by the rotation of the rollers.

The continuous film of photoresist must be trimmed for each panel on at least two sides. This technique is labor-intensive and extremely dirty due to the chips of resist generated by trimming.

However, it is useful for very thin materials and nonstandard-size panels in small lot sizes. With automatic equipment, the basics are the same but the panel enters from an automatic loader or a conveyerized preclean tool directly into and through the dry-film laminator.

This is a relatively clean operation with little handling of the panels since the photoresist is automatically trimmed to the appropriate size and placed within the board edge.

**FIGURE 26.8** Configuration of a hot roll laminator: (a) three-dimensional schematic; (b) two-dimensional schematic. (Reprinted with permission of E. S. W. Kong, *Polymers for High Technology*, ACS Symposium Series 346, Washington, D.C., 1987, p. 280.)

FIGURE 26.8 (Continued)

Equipment is available to convey even very thin panels. Panels are often heated, wetted (wet lamination), or cleaned before the actual lamination.

**26.6.3.2 Dry-Film Vacuum Lamination.** This method is similar to hot roll lamination but the temperature and pressure used to adhere the photoresist to the substrate is applied by a heated vacuum platen instead of laminating rolls. Vacuum lamination is useful for products with tall or closely spaced features that make it difficult for the photoresist to conform. The vacuum removes the air that would be trapped and pulls the photoresist into tight spaces, providing conformal coverage. This equipment is also used for material that will deform nonuniformly under the pressure of laminating rolls, such as thin unreinforced polyimides. With vacuum lamination, the pressure is evenly distributed over the panel, improving dimensional stability control.

**26.6.3.3 Liquid Coating.** A great variety of methods are used to apply liquid photoresist to panels. Roller, spray, electrostatic, and electrophoretic coating provide double-sided application and are well suited to high-volume manufacturing. Curtain coating is single-sided, requiring either two passes of the panel through the equipment with slight drying between coatings or an inline equipment layout with two coating and drying units. This causes a difference in the solvent content of the two sides. Screen-coating equipment is available for either single-side or double-side coating. In all instances, the cleanliness of the surroundings, equipment, and solutions is essential for high-yield processing. Most equipment is designed to minimize material consumption by collecting and filtering excess liquid so it can be recycled to the feed tank.

**26.6.3.4 Roller Coating.** This method places liquid photoresist on the board by transferring the liquid from one set of rollers to another (see Fig. 26.9). The exact number, physical configuration, and surface of the rollers vary, as well as how the material is metered. Often, gravure roller coating is used. Grooves or crosshatches in the rollers that contact the panel determine the amount of liquid deposited on the substrate and are set with a measured overlap or interference so that the board is squeezed between the rollers.<sup>19</sup> Photoresist viscosity also influences the coating thickness applied. Improvements in panel handling and in confining the solution to

**FIGURE 26.9** Configuration of a roll coater: (a) direct coating; (b) indirect coating.

the center of the panel allow for simultaneous two-sided “postage stamp” coverage similar to that obtained with dry-film photoresists, leaving the tooling and location holes clear of material. In commercial systems, the coater is conveyORIZED, with panels entering a clean oven immediately after coating. The throughput of these systems can be as high as 240 panels per hour.

**26.6.3.5 Spray Coating.** Although very thin and uniform coatings are possible with this method, its use in resist imaging has been limited due to concerns about waste caused by overspray.

The spray head traverses a larger area than the substrate to be coated, and the amount of liquid photoresist that becomes overspray can be significant. Exact characteristics of the coating in terms of thickness and topographical coverage depend on spray-head configuration, nozzle backpressure, droplet size, and conveyor speed.<sup>20</sup>

**26.6.3.6 Electrostatic Coating.** This method is similar to spray coating except that the rotation spray head is charged and the panel is grounded. Since the atomized photoresist is attracted to the substrate, there is less material waste than with spray coating.<sup>21</sup> Electrostatic coating is used for solder mask since it provides good coverage of conductor sidewalls. However, its use with photoresist is limited to innerlayers. It is unsuitable for outerlayers because it deposits a thicker coating on the rim of a plated through hole while leaving its interior uncoated.

**26.6.3.7 Electrophoretic Coating.** This method requires materials specially formulated for anodic or cathodic deposition. The equipment schematic in Fig. 26.10 illustrates the process sequence: preclean, coat, permeate rinse, rinse, and dry.<sup>22</sup> Panels are placed in the photoresist solution wet or are often sprayed with solution to ensure wetting, especially if the parts have blind or through vias. Voltage is applied, and within 20 sec. to 3 min. an insulating film forms.

**FIGURE 26.10** Configuration of an electrophoretic photoresist coater. (Reprinted with permission of J. Dubrava et al., "Development of a Novel Positive-Working Electrodeposited Photo Resist Process for the Production of High Density PWB Outerlayers," presentation at the IPC Conference, San Diego, California, Spring 1995.)

Rinsing removes loosely bound material that is returned to the plating cell after ultrafiltration to separate the photoresist and the counterion. This aids in maintaining the ionic balance.

After a final water rinse, the panel is dried to remove water and consolidate the film. The film is now tack-free and can be imaged.

The chemical composition of the photoresist determines whether the equipment components are made from polyvinyl chloride (PVC), polypropylene, or polyethylene. Electrodes are made of stainless steel and encased in an ion-selective membrane that is flushed to prevent the build-up of counterion migrating there during deposition. The permeate and ultrafiltration unit is important for long-term stability of the coating solution. The coating unit is often enclosed in a clean environment to reduce the amount of particles found in solution or resting on the panel as the process proceeds.

**26.6.3.8 Curtain Coating.** This method is commonly used to coat liquid solder mask materials. The panel is conveyed at high speed through a vertically falling curtain of the liquid photoresist. The coating width can be adjusted so that the edges are not covered. Temperature and viscosity are controlled for reproducible coatings, and coating thickness is determined by the conveyor speed and the solution flow rate.<sup>23</sup> Material in the curtain is returned to the sump and reused, giving very efficient material utilization. This method is one-sided, and the first-side photoresist coating must be partially dried before coating the reverse side. Due to the extra handling required to coat one side at a time and the inability to convey very thin panels through the curtain at high velocity, this method has seen only limited use with photoresist.

**26.6.3.9 Screen Coating.** Another common method for coating solder mask with either a pattern or flood coverage is screen coating. The screen mesh size and the liquid solution viscosity set the wet coating thickness. The screen is placed above the panel to be coated, and the material is forced through the openings in the screen onto the panel surface, where it forms a film.

Equipment is available for either single-side or double-side coating. With single-sided screen printers, the coating must be partially dried before the reverse side is coated. This causes a difference in the solvent content between the two sides that would result in nonuniformity for very precise lithography. In addition, the sequential nature of the coating allows debris and contaminants to be embedded into the first coating. Double-sided screen printers eliminate a drying step and minimize panel handling. The advantages of screen coating are that the equipment is relatively inexpensive to purchase and operate, “postage stamp” (small embedded areas) coating is possible, and waste is minimized.

## 26.6.4 Expose

Expose is the actual imaging step, reproducing the master pattern in the photoresist. The relief image is created after subsequent development. The expose process elements are phototool generation, registration of the phototool to the panel, and exposure through the phototool by the light source. Light-source alternatives include contact printing, either collimated or uncollimated; proximity printing; projection printing; and laser direct imaging. The noncontact methods separate the phototool from the substrate, reducing yield losses caused by contamination between the phototool and photoresist. With laser direct imaging, there is no phototool and the design data file of the master pattern drives the laser beam to expose the photoresist.

Phototools are generated on either film or glass substrates, depending on the feature sizes that are being patterned and the durability required. The panel is either mechanically aligned, with pins holding the phototool with respect to the product, or optically aligned, with alignment features dictating the movement of the phototool and product. The alignment requirements are interrelated to those achieved at composite lamination and drilling. The registration scheme is contained within the exposure equipment.

### 26.6.4.1 Conventional Imaging

**26.6.4.1.1 Artwork Generation.** Polyester and glass are the substrates used for phototools. They differ in optical properties, dimensional stability, and durability. Silver halide on polyester is used to create first-generation phototools on a laser plotter. This image is often contact printed onto diazo on polyester to make the copies used in production. Optical absorbance of the different phototool materials versus wavelength is plotted in Fig. 26.11.

**FIGURE 26.11** Optical absorbance of common phototool materials in the spectral region of PWB photoresist exposure.

Diazo phototools are the least expensive, and glass is the most expensive. Although the less-expensive materials have poorer transmission, this property is generally not limiting, except for applications requiring high intensity. Table 26.4 illustrates the impact on exposure time. Edge definition is a major difference among the options, as shown in Fig. 26.12. The photos illustrate that chromium on glass gives the sharpest edge definition. Edge definition is also affected by the pixel size of the phototool plotter and the spot's addressability (see the section on LDI). For applications that use a low-contrast photoresist and poor light collimation, these differences are not measurable on the printed photoresist image or in the patterned conductor. However, for high-density imaging, edge definition is important, as is the dimensional stability of the phototool.

**TABLE 26.4** Comparison of the Optical Transmission of Various Phototool Materials

Property	Diazo	Polyester	Glass
Absorbance at 365 nm	0.271	0.107	0.047
Transmission at 365 nm	54%	54%	90%
% increase in exposure time vs. glass	40	13	0

Film dimensions change more rapidly with temperature than glass and are also affected by humidity. Careful control of both temperature and humidity is required throughout the life of a phototool (see Table 26.5).

**TABLE 26.5** Dimensional Stability of Phototool Substrate Materials with Respect to Temperature and Relative Humidity

Substrate	Expansion coefficient, ppm/°C	Expansion coefficient, %RH/°C
Soda lime glass	9.2	0
Low-expansion glass	3.7	0
Pyrex	3.2	0
Quartz	0.5	0
Polyester	18	9

*Source:* Kodak Technical Literature (ACCUMAX 2000) for polyester film; *Tables of Physical and Chemical Constants*, Longman, London, 1973, p. 254; H. J. Fischbeck and K. H. Fischbeck, *Formulas, Facts and Constants*, Springer-Verlag, Berlin, 1987, for glass data.

The durability of the phototool is also important, especially for use in a manual contact printer. Damage depends on phototool handling, the exposure tool, the cleanliness level of the operation, and the surface of the product being contacted. Commonly, glass artwork is usable for 100 to 400 contacts with repair, while film artwork is usable for 20 to 50. For large numbers of the same part, number cost per contact may actually be lower with glass artwork, while for prototype parts, film artwork is ideal. However, the majority of production panels are exposed with film artwork. High-density applications such as chip scale packaging and multichip modules using laminate (MCM-L) may require glass artwork. The requirements of the product determine the type of phototool that should be used.

**26.6.4.1.2 Registration.** The image is placed on the panel with respect to a point of reference so that the image is well aligned to previous and future features. In multilayer construction, the innerlayer images are aligned front to back for successful lamination and drilling of the plated through holes (PTHs). The outerlayer image is then aligned to the drilled holes. The same considerations are relevant for single-layer boards. Thus, accurate alignment

**FIGURE 26.12** Optical micrograph of the image edge of common phototool materials, 1600×: (a) diazo on polyester; (b) silver on polyester; (c) Cr on glass.

is clearly part of the imaging process and also depends on knowledge and control of the dimensional stability of the product. The image must be scaled to match the dimension of the board at the exposure step; for multilayer structures with several photolithographic steps, a series of dimensional measurements are required prior to product manufacture.

Mechanical registration entails the use of fixed pins or other mechanical devices to hold the phototool and the panel in place during exposure. The actual configuration of the pins and their shape varies. Both two- and three-point systems are used. The three-point systems well define the center location since they are located at the extremes of the area to be patterned.

The shapes of the pins are either round or elongated with one flat side. In the latter case, the flat side defines the edge, while round pins center within the hole in the panel and phototool.

Film artwork alignment holes are punched with respect to the product pattern by plotting alignment targets as part of the product pattern and optically aligning and punching a slot or hole. The edges of the punched feature wear, and registration will deteriorate with use. For glass artwork, the glass is drilled at the alignment locations and a bushing is placed at the center of the hole. The pin is then inserted through the bushings in top and bottom artwork and through the panel. With use, the bushings do move and must be reset for maximum reproducibility.

Optical alignment systems operate either manually or automatically. In both instances, the phototool is plotted with alignment targets—usually an opaque dot that is smaller than a drilled or punched hole in the panel. With backlighting, the dot (phototool) is aligned to the center of the hole (product). Often, three locations at the edges of the panel are used. In manual systems, micrometers are used to move either the part or artwork. In automatic equipment, a vision system calculates the necessary movement, and motors then move either the phototool or the product into alignment. Since there is no wear on the phototool, when it is optically registered the accuracy is maintained with usage. The absolute accuracy achieved with optical methods is superior to mechanical registration, with the best accuracy and reproducibility obtained with automatic optical systems. The extra expense for automated equipment is warranted if it is needed to meet stringent product requirements.

**26.6.4.1.3 Exposure Control and Measurement.** The role of exposure is to change chemically the photoresist and its solubility in the developer solution. The appropriate energy dose is determined experimentally by measuring the combination of dose and development that is needed to produce features with straight sidewalls. The photoresist is coated on an optically clear substrate and exposed from the backside. Contrast curves, plots of the log of the exposure dose versus the thickness of the film remaining, are used to identify the functional cure point—for example, the dose that loses thickness less than 10 percent (see Fig. 26.13).

**FIGURE 26.13** Contrast curve for a negative-acting dry-film photoresist, percent film thickness remaining versus exposure dose ( $\text{mJ}/\text{cm}^2$ ).

Exposure in the region of stability ensures that the base of the material has reacted. Step wedges, film strips with a series of neutral density filters, are also used to determine appropriate exposure doses. The dose is varied to obtain photoresist residue on the area with the manufacturer's recommended step value. This technique depends on appropriate and consistent developer conditions.

Step wedges are often used to control the expose or expose-and-develop processes.

The energy incident on the photoresist is the product of the lamp intensity and the time of exposure:

$$\text{energy} = \text{intensity} \times \text{time} \quad (26.1)$$

Thus, the exposure dose can either be measured directly by using an integrating radiometer or indirectly by measuring exposure time and light intensity with a radiometer. The radiometer response must be matched to the spectral output of the light used so that representative measurements are made (see Fig. 26.14). Most exposure equipment provides the option of using either direct energy or time measurement. With a stable light source, both approaches are equally reproducible.

**FIGURE 26.14** Output of Hg/Xe light source and radiometers. (Reprinted with permission of Optical Associates, Inc., Milpitas, California, Technical Literature.)

**26.6.4.1.4 Contact Exposure Tools.** This equipment places the phototool and the panel in direct contact and draws a vacuum between the pieces for hard contact. A range of light wavelengths is used, often from a mercury or mercury/xenon light source, which is stable and has a high intensity output at ultraviolet and visible (UV/Vs) wavelengths (see Fig. 26.14). The light is distributed over the area to be exposed by placing the board at a distance from the source, either noncollimated or collimated by the use of optical elements, as shown in Fig. 26.15. Collimation refers to the angle of incidence of the light onto the photoresist, and it is critically important for fine-line images. Defining fine spaces is the challenge for both additive and subtractive conductor formation, and exposure under the opaque areas cannot be tolerated. The lamp intensity for noncollimated sources is greater, and therefore less time is required to expose the panel. Process throughput is noticeably enhanced for photoresists requiring a large dose.

In addition to collimation, good contact between the phototool and the panel is the most important factor to control in fine-line formation. Any gap will allow exposure under the

**FIGURE 26.15** Configuration of lamp and optics for a collimated contact printer. A noncollimated source is identical except for the collimation lens in the lower left. (Reprinted with permission of Optical Associates, Inc., Milpitas, California, Technical Literature.)

opaque, resulting in poor linewidth control and reduced resolution. The sensitivity to off-contact exposure varies among photoresists, and newer resists are formulated with increased off-contact latitude.<sup>24</sup> Since the lamp's spectral output degrades over time, the lamp must be routinely replaced to maintain a stable photoprocess. The exact frequency for replacement depends on the line and space definition required, but the lamp life is typically 1,000 hours.

Failure to replace a lamp can result in it exploding and damaging the optical elements in the exposure unit, which is far more costly than routine maintenance.

**26.6.4.1.5 Noncontact Exposure Equipment.** Semiconductor imaging demonstrated the yield limitations in using contact-exposure equipment. Noncontact methods had to be developed to achieve acceptable conductor yield as critical dimensions decreased to  $0.18\ \mu\text{m}$  and below.

The PWB industry is following this evolution, driven by the increased demand for products with fine features of  $25\ \mu\text{m}$  and less. Semiconductor tool concepts cannot be used directly due to important differences between IC and PWB products, namely the physical size of the substrate and features to be imaged and the flatness of the substrate. The key to noncontact methods is the use of appropriate optics for clear image placement in the photoresist (Fig. 26.16), even if the image transfer function has degraded. For PWB applications, this includes the depth of focus to allow for panel warpage and the resolving power, given the contrast of the resist. The following approaches address these concerns and are viable alternatives to contact printing.

**26.6.4.1.6 Proximity Printing.** This is the oldest method for off-contact printing and requires no modification to the equipment optics. The phototool is held out of contact from 125 to  $500\ \mu\text{m}$ . The image in the photoresist suffers since the distance between the phototool and the part allows exposure under the opaque area and imaging of debris on the phototool. Nevertheless, resolution as fine as  $75\ \mu\text{m}$  has been reported for proximity printing with thin coatings of liquid resist.<sup>25</sup>

**26.6.4.1.7 Projection Printing.** Three approaches are possible for this technique: scanning, stitching, and magnified projection printing. Scanning and stitching evolved from semiconductor

FIGURE 26.16 Image transfer for contact, proximity, and projection printing.

and MCM-D thin-film technology, where smaller, flatter substrates are used. They require movement of the phototool and/or the substrate during exposure. Magnified projection imaging is unique to the PWB application and has no moving optical components. A schematic of all three systems is given in Fig. 26.17.

- The scanning printer requires the synchronized movement of the part and the phototool during exposure. Precise alignment of the two pieces must be maintained during the motion. Periodic adjustment for flatness is usually required since this equipment has a small depth of focus. For typical PWB formats, a large phototool is needed, requiring expensive glass phototools for their flatness, rigidity, and sharp line definition. This exposure technique has demonstrated high resolution over a large, relatively flat area using a high-contrast resist.<sup>26</sup> Few PWB applications exist, but the technique is useful for flat panel display manufacture.
- Stitcher projection printers are step-and-repeat tools that use a repeating image or “stitch” together several images. The artwork generation and management in the equipment are complicated, which has hampered these printers widespread use for large panels. The usual active area size as defined by the optics is approximately 6 in. × 6 in. Thus, for a standard 18 in. × 24 in. panel, 12 artwork changes are required to expose one side. These systems have very high resolving capability and large depth of focus. Again, glass artwork is used, but these smaller plates are easier to generate and use than in a scanning projection printer.
- The magnified projection imaging concept was first demonstrated in the late 1980s with the SeriFLASH exposure tool, utilizing 436 nm illumination and a 5 in. × 5 in. liquid crystal display as the phototool. The image was magnified six times to expose an 18 in. × 24 in. panel, but demonstrated photoresist definition was limited to 125  $\mu\text{m}$  since the liquid crystal features were one-sixth of the final conductor width. The equipment was subsequently modified for 365 nm exposure with a glass phototool to improve resolution. Fifty- $\mu\text{m}$  line and 63  $\mu\text{m}$  space resolution has been demonstrated.<sup>27</sup> The exposure time required is similar to that of contact exposure equipment. With optimized optics, this may become a high-resolution tool that utilizes conventional photoresist and phototools.

**FIGURE 26.17** Configuration for projection imaging equipment: (a) scanning, (b) stitching, and (c) magnified.

**26.6.4.2 Laser Direct Imaging.** The LDI method of exposure provides the ultimate in flexibility for customized pattern compensation factors and for engineering changes to the product design since it does not require a phototool. Systems introduced in the 1980s used an  $\text{Ar}^+$  laser with visible optics, requiring specialized photoresists that were sensitive to visible light. Improved  $\text{Ar}^+$  systems relied on the UV wavelengths, making it compatible with conventional photoresists. However, high-speed photoresists were needed to achieve the productivity for high-volume production. Concerns about the lifetime (3,000 to 5,000 hours) and power consumption (60 to 80 kW) of gas lasers led to development of solid-state laser systems at various wavelengths.<sup>28,29,30</sup> The initial solid-state laser systems used 355 nm with a polygon mirror to scan the panel. Recently developed LDI systems have used digital mirror devices (DMD) instead of polygon mirrors and image at a wavelength of 405 nm. Filters are used to block 355 nm light, extending the lifetime of the DMD device. Due to the small size of the individual mirrors, about 1.5 microns, DMD technology provides better resolution than an 8,000 dpi polygon mirror system. However, the area coverage is smaller and several DMDs working in parallel are needed to expose a PWB panel. Systems have also been introduced that use no photoresist at all, laser ablating either tin for use as an etch resist or physical vapor deposition (PVD) copper on polyimide for use as a plating base.<sup>31,32</sup> In addition to varying in laser type and wavelength, specific equipment designs differ in optics, either single- or multiple-beam operation; platen design; single- or double-side exposure; pixel shape; and spot size and resolution.

Multiple-beam operation increases exposure productivity, a key requirement for economic feasibility in large-volume manufacturing. Target production rates for the various systems ranged from 60 to 180 panels per hour (18 in.  $\times$  24 in. with 50  $\mu\text{m}$  features). However, installed LDI systems have been used primarily for prototype and small-lot, quick-turn production of high-density boards. For these applications, savings are achieved due to artwork elimination and reduced setup time. For volume production of medium- to high-technology boards, it is possible to achieve an economic return through yield savings and the ability to produce designs that had not been technically or economically possible with conventional imaging.<sup>33</sup> LDI technology makes it possible to scale the electronic data and and compensate for dimensional changes in sequential build-up (SBU) structures. Although the UV systems can expose conventional photoresist, use of high-speed photoresist is needed to maximize tool throughput. Most LDI systems use a flatbed platen design and can image both innerlayers and outerlayers.

Systems with an external drum architecture, similar in design to laser photo plotters, are limited to innerlayers because the panel must have sufficient flexibility to conform to the drum (Fig. 26.18). The pixel shape can be either square or gaussian. Square pixels are made up

**FIGURE 26.18** Schematics of laser direct imaging equipment: (a) flatbed platen; (b) external drum.

**FIGURE 26.19** Computer simulation of aerial image for a  $25\ \mu\text{m}$  feature: (a) four  $12.5\ \mu\text{m}$  laser spots on  $6.25\ \mu\text{m}$  pixel spacing; (b) four  $6.25\ \mu\text{m}$  laser spots on  $6.25\ \mu\text{m}$  pixel spacing.

of many point sources of light and can theoretically achieve perfect stitching. However, in real systems there is intensity variation due to mechanical vibration and edge rounding. Gaussian pixels use a single-point source and may have less intensity variation. Due to the diffraction-limited nature of light, greater depth of focus can be achieved.<sup>34</sup> Figure 26.19 illustrates that

LASER PARAMETERS	PLOT for 2 mil line	PLOT for 2.5 mil line
Addressability 1.0 mils Spot Size 1.0 mils		Not Possible
Addressability 0.5 mils Spot Size 1.0 mils		
Addressability 0.5 mils Spot Size 0.5 mils		

**FIGURE 26.20** Final image dimension as governed by spot size and addressability of a laser plotter or laser direct exposure tool.

imaging with a smaller laser spot size gives steeper aerial image sidewalls, increasing process latitude.<sup>35</sup> In addition to spot size, addressability of the beam is important in determining the system resolution, as shown in Fig. 26.20.

In selecting an LDI system, you must consider both the capital cost and operating cost. However, the critical factor is that the equipment combined with the photoresist material is capable of achieving both the resolution needed for the product mix and the productivity needed for the production volume. Photoresists for LDI are available that are compatible with the various metallization processes.<sup>36</sup>

### 26.6.5 Develop

In this process step, the solubility difference between the exposed and unexposed areas of the photoresist creates a relief image of the master pattern. The panel is immersed in an appropriate solvent, and the process conditions are adjusted to control the clearing time for dissolving the unexposed areas for negative photoresists or exposed areas for positive ones. Total dwell time is set to approximately double the time to clear, commonly called a 50 percent breakpoint. Solution concentration, temperature, and agitation are key variables. The resulting photoresist images should be distinct, with vertical sidewalls. Failure to achieve this indicates that one of the previous steps requires adjustment. For images larger than the phototool dimension, the cause is either incomplete development, overexposure, or poor contact during exposure. For images that are smaller than expected, either the exposure dose is too low or development is too aggressive. Distorted images can be caused by problems with preclean, application, or exposure. The common equipment for developing is spray conveyORIZED, either horizontally or vertically.

Additives are used in the developer solution to prevent foaming. The solution is filtered to remove resist particles and either replenished with fresh solution to maintain a consistent dissolved resist content and solution concentration or operated continuously for a certain amount of product and then replaced. Waste-developer solution is treated (aqueous and semi-aqueous) or distilled and reused (solvent). Rinsing is important in stopping the dissolution and, for aqueous photoresists, water with a high-mineral content often improves the resist image and the conductor yield. Tank systems can also be used with photoresists that have a wide-process latitude. Ultrasonic agitation is often used to aid in the dissolution.

There are additional steps that improve the resist removal in the line channels and the conductor formation yield. Plasma treatment has been used effectively to improve product yield, especially with respect to shorts in a print-and-etch process. In addition, for some aqueous-developable dry films, a heat treatment after exposure has improved the space definition, and spaces equal to or smaller than the resist height have been resolved. Thus, these process steps ensure that tight resolution requirements can be met.

### 26.6.6 Strip

After the pattern transfer has been completed, the photoresist is removed from the substrate using equipment similar to that used for development. The stripping solution swells and dissolves the photoresist, stripping it either in sheets or as small particles. The equipment design must effectively remove and separate the skins. Often, brushes and ultrasonic agitation are added to aid in the resist removal. As with developing, filtration is important to keep the spray nozzles clean and keep fresh solution reaching the panel. For stripper chemistries that oxidize the copper, an antitarnishing agent is often added either to the stripping solution or as part of the rinsing.

## 26.7 DESIGN FOR MANUFACTURING

---

As design features are continually reduced to produce higher-density interconnects, tighter control of every step in the conductor formation process is required to achieve high yield. The maximum possible yield with an etching or plating process depends on the conductor dimensions such as the conductor pitch in terms of line and space, the conductor thickness, and the size and shape of the capture pads around plated through-holes (PTH) and vias.

### 26.7.1 Process Sequence: Etching versus Plating Considerations

For a specific circuit design, there is often a question of the appropriate process sequence. Although the capabilities of imaging and the pattern transfer step dictate the overall limitations, the decision depends on the unique capabilities of the manufacturing line to be used. Some general considerations can clarify the true issues for most production situations.

Photoresist patterning has different constraints for etching and plating. For etching, a thin photoresist is desirable to maximize the etchants' attack in the channel developed in the photoresist. Resolution does not limit the process, since very small spaces can be resolved in either liquid or thin dry-film photoresists. The etching process itself is key to conductor formation.

Etching the copper from the channel becomes increasingly difficult as feature size is reduced, particularly for thicker metal layers. Therefore, the key criteria defining the capabilities of the print-and-etch process is the minimum space cleared, constrained by the final conductor height and the etchant chemistry and equipment.

For pattern plating, the photoresist thickness must be greater than or equal to the final thickness of the conductor, and it must be possible to develop a photoresist channel equal to the final conductor width. As conductor thickness increases, it becomes more challenging to produce channels with a higher aspect ratio. Since photoresist resolution is on the order of its thickness, it would be difficult to resolve smaller than a 38  $\mu\text{m}$  photoresist channel for 25  $\mu\text{m}$  thick plating, irrespective of the final conductor spacing. Thus, the challenge for pattern plating is to resolve and develop fine channels in thicker photoresist materials and then ensure that the plating solution wets the bottom of the narrow photoresist channels.

Thus, in choosing the conductor formation process, the thickness of the conductor and the linewidth and spacing are the key parameters. A generalized relationship between them is

**FIGURE 26.21** Sample plot of manufacturing line process capability to aid in processing sequence decisions.

found in Fig. 26.21. It is important that this type of plot is known for the production area before the process sequence is determined.

### 26.7.2 Line and Space Division for a Fixed Pitch

It is common for product designs to have a fixed pitch, whether it refers to the I/Os for direct chip or packaging attachment or to the spacing between PTHs. This space is often divided equally between conductors and spacing. For etching or pattern-plating processes, avoiding their respective resolution limitations can increase the pattern transfer yield.

In etching, the etchant undercuts the photoresist and an etch factor is used to obtain straighter sidewalls and improved linewidth control. If lines and spaces are equally allocated in the circuit design, then the photoresist must resolve a smaller space than a line. This is difficult for fine features, except for very thin photoresists. For fine pitch, having a larger space than line will give higher yield. For pattern plating, the spacing in the photoresist is the limiting factor. After pattern transfer, this will become the line. In this instance, equal line and space is more acceptable, but based on the photoresist concerns, a wider final line than space is preferred. At the same time, it is desirable to increase the spacing for reduced incidence of line shorting, which translates to a wider “line” in the photoresist. The former is usually more important. Therefore, for both processes there is preferably balance between linewidth and spacing.

### 26.7.3 PTH Capture Pad Size and Shape for Optimum Line Formation

Just as the conductor line and spacing can be optimized, the PTH capture pad shape and size can also be altered to increase the yield. The absolute dimension of the feature is dictated by

the placement accuracy of the drilling process and the overall dimensional stability of the product. The feature is sized to ensure that the PTH and conductor are connected. There are varying specifications as to the extent of capture that is required.

Feature dimensions above the line would be processed with pattern plating, and those below the line with print and etch.

Depending on the direction and magnitude of the dimensional stability and the drill wander and accuracy, the shape required to capture the PTH can be changed. This would reduce the size of this feature in at least one direction. In consequence, the spacing between the line and pad increases. Since this location is a change to the nominal line-to-line spacing, the narrowing of the channel results in shorting between the features in both a print-and-etch process and additive processes. In the former case, it is more difficult to clear the space, and in the latter, the narrower resist width is often underplated. Thus, when possible, an elongated pad will benefit the final conductor yield.

## 27.1 INTRODUCTION

---

Printed circuit board (PCB) structures and processes continue to be driven by device miniaturization, functional densification, and speed. The choice of components, actives and passives, and connectors are primary determinants of layer count and layer options, such as copper foil weights. Reductions in chip voltages are matched by an increase in current demand; this in turn causes increases in the number and thickness of the plane layers. More device leads combined with decreasing pitch increases the number of vias and interconnecting layers, while miniaturization and weight reduction at the product level forces reduction in the physical package for the product.

New structures or advancements on existing structures are then needed to make these interconnections. These structures—such as blind and buried vias, multi-lamination (sub-laminations), and build-up technologies—directly impact multilayer processing. Deeper blind vias and buried vias have caused a major increase in the demand for reliable via filling materials and methods. Relatively new materials, equipment, and processes have and are being developed to address this need. A new section in this chapter, “Filled Via Processing and Sequential Lamination,” addresses filled vias internal to the PCB.

Ever increasing frequencies continue to shift demand to materials with lower attenuation and propagation delay. To guarantee the electrical performance requirements of this product type and to benefit from the increased raw material and processing costs, the industry is specifying each element in the construction more so than in the past, and with less latitude. For instance, requirements for post-pressed thickness tolerance on a prepreg fill section, or surface roughness of the treatment side of the copper foil, or percent resin of the prepreg or core are much more likely to find their way onto fabrication prints.

Globalization of sourcing for PCBs continues to have a major impact on the physical design or the fabrication processes for the PCB construction. Mass lamination techniques have scaled to higher layer counts, and alternate tooling methods and panelization approaches

have contributed to increases in material utilization and throughput. These technologies increase production volumes and reduce costs and are discussed in this chapter in Secs. 27.4.4 and 27.4.6.

The latest challenge to the physical PCB is coming from regulatory bodies and consumers who demand products that are less damaging to the environment. Materials developed to meet these demands are known colloquially as either lead-free or RoHS-compliant (that is, in accordance with the Restriction of the Use of Certain Hazardous Substances in Electrical and Electronic Equipment Directive). This chapter will not deal at length in the specific requirements of this directive, but will address the major impacts to the PCB materials (see Section 27.2.3) and subsequent processing (see Secs. 27.5.5 and 27.6.2).

Lead-free joints, which have no appreciable lead content (for what “appreciable” means in this context, refer to the appropriate directive; see also Chapter 10) reflow at temperatures 30 to 40°C higher than the melt point of eutectic solder. These temperature increases have necessitated the development of newer resins or blends, different curing agents, and fillers to provide a laminate system that can survive and remain reliable after these elevated heat excursions. The changes to the laminates themselves are covered elsewhere in more detail (see Chapters 6 and 7), but those properties directly applicable to the performance of the PCB are discussed in this chapter in Sec. 27.2.2.

In some market segments, particularly the consumer market, “green” technology is an important product differentiator or even a market requirement. This chapter also introduces halogen-free laminates in Sec. 27.2.

### 27.1.1 Relevant Specifications, Standards, and Test Methods

Industry standards groups such as the IPC have defined properties requirements and performance specifications to facilitate the choice of laminates. Design standards are available to inform the material selection process to achieve a desirable form, fit, or function. Standardized property tests have been developed to provide a common method to test for property values and to interpret results. Some of the most commonly used are:

- IPC-2221, “Generic Standard on Printed Board Design”
- IPC-4101, “Specification for Base Materials for Rigid and Multilayer Printed Boards”
- IPC-4104, “Specification for High Density Interconnect (HDI) and Microvia Materials”
- IPC-4652, “Metal Foil for Printed Wiring Applications”
- IPC-TM-650, “Test Methods Manual”

Table 27.1 lists some laminate tests covered in IPC-TM-650.

**TABLE 27.1** IPC-TM-650 Laminate Tests

2.4.24.4	“Glass Transition and Modulus of Materials Used in High Density interconnection (HDI) and microvias—DMA method”
2.4.24.5	“Glass transition temperature and thermal expansion of materials used in high density interconnection (HDI) and microvias—TMA method”
2.4.24.6	“Decomposition temperature ( $T_d$ ) of laminate material using TGA”
2.4.25C	“Glass transition temperature and cure factor by DSC”
2.6.25	“Conductive anodic filament (CAF) resistance test: X-Y axis”

## 27.2 PRINTED WIRING BOARD MATERIALS

A basic understanding of material performance is necessary for both the designer and fabricator of the printed wiring board (PWB). Understanding the materials available is one of the primary tasks for designing for manufacturability and performance. It is necessary to match the product end-use performance requirement as well as the environmental exposure the board experiences in the fabrication and circuit card assembly (CCA) processes with the capabilities of the material. It is common for boards to experience as many as five thermal excursions in CCA.

With the introduction of the RoHS directive, the temperature at which the board is assembled is typically 30 to 40°C higher than usual eutectic reflow temperatures. Current lead-free pastes require peak temperatures from 230 to 250°C. The actual peak temperature for any CCA is a variable based on the specific alloy paste, the component lead metallurgy, and also the combined component and board mass. Many studies have reported data that document the plated through hole damage that accumulates from successive reflows as a function of the expansion of the laminate with increasing temperature. Other experiments have demonstrated that the peak temperature has a primary effect on the ability of the PCB to withstand assembly without delamination or ruptured vias. Materials have been developed to withstand these higher lead-free assembly (LFA) temperatures with residual life cycle reliability. However, quality and reliability of any unique part is codependent on processing and design variables in conjunction with the proper material selection.

### 27.2.1 IPC-4101 Specification

To facilitate the many choices of laminates and their associated properties, industry standards groups such as the IPC have defined minimum performance specifications and have issued several specifications to inform the selection process. Some of the most commonly used material specifications are those that deal with laminate, prepreg, and copper foil. IPC-4101, "Specification for Base Materials for Rigid and Multilayer Printed Boards," and IPC-4652, "Metal Foil for Printed Wiring Applications," are the primary specifications for clad laminates, prepregs, and foils. Another specification, IPC-4104, "Specification for High Density Interconnect (HDI) and Microvia Materials," deals with many of the new materials for HDI, such as epoxy-coated microfoils, as discussed in this chapter.

The bare-board base materials are identified by using the classification system found in IPC-4101, which has specification sheets for various grades of material. The specification sheet is also known as a *slash sheet* since each material specification is preceded by a forward slash (/). Each sheet's heading typically identifies the resin system, the reinforcement, flame retardant, presence of fillers, as well as some performance parameters, such as glass transition temperature ( $T_g$ ) or decomposition temperature ( $T_d$ ). More detail is in Sec. 27.2.2.

**27.2.1.1 Keywords.** IPC-4101B includes "Keywords" to assist the user to select slash sheets that have applicability to a typical use. The specification cautions that Keywords are not specification requirements and "having a particular Keyword in the header section, does not guarantee the acceptability of this material for a specific application." Nor are Keywords meant to convey the "only" use for that material. The Keywords used in this chapter to point to particular materials by slash sheet are: "RoHS compliant," "Low Halogen Content," "CAF Resistance," and "High Decomposition Temperature."

**27.2.1.2 Limitations of Specification.** IPC-4101B also includes guidance on qualification assessment for base materials. The user of this specification should be aware, however, of the boundaries and caveats of this specification and the consequent responsibility on the stipulator

to understand these limits. The tests proscribed in IPC-4101 are on either raw cores or prepregs laminated into simple cores. The manufacturer of base laminates must test its laminates for the inherent properties of the materials, before transformation by fabrication processes. This means that the data are relevant to compare materials to a baseline value and like materials to each other, but these are not tests for post-fabrication long-term reliability or time to failure in the end-use environment (with the exception of CAF resistance, which is an optional test), although they can be and are indicators of reliability for a particular use when properly understood.

**27.2.1.2.1 Conductive Anodic Filament (CAF) Resistance.** The Keyword “CAF Resistant” is more of a descriptive than quantitative term. CAF growth resistance is tested per test method 2.6.25, but the acceptability of the results is stated only as “Pass/Fail.” Acceptability is as agreed upon between user and supplier (AABUS). Furthermore, the voltage applied during the test is a variable, although the specification recommends 100VDC for material evaluations. The “CAF Resistant” Keyword essentially means that the laminator has conducted some level of CAF testing on the material and/or has optimized some element of the system to reduce CAF propensity. When reviewing a laminator’s CAF test results, the user should know what applied voltage was used and if that is sufficient for the user’s product reliability requirements, the test population, and the distribution of the “failed” nets as a function of the interaction of distance and time.

**27.2.1.2.2 RoHS-Compliant.** The Keyword “RoHS Compliant” is also descriptive, intended to convey that the laminate is sufficiently thermally robust to withstand the rigors of lead-free reflow assembly temperatures. For a more quantitative approach, look for materials that comply with slash sheets that show results for time to delamination ( $T_d$ ) by thermal mechanical analyzer (TMA). This test is optional and the results, given in minutes to delaminate at three benchmark levels of 260, 288, and 300°C, are minimums. The establishment of these levels and the minimum time to delamination puts a laminate in the class of the more thermally robust materials, but does not guarantee any minimum performance for a particular multilayer board (MLB) in its specific assembly temperature exposures.

Table 27.2 shows elements defined in the slash sheets in IPC-4104. Table 27.3 shows 20 slash sheets from the 55 in IPC-4101B, and some of the key elements from over a dozen listed properties.

## 27.2.2 Critical Properties

In addition to providing circuit interconnection, a multilayer printed wiring board (ML-PWB) provides the electrical and mechanical platform for the system. This means that the electrical and thermal properties of the ML-PWB material are very important for the proper functioning of the system. Among the properties of importance are dielectric constant,  $D_k$  (also known as  $Er$ ); dielectric loss,  $D_f$  (or  $\tan \delta$ ); glass transition temperature,  $T_g$ ; time to delamination,  $T_{xxx}$ ; thermal decomposition temperature,  $T_d$ ; coefficient of thermal expansion, CTE; and moisture absorption. The following sections discuss the importance of these properties to an ML-PWB substrate.

**27.2.2.1 Electrical Properties.** Electrical properties include the dielectric constant and dielectric loss.

**27.2.2.1.1 Dielectric Constant ( $D_k$ ).** Impedance and transmission speed are both affected by  $D_k$ . Since impedance must be matched throughout a high-speed circuit, this means that the impedance of other circuit elements determines the required impedance of a circuit line. The designer can use standard equations to select values for line width, dielectric thickness, and dielectric constant that will achieve the desired impedance (47, 50, and 60 ohms are common requirements). However, factors such as interconnection density and ML-PWB imaging capability can constrain the line width, leaving the trade-off available to the designer between dielectric thickness versus dielectric constant. As the average number of layers in ML-PWBs increases, the

**TABLE 27.2** Slash Sheet IPC-4104 Series

dielectrics between layers must decrease to keep the overall thickness constant. Thinner dielectrics require either lower  $D_k$  value material or thinner lines for constant impedance, sometimes both. Low  $D_k$  value materials are frequently the enabler to achieve higher layer count PWBs.

There are also applications that require higher  $D_k$  material. This allows finer lines to achieve a target impedance when dielectric thickness is already established, providing for greater densification.

Transmission speed is important because the signal transit time affects device timing and determines at what circuit length transmission line effects become important. The transmission speed of an electromagnetic wave in a dielectric medium is the speed of light divided by the square root of  $D_k$ . Air has a  $D_k$  of 1.0, and electromagnetic waves travel at the speed of light (12 in./ns). At 1 GHz, standard FR-4 ML-PWB materials have a  $D_k$  of 4.4 and the transmission speed is reduced to 5.7 in./ns. With a material having a  $D_k$  of 3.4, transmission speeds reach 6.5 in./ns, while even lower  $D_k$  materials can achieve speeds up to 8 in./ns. Although these are small improvements, the higher transmission speed provided by a low- $D_k$  material may be important in some high-speed applications.

**27.2.2.1.2 Dielectric Loss ( $D_f$  or  $Tan \delta$ ).** The energy absorbed by the dielectric media is called dielectric loss. Attenuation is proportional to  $\tan \delta$  and signal frequency. For standard FR-4 ML-PWB materials,  $\tan \delta$  is 0.02, which translates into serious losses at frequencies above 1 GHz. For circuits operating above 1 GHz, a lower loss material is required. There are a number of material choices for lower dielectric attenuation, including blended epoxies, hydrocarbon ceramic, polytetrafluoroethylene (PTFE), and PTFE with ceramic. The  $\tan \delta$  values of these materials are approximately .01, .004, .002, and .001, respectively.

**27.2.2.2 Thermal Properties.** The important thermal properties of a laminate are the glass transition temperature, the coefficient of thermal expansion, the time to delamination, and the decomposition temperature.<sup>1,2,3</sup> These properties quantify the material's reactions to extreme temperatures and so are indicators of the materials' suitability for a particular reflow profile and residual capacity for withstanding heat input (such as rework or hot use environments).  $T_g$  alone is insufficient to predict a materials response to LFA temperatures. In fact, since each test measures a different response to temperature, all the tests together provide a broad determination of suitability to a particular use.

**27.2.2.2.1 Glass Transition Temperature ( $T_g$ ).** The  $T_g$  of a resin is the temperature at which the resin reversibly changes from a glassy state to a rubbery state. This loss of modulus creates an effective limit on the operating temperature of the system.  $T_g$  also affects the thermal fatigue life of the plated holes in the ML-PWB. Higher values of  $T_g$  translate into lower total z-axis expansion, which in turn means less stress on the plated through holes (PTHs), all other variables being held constant. There are three methods that are currently used to evaluate  $T_g$ : differential scanning calorimetry (DSC), thermomechanical analysis (TMA), and dynamic mechanical analysis (DMA). Results from the three methods vary since they measure different properties associated with the glass transition. Each has its rationale, strengths, and weaknesses. It is important to note not only the value of  $T_g$  given for a particular material, but the method by which the  $T_g$  was determined; only then can meaningful comparisons between materials be made.

$T_g$  measurement by differential scanning calorimetry (DSC) defines the  $T_g$  as a change in the heat capacity of the material. The deflection in the heat rate absorption curve,  $W/g/^\circ C$ , is used to identify the second-order thermodynamic change from a glassy solid to an amorphous solid that is the glass transition.

DSC is the method most commonly used by laminators for determining, and reporting, the  $T_g$ . The sample for DSC weighs between 15 to 25 mg and is tested with copper foil on both sides. This method is well suited to the testing of laminates and provides a precision measure for  $T_g$  on cores and cured prepreg (laminated to foils) for the laminator. These results are used for product acceptance and process control. DSC results are generally 5 to 10°C higher than when the test is conducted by TMA.

$T_g$  measurement by thermomechanical analysis (TMA) determines the  $T_g$  by the change in thermal expansion as the polymer goes from glass state to rubbery state due to a change in free molecular volume. A change in the slope of the z-axis expansion rate indicates the glass transition. Typically, the data sheet will report the  $T_g$  and the CTE (discussed in more detail later in the chapter) in the z-axis above and below the  $T_g$  (“% CTE <  $T_g$ ” and a “% CTE >  $T_g$ ”), where the slope (viewed when graphed with temperature on the x-axis and percentage expansion on the y-axis) is much steeper above the glass transition. Alternately or additionally, the data sheet may report the percent thermal expansion (PTE), which is the total change in thickness over a temperature range of interest—for instance, from a temperature below  $T_g$  to the anticipated soldering temperature (e.g., 245 °C, 260 °C). IPC-4101B slash sheets 99, 101, 121, 124, 126, and 129 have a new requirement for reporting z-axis CTE in %TE from 50 to 260 °C.

Both the slope above  $T_g$  and the temperature at  $T_g$  are important to understanding the total expansion of the material. When the data sheet lists PTE, and the top temperature is sufficient to your application, then it is far easier to compare competing materials to each other and their expansion response to the assembly temperature.

For Test Method TM-2.4.24 (TMA), the sample is 0.25 × 0.25 in. × 0.20 in. minimum; for increased accuracy, the sample should be between 0.030 and 0.060 in. The sample has no internal or external copper, with only the resin, fillers (if applicable), and reinforcing system affecting the result. Test Method 2.4.24.5 (TMA) is used to determine the CTE ppm/°C values for the x- and y-axis, using Method B, a thin specimen (≤ 0.020 in.); it can also provide the  $T_g$  and PTE. TM 2.4.24.5.(TMA) Method A, will provide z-axis expansion (but not x- and y-axis expansion),  $T_g$ , and PTE for thicker specimens (≥ 0.020 in.).

Since TMA measures  $T_g$  as a function of the expansion of the material, and will also provide the z-axis CTE, it is the method fabricators use most commonly for  $T_g$  determination to infer a materials’ thermal stability during assembly. For dielectric materials used for the formation of HDI layers (thinner layers, = 0.006 in., adjacent to or forming the outerlayer, and having microvias to provide interconnection with the balance of the construction), IPC-4104 states that the preferred method for determining  $T_g$  and CTE above and below  $T_g$  is Test Method 2.4.24.5.

$T_g$  measurement by dynamic mechanical analysis (DMA) determines the elastic modulus (or storage modulus) as a function of temperature, thereby identifying the glass transition region in plastics. The  $T_g$  is accompanied by a rapid reduction of the flexural strength. DMA typically gives  $T_g$  values 10 to 15°C higher than DSC.

DMA has not traditionally been used by the board fabrication industry; however, some evidence suggests that this technique might be a better differentiator for and indicator of a materials’ inherent thermal stability in the LFA reflow environment since it combines temperature with torsional oscillation. Additionally, this test has the advantage of being very sensitive and accurate with thin film materials.

27.2.2.2.2 *Time to Delamination ( $T_{xxx}$ )*. Time to delamination is a test to determine the elapsed time at an elevated temperature when a sudden and irreversible expansion, indicative of a delamination, occurs. This is at a temperature higher than the  $T_g$  of the material. Historically this test called for an isothermal temperature of 260°C (hence the abbreviated common test name, T260) until expansion due to delamination is detected by TMA. See Fig. 27.1 for an example of a TMA plot. For common materials, the T260 varies from a few minutes to hours. With the advent of LFA, higher temperatures 288°C and 300°C are now used to evaluate and differentiate materials. The test is the same as T260 with the exception of the isothermal temperature. IPC-4101 RoHS-compliant laminates pass T260 at 30 min. minimum, T288 at 15 min. minimum, and T300 at 2 min. minimum, when tested by TM 2.4.24.1.

27.2.2.2.3 *Thermal Decomposition Temperature ( $T_d$ )*. The thermal decomposition of a laminate is a test to determine the temperature at which a set weight loss percentage occurs. This is indicative of an irreversible degradation of the chemical bonds within the system coincident with the alteration of the laminate’s physical properties, or indicative of outgassing of volatile products. The mass of the sample is weighed; the sample is then placed in the thermogravimetric analyzer (TGA). The temperature at which there is a 2 percent weight decrease is

**FIGURE 27.1** TMA plot: time to delamination at 288°C.

recorded ( $T_d$  2 percent), and the temperature to a 5 percent weight decrease is subsequently recorded ( $T_d$  5 percent). IPC-4101 RoHS-compliant laminates pass  $T_d$  5 percent at 340°C minimum. Delta  $T_d$  ( $T_d$  5 percent– $T_d$  2 percent) is considered by some as an indicator for the onset and rapidity of decomposition. For laminates with identical  $T_d$  5 percent values but differing  $T_d$  2 percent values, the lower the delta  $T_d$  the more thermally resistant the material. Note that  $T_g$  and  $T_d$  do not correlate. A low  $T_g$  material can have a high  $T_d$  and vice versa. Materials with identical  $T_g$  can have different  $T_d$ . See Fig. 27.2 for an example of a TGA plot.

**27.2.2.2.4 Coefficient Of Thermal Expansion (CTE).** The CTE of a laminate is comprised of values for x-y axis, or in-plane expansion, and z-axis, or vertical expansion (which is further comprised of the percent expansion below and above the glass transition temperature). The data are reported in ppm/°C; a typical plot is shown in Fig. 27.3.

The x-y CTE for standard FR-4 at 14 to 20 ppm/°C is higher than for ceramic or silicon. The resulting thermal expansion mismatch between an ML-PWB and the attached devices can lead to solder joint fatigue failures when the system undergoes multiple heat cycles during power-up and power-down. Packages with compliant leads can accommodate the CTE mismatch and so can be used with standard ML-PWB material systems.

The z-axis CTE for standard 130 to 135 °C  $T_g$  FR-4 is typically about 40 ppm/°C  $T_g$  and 250 ppm/°C  $> T_g$ . At LFA temperatures of 245 to 260°C, the material expansion is so dramatic that the traditional materials experience delamination and PTH ruptures. The new generation of Lead Free Assembly Capable (LFAC) FR-4 laminates generally utilizes one or both of the following approaches to minimize the CTE above  $T_g$ : a change to non-dicy curing agents, typically phenolic, and/or the dispersion in the resin of some amount of inorganic fillers to restrain the z-axis expansion.

FIGURE 27.2 TGA plot: decomposition temperature.

FIGURE 27.3 TMA plot:  $T_g$  and CTE.

**27.2.2.2.5 Moisture Absorption.** Moisture is the enemy of an ML-PWB. Absorbed water raises  $D_k$  somewhat and can raise  $\tan \delta$  significantly, hampering the functioning of the circuit at high frequencies. For applications in humid environments, a low moisture-absorbing material should be selected. Additionally, moisture absorption increases leakage current, which in turn degrades the ability of the material to resist CAF formation under bias.

Trapped moisture expands with temperature, so the board sees more thermal expansion (additive to the effects of the laminate CTE) at assembly, which causes thermal defects such as delamination, blistering, or barrel cracking. The severity of these problems depends on the storage environment prior to soldering and the peak temperature of the reflow. If storage times are short, humidity is low, and reflow temperature is moderate, moisture will not be a serious issue. However, if the ML-PWB material has high moisture absorption, or is subjected to high humidity for an extended period of time, or if the assembly temperature is especially high, special care must be taken. This can include storing with a desiccant, baking prior to assembly, or both.

### 27.2.3 Properties of the Resin Systems

Materials with highly cross-linked epoxy resin reinforced with woven fiber glass are the most common in use. Bromine is reacted with the epoxy matrix and is used to provide fire retardancy. Most epoxy-based materials satisfy the Underwriters Laboratories (UL) classification of V-0 for fire retardancy. The generic term for this family of epoxy resin materials is “FR-4,” with “FR” standing for flame retardant and “4” an assigned number indicating “epoxy.” Epoxy-fiberglass materials are sold by many suppliers and have become a commodity material.

**27.2.3.1 Epoxies.** A variety of epoxies are available for use, including halogen-free epoxies and materials with enhanced thermal, electrical, and mechanical properties.

**27.2.3.1.1 Standard Epoxies.** Two resin systems are used to make GF laminate: difunctional and tetrafunctional. These systems are distinguished by the nature of the epoxy cross-linking. In a difunctional system, the epoxide molecule has two cross-linking sites, and the cured epoxy contains long linear molecular chains. Pure difunctional laminates have excellent physical properties, and for many years were the mainstay of the industry. They have a  $T_g$  of 120°C, which is adequate for most use environments, but is low for some applications and too low for LFA.

The epoxide molecule of a tetrafunctional epoxy has more than two cross-linking sites. This allows a high cross-link density and a high  $T_g$ . A pure tetrafunctional system is expensive and difficult to work with. To meet the need for a  $T_g$ , above 120°C, laminators blend difunctional and tetrafunctional resins, producing a mixture referred to as multifunctional. Around 1985, some laminators began to sell a multifunctional epoxy blend with a  $T_g$  between 130 and 145°C. This blend was called tetrafunctional, even though it actually contained both difunctional and tetrafunctional epoxies. This blend is available at little or no price premium over a difunctional laminate. Laminates with a higher fraction of tetrafunctional resin are available. These systems, which are called multifunctional, have  $T_g$  values in excess of 170°C and are sold at a price premium of approximately 10 percent over difunctional systems. Multifunctional blends often have lower moisture absorption and higher thermal degradation temperature than difunctional systems. However, in some multifunctional systems, these properties are not improved. Care must be taken in selecting a multifunctional system to ensure that all properties of importance are enhanced.

Modern ML-PWBs often operate at elevated temperatures due to the heat output from semiconductor devices. As boards become thicker and holes smaller, these thermal cycles result in an increasing threat to the reliability of plated holes. For example, plated holes have been shown to fail when subjected to multiple thermal cycles up to temperatures near the  $T_g$  of the base material. These cycles can easily occur when a high-power device is turned on and off. One solution to this problem is to use materials with a higher  $T_g$ .

ML-PWBs often have surface-mount devices on both sides of the board, and they receive three or more solder operations during the assembly of connectors and devices. In addition, because of the value of a completed assembly, the board must be able to withstand additional soldering operations needed for occasional removal and replacement of defective devices. Boards made with difunctional GF epoxy can suffer from lifted lands, cracked PTH barrels, or substrate blisters during these multiple soldering operations. The solution is to use materials with low moisture absorption and high thermal degradation temperature.

**27.2.3.1.2 RoHS-Compliant Epoxies (Non-Dicy Cure Agent).** Conventional epoxy resin systems have commonly used dicyandiamide (dicy) as the curing agent. Experiments reported in the industry have concluded that dicy-cured FR-4 PWBs even with high  $T_g$  and optimized PWB fabrication do not withstand the thermal stress of lead-free assembly conditions. Phenolic-cured (novolac) epoxies had demonstrated better thermal stability than the dicy-cured systems. Many of the new RoHS-compliant LFAC laminates use a phenolic curing agent. Many of the new laminates, in addition to changing the curing agent, also incorporate some percentage of inorganic fillers to restrain the z-axis expansion of the system.<sup>4</sup>

These changes fundamentally impact the fabrication of the base materials into ML-PWBs especially in the lamination, drilling, and hole-preparation processes. The process impacts will be discussed in later sections.

**27.2.3.2 Halogen-Free.** Halogen-free laminates are a response to the European Union direction to require original equipment manufacturers (OEMs) to reclaim electronics to remove hazardous substances from the waste stream (leaving aside the discussion of which substances are hazardous and how hazardous those substances are considered to be). Waste management of PCBs containing halogens will be costly. Halogen-free (HF) technology is sometimes used to refer to laminates that have no tetrabromobisphenol A (TBBPA), which is the primary flame retardant used in FR-4 laminate. TBBPA is an organic molecule whose composition includes approximately 59 percent bromine. There is no legislation or regulation calling for the removal of TBBPA; however, the driver for halogen-free technology is the eco-friendly consumer market. For this reason, these laminates are also sometimes called “green” laminates. HF laminates can be identified by a non-bromine flame retardant in the composition.

The main chemical families used for nonhalogenated flame retardants are phosphorous compounds, nitrogen compounds, inorganic fillers, and compounds containing aluminum, magnesium, or red phosphorous. Curing agents are available that improve cross-linking with epoxy systems, completely curing the resin. These proprietary curing agents, when combined with fillers such as alumina trihydrate (ATH) up to 50 percent by weight, can achieve higher  $T_g$  values, comparable to multifunctional epoxies, and provide better flame retardancy. Various formulation recipes can lower CTE and decrease moisture absorption.

HF laminates, however, require different processing than brominated FR-4s, in lamination, wet processing, and drilling. Also, HF laminates differ from each other based on the flame-retardant system; they are not as similar to each other as one FR-4 is to another FR-4. The fabricator needs to work closely with the laminator to develop processes suited to the particular formulation. The engineer specifying the HF material for the product needs to understand both the properties of the specific brand of HF material, and the capabilities of the fabricator to produce quality MLBs given the design’s properties and performance requirements.<sup>5,6,7</sup>

**27.2.3.3 Materials with Enhanced Thermal Properties.** There are three alternate resin systems commonly available for applications requiring thermal properties superior to those available from the enhanced multifunctional epoxies: polyimide (PI), cyanate ester blends (CE and BT), and polyphenylene oxide (PPO) blends.

**27.2.3.3.1 Polyimide.** Probably materials in the polyimide family provide the best thermal stability. This family of materials has a  $T_g$  in excess of 250°C, a high thermal degradation temperature, and a CTE less than that of epoxy. Polyimide resins can be coated on glass fabric to produce an ML-PWB substrate that processes like epoxy. With a high  $T_g$  and high thermal degradation temperature, polyimide ML-PWBs provide high-temperature reliability.

For systems that must operate at temperatures above 200°C, polyimide is a good choice. The combination of a high  $T_g$  and a relatively low CTE results in excellent fatigue life for plated holes. This makes polyimide a good candidate for very thick boards and for applications where the system must survive multiple thermal cycles over a wide temperature range.

Polyimides have several disadvantages. Early versions used a solvent called MDA, which is widely viewed as carcinogenic. Although there was no evidence of MDA release during ML-PWB fabrication or use, many fabricators refused to process MDA-containing polyimide. Fortunately material suppliers have been able to formulate MDA-free versions of polyimide, and most polyimide on the market today is rated as MDA-free. The second disadvantage of polyimide is fast moisture uptake. Generally, polyimide users combat moisture by including multiple bakes in the board fabrication and assembly processes. The third disadvantage of polyimide is cost. The cost of a polyimide laminate is up to two to three times that of an epoxy laminate. In addition, ML-PWB fabrication requires a high-temperature lamination.

Polyimide material has been used in low volume since the early 1980s. Broad acceptance was always limited by cost and fabrication issues. This material family should be specified only for systems that must operate with high reliability in an extreme environment, such as a high ambient temperature or extremes in thermal cycling. This includes some military applications and potentially a few consumer applications such as under-hood automotive electronics. For most commercial applications, lower-cost materials—such as conventional epoxy blended with CE or PPO resin—may be used.

**27.2.3.3.2 Cyanate Ester Blends.** The second most stable resin system is the triazine or cyanate ester family. In its pure form, the cyanate ester resin is brittle and is difficult to drill without cracking. Low peel strengths are typically associated with its use. In addition, cyanate ester is an expensive resin system. As a result, cyanate ester resin is often blended with epoxy and a small amount of polyimide. This blend, called BT (after its two ingredients, bis-maleimide and triazine), can be coated on conventional glass cloth to produce a laminate.

BT laminates have a  $T_g$  of 180°C and a high degradation temperature. For most high-temperature applications, they are a direct substitute for polyimide. They have the added advantage that the moisture sensitivity and processibility of BT are much closer to those of conventional epoxy than those of polyimide. Other than a high-temperature post lamination bake required for a full cure, the BT process is the same as an epoxy process. The major drawback of the BT laminate is cost. Although BT is much less expensive than polyimide, it is still up to 1.5 times the cost of epoxies. The result is that BT is a popular replacement for polyimide, but its use is limited to specialty applications. The trend for most high-temperature commercial applications is either a multifunctional epoxy or an epoxy-PPO blend.

**27.2.3.3.3 Polyphenylene Oxide (PPO)-Epoxy Blends.** One of the cost-effective high-temperature laminates in use is a material based on a blend of PPO and epoxy resin. This material has a  $T_g$  of 180°C and a T260 of 60 minutes or more. When coated on glass, the PPO blend processes like epoxy. The only exception is the need for a high-temperature bake to achieve full cure. The major advantages of this laminate family are very low moisture absorption and a small cost premium. The disadvantage of PPO is that it has a broad  $T_g$  with softening beginning well below 150°C. This has an adverse effect on the ultimate fatigue life of high-aspect-ratio holes. Care should be taken in using this material in applications where the system must operate over a very large number of thermal cycles that include temperatures in excess of 130°C.

**27.2.3.4 Materials with Enhanced Electrical Properties.** The resin and the reinforcement determine the  $D_k$  and  $\tan \delta$  of a composite material. Standard FR-4, made up of epoxy resin and woven glass, has a  $D_k$  in the range of 4.0 to 4.4 and a  $\tan \delta$  of 0.02. This may be reduced somewhat by replacing some or all of the epoxy resin with PPO, cyanate ester, or PTFE. Further reductions require replacing the glass reinforcement, which contributes a  $D_k$  of 6.0 to the effective  $D_k$  of the system.

**27.2.3.4.1 Cyanate Ester Blends.** Both the  $\tan \delta$  and the  $D_k$  of the cyanate ester resin system are much lower than those of epoxy. The best results are achieved with pure cyanate ester. However, as mentioned earlier, this resin is brittle and difficult to drill. The BT blend provides an excellent compromise. BT has a  $D_k$  of 2.94 and a  $\tan \delta$  of 0.01. This improvement is useful in some applications; however, it is inadequate for many high-performance applications, and the approximately 100 percent cost penalty for BT has prevented its broad acceptance.

**27.2.3.4.2 PPO Blends.** As with cyanate ester, both the  $\tan \delta$  and  $D_k$  of the PPO resin are lower than those of epoxy. For processibility and cost reasons, a blend of approximately 50 percent PPO and 50 percent epoxy is generally used. This gives electrical performance similar to that of BT, but with a cost penalty of only 20 to 50 percent above standard epoxy. It is likely that PPO will find wide use in those applications such as high-performance workstations that need a small improvement in electrical performance. Unfortunately, the characteristics of a PPO-epoxy blend are often inadequate for very high-speed applications such as supercomputers and wireless (RF) applications.

**27.2.3.4.3 PTFE-Based Laminates.** This resin system is commonly known as Teflon. Of all resin systems in common use, the best electrical performance is provided by PTFE. The  $D_k$  of PTFE is close to 2.0 and the  $\tan \delta$  is less than 0.001. This is a significant improvement over all other materials. In addition to offering excellent electrical properties, PTFE has excellent thermal properties. It is a thermal plastic that can operate at temperatures above 300°C without softening, oxidation, or other forms of degradation. PTFE is naturally fire retardant, so it does not need bromine addition to achieve the UL rating of V-0. It has very low moisture absorption.

For ML-PWB applications, PTFE has three serious disadvantages:

- **Poor processibility** Because PTFE is a high-temperature thermoplastic, it is generally laminated in a high-temperature lamination cycle not achievable in conventional lamination presses. The fabricator can avoid this poor processibility by using a low-temperature adhesive, but this can lead to serious compromises with electrical and thermal properties of the laminate. The second major difficulty in processing PTFE is the hydrophobic nature of the material. This makes it difficult to clean and metallize the holes. Generally, plating must be immediately preceded by a special fluoride etch, TETRA-ETCH, that activates the hole wall and enhances wetting. As an alternative, some PTFE systems can be activated in plasma etch; however, this does not work with all PTFE materials.
- **High CTE** PTFE maintains full strength up to and above solder temperature. When this strength is combined with a high CTE, PTH reliability is a serious concern. This is a particular problem with glass-reinforced PTFE, where the x-y constraint of the glass magnifies the out-of-plane expansion. A second problem attributable to high CTE is excessive warpage whenever Teflon is combined with epoxy based laminate in an unbalanced hybrid structure.
- **Cost** PTFE-based laminates are often 100 times more expensive than epoxy-based laminates. This makes it difficult to justify the use of PTFE if any alternative exists.

At least three types of laminate systems are available with PTFE resin:

- **PTFE resin coated on a conventional glass mat** Although the construction of this laminate is most like standard FR-4, it is not recommended for ML-PWB applications. The large CTE of PTFE coupled with the in-plane strength of the glass reinforcement leads to a very high out-of-plane expansion that can easily fracture a plated hole during soldering. In addition, the glass cloth raises the  $D_k$  of the composite. This material is commonly used in applications such as antennas or RF microstrip cables, where the circuit is placed on one side of the substrate and a ground plane on the other. Plated holes are not needed, and a very low  $D_k$  is not critical.
- **Expanded PTFE film impregnated with cyanate ester or epoxy resin** This material has no glass cloth reinforcement. The resulting increase in in-plane CTE reduces the out-of-plane expansion, allowing the reliable use of plated holes. Although the non-PTFE resin

impregnating the PTFE film increases  $D_k$  and  $\tan \delta$  over those of a pure PTFE layer, this composite is at least as good as glass-reinforced PTFE. Because of the conventional resin surface of this material, it can be laminated using conventional methods and materials, allowing the fabrication of ML-PWBs containing a mixture of PTFE and epoxy layers. The resulting hybrid board can contain any symmetrical mix of epoxy and PTFE layers. The high in-plane CTE of the PTFE layer leads to severe warp in any nonsymmetrical stack-up. Hybrid boards are less expensive than pure PTFE boards because they are laminated in a conventional press and they minimize the use of costly PTFE layers. However, the high cost of PTFE and the need for a fluoride etch still makes these boards expensive. The major application for this material is in supercomputer designs that have high-speed circuits requiring enhanced electrical properties mixed with others that operate on FR-4. This approach does not work in applications where a mixture of RF signals and digital logic requires a nonsymmetrical design with low-loss material on one side and standard material on the other.

- **PTFE mixed with a low- $D_k$  ceramic** A third approach, in which up to 60 percent ceramic (by weight) is combined with PTFE resin, results in a very interesting material. This material has a low CTE, low  $\tan \delta$ , and low  $D_k$ , and, by a proper choice of the ceramic, it is possible to have an in-plane CTE that matches that of epoxy. This allows the fabrication of an unbalanced hybrid structure without excessive warp. The high ceramic loading typical of this material minimizes PTFE use and reduces costs. A commercial version of this material is available with a cost in the range of four to five times that of standard FR-4, rather than the 100 times typical of other PTFE options. The only serious drawback of this material is the use of a special process such as plasma etch to ensure hole wall wetting. Success has been reported with using  $H_2$  or He mixed with  $O_2$  to activate the hole for plating.

**27.2.3.5 Materials with Enhanced Mechanical or Conduction Properties.** In cases where the device package (leadless area array with ball grids) is incompatible with the CTE of a standard material, a low-expansion substrate must be used. This can be achieved in several ways. In the past, leadless surface-mount technology (SMT) focused on replacing the woven glass in standard FR-4 with woven quartz or aramid fibers. Although this reduced the expansion of the substrate, both materials were expensive and difficult to process.

**27.2.3.5.1 Aramid.** A better solution for CTE match is to use a non-woven aramid mat material that is resin-impregnated; it is available with either modified epoxy or polyimide resins. Non-woven aramid has lower in-plane expansion under heat input, and is closer to the in-plane expansion of leadless ceramic chip carriers (LCCCs) or thin small outline packages (TSOPs). A low in-plane expansion reduces the strain on the solder joint, which in turn improves assembly yields and long-term field reliability.

As a random fiber, it also provides a more consistent environment for high-frequency signals since the material under the signal at any point along its length has the same effective dielectric constant. (Woven fiberglass-reinforced laminates impart discontinuous effective dielectric constant along the length of the conductor varying between the resin-rich and glass-dominant sections of the laminate.) In addition, the interface with the bottom of the conductor is smoother, reducing attenuation of the copper trace. The aramid layer is usually only the outermost layer where the chip is attached, whereas the balance of the layers consists of standard fiber-glass reinforced materials. Aramid-reinforced materials process much like traditional FR-4 and are compatible for mixed dielectric constructions. This material is also very compatible with laser drilling.

There are trades-offs to consider with aramid. The total thickness of the board is usually kept low, since the aramid has a high out-of-plane or z-axis expansion. Typically, a thickness of at least 0.015 in. is needed to offset the effective x-y CTE of the balance of the MLB, which in turn means that outerlayer line widths are wider for a 50-ohm impedance. Also to be considered is the lower copper peel strength and high moisture uptake.

*27.2.3.5.2 Carbon Composite Laminates.* Another past approach was to laminate a low-expansion metal such as Invar into the ML-PWB. The Invar plane could double as a heat sink or a power/ground plane. This approach, however, added much weight and thickness to the product and is in limited use.

New materials such as STABLCOR<sup>8</sup> are thinner and lighter. Epoxy glass systems have a thermal conductivity of approximately 0.3 W/m<sup>2</sup>K; the conductivity of copper is approximately 385 W/m<sup>2</sup>K; STABLCOR has products with a 325 and a 650 W/m<sup>2</sup>K conductivity capability. Carbon composite laminate has a very low negative CTE, approximately -1.10 ppm/°C, so it contracts very slightly as temperature rises. The user can tailor the surface CTE of a standard ML-PWB from 3 to 12 ppm/°C. With a very high tensile modulus of elasticity, this material adds considerable rigidity for applications needing high stiffness.

The material is used typically as a ground (GND) plane in the circuit. If 1 GND is used it must be in the center. If two are used then they do not need to be in the center, but they must be symmetrical within the stackup. Three can be used if one is in the center and the other two are symmetrical in relation to each other, and so forth, with even GNDs symmetrically placed and the last (odd) GND in the center. This does add height to the circuit. Also the  $D_k$  is higher at 13.36, but since the usage is as GND, that does not negatively affect the electrical performance of the circuit.

Holes not connected to the GND must be predrilled and back-filled to provide clearance from the plane (which is entirely conductive, as opposed to laminate cores, which are conductive only on the foil surfaces). The extra processing, extra layers, and cost of the material make this a specialty solution for specific applications needing high heat dissipation or very low CTE or very high stiffness.

## 27.2.4 Materials Summary

Material properties affect PWB operation in important ways. The preceding discussion focused on thermal and electrical properties. The use of small, high-aspect-ratio holes, thick boards, and high-power devices drives the need for materials with improved thermal properties. The transition to LFA requires materials with high thermal stability. Similarly, the use of high-speed devices, including the RF circuits in wireless applications, drives the need for improved electrical performance. Materials exist with improved properties, but the ideal material that combines low cost with improved thermal and electrical properties does not exist. Therefore, the designer must consider the needs of each design before selecting a cost-effective material.

The need for improved thermal properties includes a material with high  $T_g$ , low CTE, high thermal decomposition temperature, long time to delamination, and low moisture absorption. Polyimide meets the first four needs at the expense of increased moisture absorption and high cost. BT satisfies all these needs, but cost remains an issue. The most economical solutions are the multifunctional epoxies and the epoxy-PPO blends. Multifunctional epoxies are relatively inexpensive, provide a significant improvement in  $T_g$ , and, in some cases, provide small improvements in thermal degradation temperature and moisture absorption. The PPO blends provide significant improvement in all areas at a slightly higher cost. If moisture absorption is an issue, the PPO blend may be the best choice. For LFA the “RoHS-compliant” formulations may be necessary.

Both BT and PPO-epoxy boards provide small improvements in electrical properties. If the real need is to reduce  $D_k$  so that the board thickness can be reduced, these materials may be useful. However, if dielectric loss is a serious problem, the only real solution is to use PTFE. Unfortunately, PTFE is very expensive and difficult to process, so it should be specified only where absolutely necessary. For example, RF circuits will nearly always require PTFE.

The ceramic-PTFE blends used in a hybrid construction may be the most cost-effective solution for these applications.

## 27.3 MULTILAYER CONSTRUCTION TYPES

The construction of the rigid multilayer ML-PWB can take on many variations. To help categorize the various constructions, the IPC has developed industry PWB design specifications, defining them by class and type. Grouping the ML-PWB into categories facilitates the ability of designers and fabricators to communicate using a common format.

### 27.3.1 IPC Classifications

IPC classifications specify generic PBC design and rigid organic printed board structure.

**27.3.1.1 IPC-2221: Generic Standard on Printed Board Design.** There are many ML-PWB structures. This section discusses the methods and materials for the basic and several of the advanced structures. The IPC has two comprehensive standards for the design of rigid printed circuits, IPC-2222 and IPC-2226. The classification system within these standards for the ML-PWB by structure is shown. The distinction between the two is the focus on microvias in the later standard.

**27.3.1.2 IPC-2222: Rigid Organic Printed Board Structure Design.** This standard covers products with conventional feature sizes:

- **Type 3** This is a multilayer board without blind or buried vias (see Fig. 27.4)
- **Type 4** This is a multilayer board with blind and/or buried vias (see Fig. 27.5)

**FIGURE 27.4** Type 3 (eight-layer ML-PWB) multilayer board without blind or buried vias.

**FIGURE 27.5** Type 4 (eight-layer-B/V MLPWB) multilayer board with buried vias.

**FIGURE 27.6** Type I (six-layer HDI MLPWB) high-density multilayer board with blind vias from top and bottom layers and through vias connecting the outerlayers.

**FIGURE 27.7** Type II (six-layer HDI MLPWB) high-density multilayer board with vias as well as buried vias in the core and through vias connecting the outerlayers.

**FIGURE 27.8** Type III (eight-layer HDI MLPWB) high-density multilayer board with blind vias as well as buried vias in the core and through vias connecting the outerlayers.

### 27.3.1.3 IPC-2226: Design Standard for High-Density Interconnect (HDI) Printed Boards.

This covers products with high-density feature sizes:

- **Type I** 1[C]0 or 1[C]1 has through vias connecting the outerlayers (see Fig. 27.6).
- **Type II** 1[C]0 or 1[C]1 has buried vias in the core and may have through vias connecting the outerlayers (see Fig. 27.7).
- **Type III** >2[C]>0 may have buried vias in the core and may have through vias connecting the outerlayers (see Fig. 27.8).

## 27.3.2 Basic Type 3 ML-PWB Stack-Ups

The type 3 construction can be said to be the most basic of PWB multilayer technologies. An ML-PWB is fabricated by the bonding (laminating) of copper-clad details consisting of imaged and etched laminates (typically double-sided). The bonding medium, known as prepreg, is a B-staged (partially cured) reinforced resin. The imaged details consist of C-staged (fully cured) laminate. These material components are arranged by layering according to the design documentation. This layering method in fabrication, known as the stack-up, follows the layer numbering order of the design. The stack-up formation method is often loosely defined in the design documentation; therefore, a good understanding of the lamination options is necessary. The lamination options described in this discussion refer to methods used to form the outerlayers and to form layer pairs. The material resin system should be defined on the design documentation. Refer to IPC-2221/2222 for minimum suggested design documentation requirements.

**FIGURE 27.9** Foil outer stack-up (eight-layer ML-PWB), a typical stack-up for a foil board.

The basic ML-PWB stack-up can be constructed with two options to produce the outerlayers and to form layer pairs. A third option that employs single-sided “capped” clads is rarely used and is not discussed. Often, in the case of designs having an odd number of layers, a combination of these methods is employed. The following three-layer stack-up methods are discussed:

- **Foil outerlayer construction (foil outer)** In this stack-up, the outerlayers are formed by using a sheet of copper foil per side.
- **Clad outerlayer construction (clad outer)** A clad detail provides the copper for the outerlayer.
- **Odd-layer construction** This stack-up method balances a construction consisting of an odd number of layers.

**27.3.2.1 Foil Outer Stack-Up.** A board produced with copper foil outers is fabricated from one or more patterned innerlayer details and two copper sheets. The copper sheets form the outerlayers of the fabricated ML-PWB. This stack-up is the least expensive way to fabricate an ML-PWB and is by far the most popular design option. Figure 27.9 shows a typical stack-up for a foil outer board consisting of eight layers.

The stack-up shown contains three imaged clad details bonded with two sheets of prepreg at each opening and having two sheets of copper foil on the outside. When possible, the higher resin content prepreg ply should face the signal layer side. This is especially important when the signal is a heavyweight copper (2 oz. or more). The copper layers, numbered from L1 to L8, begin with the top foil layer (typically called the primary side). In the design pictured, the layers L2, L4, L5, and L7 represent signal layers. Layers L3 and L6 represent power/ground layers. When the final imaged patterned is produced, it can provide another signal layer pair or a set of ground layers, or a “pads-only” pattern to support

vias and component holes, as well as the device footprints of the electrical components and their associated fan-out patterns. Some of the advantages of this bonding method are:

- **Lower raw material cost** Loose sheet copper foil and prepreg sheets are more economical than clad laminate.
- **Lower consumable material cost** The reduction in imaging resist and chemistry results in a cost savings.
- **Lower labor cost** The reductions in material handling and in the processes of imaging and pre-lamination result in less total labor.

**27.3.2.2 Clad Outer Stack-Up.** Figure 27.10 depicts the same eight-layer design as Fig. 27.9, except the outerlayers are formed with a clad laminate. This stack-up arrangement requires four clad details, as compared to only three for the foil-stacked board shown in Fig. 27.9. This makes the clad outer board more expensive than the more commonly used foil outer construction.

However, the clad outer design has one less B-stage opening and no copper foil. In addition, the clad outer boards are patterned on only one side prior to lamination. These factors partially offset the higher cost of this design. In Fig. 27.10, notice how the layer pairs have changed position placement. Layers L3 and L6 are now paired with a signal layer, which may

be advantageous for controlling the dielectric thickness. See Sec. 27.3.3 for a discussion on controlled impedance. Some of the advantages of using the clad outer bonding method include:

- **Improved surface topography** When surface flatness is critical, the clad outer construction provides a smoother surface. When a signal layer of heavyweight copper is the first layer down, it is possible for weave texture imprinting to occur. This topography condition, sometimes referred to as “telegraphing,” can sometimes imprint the circuit pattern when using a foil build-up.
- **Improved handling** Depending on the layer pairing, sometimes additional copper can be retained, as in a case where a signal-to-signal imaged detail can be avoided. This is mostly the case when the layer pair details are being produced on very thin core laminate.
- **Improved dielectric thickness control** Sometimes, it is necessary to control the thickness at a specific layer pair tightly. This could be due to high-voltage considerations or to aid in the precision spacing of a signal plane to a ground plane where controlled impedance is necessary. This is possible because the C-staged (fully cured) clad laminate typically has an improved thickness tolerance.

The chief disadvantage with a clad outer layer design is in the potential for lower yield. This is because the external copper foil must be protected by the image mask during all the internal layer image, etch, strip, and oxide processing steps; then the mask must be removed at a later point in the process so that the external details can be fabricated. The potential exists to scratch the photomask during all the handling steps, which will result in shorts or opens (depending at which point in the process the scratch occurs).

**27.3.2.3 Odd-Layer Stack-Up.** Sometimes, due to signal routing or the need to have a greater dielectric space, an odd-layer circuit is formed. Similar in characteristics to the clad stack-up, the odd-layer construction technique employs a non-imaged single-sided clad laminate. Material can be procured with a single side, but a warning is associated with its use due to a lack of bondability. When this material is manufactured at the laminator supplier with only copper on one side, a release sheet is used against the non-copper side. The release sheet produces a slick, smooth surface. The non-copper surface thus requires an aggressive surface preparation to promote bondability. One alternative to gain the same benefit of the single-sided clad is to etch the copper off one side of a double-sided clad. The etched side becomes the bond surface, which has greater adhesion due to the copper tooth imprint left behind. See Fig. 27.11 for an example of a balanced odd-layer construction.

**FIGURE 27.10** Clad outer stack-up (eight layer ML-PWB) multilayer board design with the out-erlayers formed with a clad laminate.

**FIGURE 27.11** Odd-layer clad stack-up (five-layer ML-PWB), an example of a balanced odd-layer construction.

Some of the uses of the single-sided odd-layer stack-up are:

- **Odd-layer construction option** The single-sided construction technique allows an opportunity to supply a layer for circuit designs having an odd layer count.
- **Odd-layer core balance** One of the problems associated with a build-up of odd-layer circuits is the ability to maintain a balanced construction of the cores. Depending on the overall design thickness and layer count, this can become a major concern to reduce warping. Figure 27.11 depicts an example of an odd-layer stack-up with three equal core thicknesses.

### 27.3.3 Controlled-Impedance Stack-Up

The number of ML-PWBs containing controlled impedance signals is significant. The signal lines in an ML-PWB have a characteristic impedance value expressed in ohms ( $\Omega$ ). Active devices, connectors, and transmission lines also have characteristic impedance. In a high-speed circuit environment (typically starting at 2 to 3 MHz and above), if the signal energy is reflected rather than transmitted, the signal impedance mismatch is known to have discontinuity. This means that, to avoid signal losses due to reflections, all impedance characteristics must be matched. The physical relationship between a signal line and the surrounding power/ground layers determines the impedance of that signal line.

The controlled-impedance stack-up requires specific manufacturing discipline that must be adhered to in order to maintain the integrity of the designed circuit. An ML-PWB design requiring a controlled-impedance fabrication for a design for manufacturing (DFM) discussion between the designer and manufacturer in order to avoid producibility traps and induced error. Several resources are available to assist in developing the proper manufacturing parameters to ensure that the product meets the specified tolerance. IPC-2141, "Controlled Impedance Circuit Boards and High Speed Logic Design," and IPC-317, "Design Guidelines for Electronic Packaging Utilizing High-Speed Techniques," are two of the industry standard documents that contain formulas and examples of various impedance configurations.

Typical producible process tolerances for common impedance values are as follows:

- 50  $\Omega$  traces typically have a tolerance around 5 to 7 percent.
- 75  $\Omega$  traces typically have a tolerance around 12 to 15 percent.
- 100  $\Omega$  traces typically have a tolerance around 17 to 20 percent.

When tolerances are required to be tighter than this, it places more significance on the stack-up and etch of the circuit. The design requirement should be clearly specified in the ML-PWB documentation. The preferred way to specify an impedance requirement is in a drawing note rather than by applying dimensional boundaries. Firm dimensional boundaries do not allow the manufacturer freedom to meet the end requirement based on process knowledge.

It is recommended that during the design process software modeling be performed and then confirmed with the manufacturer before fabrication. Several excellent simulation software tools are available commercially. Some also exist as freeware and shareware. However, it is best to

FIGURE 27.12 Example of impedance test coupon design and layout.

confirm the models' predicted values by actual process verification. The most versatile method of verification is with a test coupon. The test coupon should accurately represent the construction configuration of the stack-up, except it requires a few special prerequisites in order to yield reliable test data. Figure 27.12 shows a typical impedance test coupon stack-up. Note that the signal reference planes of the coupon are shorted together. Also, the simulated signal line is isolated and open-ended; the signal lines are usually at least 6 in. long. The footprint of the coupon via holes that feed through to the surface should be verified to match to the spacing of the time domain reflectometry (TDR) instrument probe. This will reduce the risk of rendering the specimen not testable or necessitating the use of expensive adjustable probes. The IPC test method IPC-TM-650 2.5.5.7 contains suggested spacing, but it is best to confirm this with the manufacturer's preference. Examples of some common impedance types are shown in Fig. 27.13.

The factors most influential on characteristic impedance are:

- **Dielectric separation (H)** The separation of the signal line between the reference planes has a significant influence on characteristic impedance. The variability of the dielectric layering must be reduced to minimize the effect on tolerance. This is where stack-up selection becomes critical when determining whether the signal-to-plane opening will be made with a clad laminate or within the bondable area of the B-staged (prepreg) resin. This is also where glass

FIGURE 27.13 Examples of common impedance stacks.

style selection becomes important. The glass style and subsequent resin content will have different effects on the nominal thickness obtained.

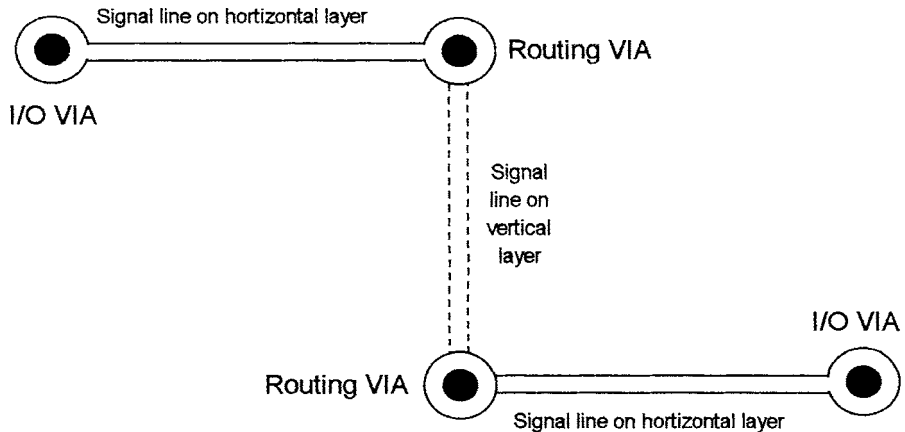

- **Conductor width (W)** The finished width of the conductor can produce variance, which is likely to occur from lot to lot. Therefore, process control measures are necessary when producing controlled impedance circuits. The density of neighboring circuits will have an effect on the final etch. Often it is advantageous to modify the artwork line width at phototool generation for predicted variance.
- **Dielectric constant ( $D_k$ )** Choosing a laminate resin system with a consistent dielectric constant has an influence on characteristic impedance over higher frequencies. The influence of dielectric constant becomes most critical when the ML-PWB design is a high-layer-count design. The lower the  $D_k$  value of the resin system, the thinner the overall board can be. Typically, the manufacturer has little opportunity to affect the dielectric constant, because the material type is specified by the design. Here, it is important that the designer/manufacturer know the  $D_k$  value range of the laminate supplier's resin system. Caution: Do not use the  $D_k$  value of the neat resin, but that of the composite laminate, which will vary somewhat with glass style. This is sometimes referred to as effective  $D_k$  (Eff  $D_k$ ).
- **Conductor thickness (T)** The conductor thickness or copper weight can also affect the final impedance value. Here, as with conductor width, manufacturing process variations can have an inverse effect on the precision of the impedance value. Some modern software simulation tools, such as those from Polar Instruments, Inc., allow values for conductor profile (area) to be included in the simulation. This is more significant when lines are of heavy copper. It is best to avoid routing of impedance lines on plated subcores due to the added variability.

For external impedance tracks and internal plated-up tracks such as on subcores, autothieving patterns will minimize large variations in plating height between tracks in dense areas and those in uncongested areas. This will increase the fabricator's ability to produce impedance values consistently within a smaller range.

### 27.3.4 Sequential Laminations

When a design includes buried and/or blind vias, it typically requires a set of sequential lamination and plating cycles. These technologies are defined in the industry design standard IPC-2221/2222 and are known as Type 4 ML-PWBs. These build types, when employing industry standard feature sizes, are mature in the industry. Complementing technologies, employing use of sequential processes for ML-PWB designs containing microvias less than 0.15 mm, are considered as build-up technologies. The terminology of build-up technologies encompasses many design stack-up variations; they can take on many forms and employ a multitude of methods. The build-up technologies defined in IPC-2315 and IPC-2221/2226 include categories named Type I, II, III, IV, V, and VI. The advanced build-up technologies use the materials found in IPC-4104. These include materials for layer forming, dielectric insulation, and interconnectivity. Included are photo-imageable and non-photo-imageable materials (liquid, paste, or dry-film nonreinforced dielectric); adhesive-coated dielectrics (reinforced and nonreinforced); and conductive foils and paste (coated and non-coated, photo-imageable). For a detailed discussion of these processes, see Chap. 22 and 23. This discussion will limit itself to addressing processes for standard technology Type 4 and advanced technology build-up Types I, II, and III, which can be manufactured with conventional processes.

**27.3.4.1 The Buried Via Stack-Up.** To avoid hopelessly complex routing, each signal net is generally routed using only one pair of layers with what is called *Manhattan geometry*. This means that diagonal routing is avoided and all signal lines run in a horizontal or a vertical direction. To avoid blockage and side-to-side cross-talk problems, horizontal lines are run on

**FIGURE 27.14** An example of a net routing using Manhattan geometry.

one layer and vertical lines on the other. This means that, in addition to a via at each end of the net (I/O via), most nets need one or two additional vias (routing vias) to change direction from horizontal to vertical. Figure 27.14 shows an example of Manhattan geometry.

The net shown in Fig. 27.14 has two I/O vias and two routing vias. The I/O vias connect the signal lines to the board surface, where the net connects to an input or output point of an active circuit. The routing vias are used to change directions from horizontal to vertical. With through-hole vias, the routing vias pass through all layers, consuming valuable routing space. A high-layer-count board with many signal layer pairs can run out of via sites. In this case, additional layers will not improve routing completion and the board is said to be via-starved. One solution to a via-starved board is to use buried vias. The buried via connects two adjacent signal layers and provides routing vias without affecting routing on other layers. Figure 27.15 shows an eight-layer board with two buried via layers.

Buried vias do not pass through the board, so they do not congest the routing on other layers. In addition, the same via site can be used simultaneously on different layer pairs. Since buried vias are drilled and plated in the thin laminate prior to lamination, they can be very small and positioned very accurately, saving additional routing space. In some applications, buried vias are placed where needed with no reference to a predetermined grid. This gridless routing approach gives very high computer-aided design (CAD) autoroute completion.

To benefit from buried vias, signal layer pairs must be routed on opposite sides of the same C-stage component. In Fig. 27.15, L4 and L5 are the only buried via candidates. In Fig. 27.10, no signal layers can benefit from buried vias. The design shown in Fig. 27.15 is able to use buried vias on two layer pairs because a power/ground layer pair separates them. In non-buried via designs, it is best to use one power/ground plane between each signal layer pair. This gives cross-talk isolation and impedance reference. A buried via design uses a second redundant layer to force the next signal layer pair onto the same imaged detail. In other words, for a high-layer-count design to use buried vias on all signal layer pairs, power/ground plane pairs must be inserted between each signal layer pair. This increases the number of layers in the board and increases cost. Another disadvantage of buried vias is the cost associated with the extra drilling and plating operations.

**27.3.4.2 The Blind Via Stack-Up.** Another via option is the blind via, which connects the surface layer to one or more internal layers but does not go through the board to the opposite outside layer. Figure 27.16 shows an example of an eight-layer ML-PWB with both blind and

**FIGURE 27.15** Type 4 (eight-layer B/V ML-PWB), an eight-layer board with two buried via layers.

**FIGURE 27.16** Type 4 (eight-layer blind and buried via ML-PWB). The design contains buried vias connecting L5 and L6. Blind vias connect layers L1 and L2.

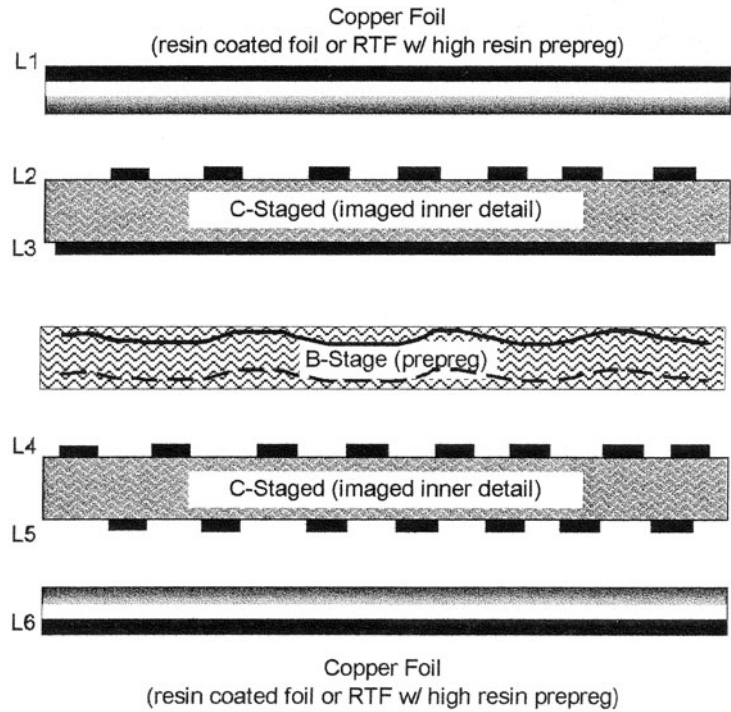

buried via. The design shown in Fig. 27.16 contains buried vias connecting L5 and L6. Blind vias connect layers L1 and L2. The buried vias can be fabricated in layer details as described earlier or can be fabricated by blind drilling. Blind vias may become very important in very dense double-sided surface-mount designs that have interference between I/O vias from opposite sides on the board. If this is particularly troublesome, a via-in-pad (VIP) approach or dog-bone escape pattern is used. The VIP approach places a blind hole directly in the device I/O pad. The dog-bone approach places a blind hole in an adjacent pad next to the solderable land.

A second application for buried vias is to ensure complete side-to-side electrical isolation. This is particularly important in wireless designs where the RF circuits must be shielded from other circuits. Through vias allow RF electric fields to escape from a shielded region. A blind via eliminates this problem and allows RF functions to be combined with logic and control functions on the same board.

The ultimate use of blind vias is effectively to convert a dense double-sided surface-mount design to a pair of less-dense single-sided surface-mount designs. To see how this is possible, visualize an ML-PWB with fine-pitch SMDs on both sides as two separate boards with some level of side-to-side interconnection. If the board is manufactured as two separate subassemblies, the I/O connections on one side will not interfere with the I/O connections on the opposite side. For example, consider a 16-layer board fabricated as two 8-layer subassemblies. The subassemblies are laminated, drilled, plated, and patterned like a standard ML-PWB, with the exception that the sides that will become the board exterior are blanket-metallized. After patterning, the two subassemblies are laminated together and then processed as a standard ML-PWB. This process is another form of sequential lamination. The only through holes required in this design are the relatively few that provide side-to-side interconnection. Since each via site is used twice, a 100 mil. grid may replace a 50 mil. grid, providing a significant increase in innerlayer routing resources. This type of ML-PWB structure is very costly and has mostly been replaced with the routing features of the high-density design.

**27.3.4.3 The High-Density Stack-Up.** The buried via stack-up design came about for a solution to gain signal routability when CAD routing solutions were pressed to the limit. Early on, Type 4 designs were considered specialty products and utilized standard-feature-size characteristics. With the advent of more sophisticated CAD routing tools, it became possible to auto-route with greater efficiency, sometimes avoiding the necessity and cost of buried vias. Soon high-I/O, full-matrix components created new interconnectivity demands. Today buried via sections defined as cores in IPC-2221/2226 are used for the central starting point of manufacture, and then build-up layers are applied to complete the design as an HDI structure. As noted earlier, the common discriminator that separates the high-density design from a conventional Type 4 is mainly the feature size. For example, the HDI Type II, as shown in Fig. 27.7, uses a conventionally processed ML-PWB Type 3 board as the core (L2 to L5) and the PTHs become buried after the high-density features of L1 and L6 are added. Microvias are used to form a connection to L2 and L5; then through holes are formed to tie L1 through L6. The microvias and holes are now metallized in one cycle. The build-up layers in the example use thin dielectrics to provide a close proximity to the adjacent layer. This is required to accommodate the microvia connection and maintain producibility for metallization.

Figures 27.17 to 27.19 show a comparison of the HDI build-ups for Types I, II, and III. In each case, complexity is added by building add-on layers sequentially. The build-up layers are typically for signal routing and contain low copper weight. Dielectric-coated (nonreinforced) microfoils (as thin as 9 to 12  $\mu\text{m}$ ) are employed to provide a low-profile thickness after copper plating. This is needed to facilitate the image of fine-line widths typically associated with HDI. These styles of circuits offer some economy through use of a variety of dielectrics. The use and style of construction type must be matched with the product's expected application environment and operating life. Often the need for CTE match of area array components compels the application of a non-woven aramid layer at the surface. The resin system selection should be based on the expected CTE mismatch concerns, such as when a ceramic device is surface-mounted to the assembly. Thermal cycling of power on and off can cause earlier failure when a large mismatch is present.

**FIGURE 27.17** Type I (six-layer HDI stack-up) shows one example of how to stack up an ML-PWB with HDI features.

**FIGURE 27.18** Type II six-layer stack-up having at its core a four-layer board with through holes, which later become buried.

**FIGURE 27.19** Diagram showing how an HDI Type III (eight-layer HDI stack-up) might be produced employing conventional lamination techniques.

Manufacturing capability becomes critical when targeting HDI features. The IPC has taken the responsibility of developing industry standards to assist in benchmarking and quantifying capability limits. Manufacturing features such as imaging, etching, hole formation, plating, and lamination registration are all strained and must be optimized. Other processes that are equally challenged are the end-product continuity testing to access the high-density features.

**27.3.4.3.1 HDI Type I Stack-Up.** Figure 27.17 shows one example of how to stack up an ML-PWB with HDI features. The economies of this design are obvious because it requires only one lamination cycle. The density push in this level of HDI focuses on imaging and microvia routing. By routing at a high circuit density, the surface area of the board is better utilized. The outerlayers are typically formed with a low height dielectric. When utilizing conventional lamination, this is usually a resin-coated foil or a microfoil bonded with a high-flow non-woven aramid prepreg. Special non-woven series of aramid fiber laminates have been developed to yield an equivalent dielectric thickness of 1.9 mil.

Special handling is required for the microfoils, which are usually 9 to 12  $\mu\text{m}$  thick. To facilitate handling, a sacrificial carrier foil is sometimes cohered to the microfoil externally for added stiffness. After lamination, one option is to process the microvias through laser drilling and conventional through-hole drilling. Sometimes a clad outer construction may be best, depending on the laser technology chosen. For example, infrared (IR) ( $\text{CO}_2$ ) laser ablation using an etched mask (small etched openings the size of the via) in the outer copper can be performed at primary print. This process helps reduce possible misregistration error. One metallization cycle is required to tie in all vias electrically. This reduces costs compared to sequential cycles.

**27.3.4.3.2 HDI Type II Stack-Up.** Density demands, when not met by the single lamination approach of Type I, must then address the use of sequential processing when employing standard ML-PWB techniques. The Type II stack-up shown in Fig. 27.18 has at its core a four-layer board with through holes, which later become buried.

**27.3.4.3.3 HDI Type III Stack-Up.** The use of a Type III structure may be employed when routing densities are greatly pressed. At this point of complexity and above, alternative

HDI approaches should be investigated because of the extra cost associated with performing repetitive cycles with conventional ML-PWB processes. Alternatives to lamination provide build-up of the dielectric and conductive layering through other means. These should be discussed with the manufacturer prior to selection. It is important to remember that the manufacturing method related to fabrication can have a great impact on the design rules chosen at CAD layout. Figure 27.19 represents how an HDI Type III might be produced employing conventional lamination techniques. Here, the core substrate is a four-layer ML-PWB detail similar to the Type II starting construction discussed earlier. Processing for the first pair of build-up layers follows the processing analogy of the Type II structure. Here, as in other foil laminated build-ups, the starting copper thickness should be kept to a minimum. Plating uniformity becomes critical when attempting to image/etch high-density features. After L2 and L7 have been defined, the final copper layer pair (L1 and L8) is laminated. At this final build-up, since no through holes are present, the flow of the resin-coated foil or prepreg should be sufficient to fill the microvias and flush the circuits. Once the additional layer is laminated, another level of microvias may be produced.

### 27.3.5 Filled-Via Processing and Sequential Laminations

The requirement to fill vias is driven most often by routing density. When high-density-area array components are utilized, the quantity of vias per square inch greatly increases in the local area under the device. Buried vias or blind vias are frequently the solutions to through-via starvation.

Buried vias, unless otherwise prefilled, will fill with resin during final lamination. The volume of resin necessary to fill the buried vias is dependent on the diameter, length, and total quantity. Buried vias might straddle a single core, or might interconnect several cores and dielectric separations in a sub-lamination section. If there is insufficient resin in the prepreg to fill the buried vias, those vias can starve bonding resin from the local area where they are concentrated. To prevent the prepreg resin from entering the buried hole, the fabricator often is required to prefill the vias prior to a build-up lamination with a resin or paste formulation. Other design constructions require blind vias that are planar and within the land pattern at the surface mount attachment locations. These VIP structures free up real estate on the component attachment surfaces and provide enhanced signal integrity at high frequencies. Prefilling internal buried vias or blind VIPs with a hole-fill resin can provide a more robust interconnect structure, improved lamination integrity, and a planar surface in the case of the blind vias.

**27.3.5.1 Fill Materials.** Since the fill material is an additional fabrication material that becomes a part of the design construction, procurement documentation is required to specify a fill material type and thereby implement the via fill process. The selection and documentation of the fill material require the same consideration as the base laminate preference. This is especially critical when targeting a lead-free-compatible process. Currently, an industry-based material specification for via fill material does not exist. Therefore, specific fill-material brands may be named on the drawing, or some other form of user/supplier agreement must be established. The fabricator has preferences for the type of material used for via fill. Just as suppliers often have preferences for a specific solder mask brand, they also often prefer to use of a specific via fill material around which they have developed their principal processes. Supplier preferences can be driven by specific via fill material characteristics, such as accessibility, equipment compatibility, process supportability, plateability, and/or shelf/pot life. This may complicate source selection, or it might influence the use of a dedicated service center for the hole-fill process. The fabricator may not always know the reliability of its preferred material for a given via structure or end-use environment.

Determining the properties of the various fill materials may be difficult for the user. Obtaining properties from the material suppliers' data sheets may be possible for some properties, whereas others are more difficult to obtain; for example, many manufacturers' data

**TABLE 27.4** Common Via Fill Manufacturers and Material Properties

Mgf. (Link)	Type	Material <sup>3</sup> (part number)	Pencil Hardness	Color & Plateability	Thermal conductivity (W/m/°K)	T <sub>g</sub> °C	CTE under T <sub>g</sub> (ppm)	CTE over T <sub>g</sub> (ppm)

*Notes:* Some via fill materials are not typically compatible with permanganate chemical processing. Confirm with the specific supplier before using. The denotation of N/A indicates that the data were not readily available.

<sup>1</sup>Compatible with Plasma desmear, requires electroless followed by electrolytic processing.

<sup>2</sup>Compatible with Plasma desmear, conventional electroless recommended but may be use direct electrolytic processing.

<sup>3</sup>Capability with a lead-free profile should be verified; typically the higher T<sub>g</sub> materials with a lower ppm above T<sub>g</sub> will be more compatible.

sheets omit the modulus. Table 27.4 provides a cross-reference for some of the more common material types with properties available. Additional properties and performance data may also be found at the specific manufacturer web page.

**27.3.5.2 Concerns and Common Defects.** Concerns have been associated with filled-via structures arising from a lack of process maturity and the potential impact on reliability. These concerns include plating adhesion, air entrapment (voids) created during the filling operation, CTE mismatch with the bulk resin, and the risk of overplanarization to remove excess resin. Entrapped voids are suspected to have an effect on hole wall integrity due to outgassing; CTE expansion mismatch could have an adverse interaction with the material and copper CTE properties. Overplanarization can grind down the plated hole wall knee, weakening the interconnect at the barrel plate. This is commonly called a reduction in wrap copper. A lack of wrap copper will leave a butt joint at the interconnect that is vulnerable to pad rotation (lift) knee crack. Limited reliability data are available within the industry for these structures, yet they are being widely deployed. The performance criteria for the via fill method cannot be properly quantified for a definitive requirement without tangible reliability data. Additionally, to apply the most cost-effective via fill method with confidence, the fabricator must know the method's compatibility with the assembly process and targeted mission criteria. For all these reasons, qualification testing to the end-use environment with a preproduction build is recommended.

Designers need to be aware of potential processing issues associated with specifying via fill. Although the risks are becoming better known, the manufacturing issues are often difficult to detect from standard coupon analysis. Construction integrity weaknesses often are not found until latent defects occur or become revealed by aggressive thermal stress screening. Figure 27.20 is an example of a design employing conductive via fill within two via structures (blind and through holes) sharing a common surface layer. This example is free of plating interconnect defects; the buried structures are fabricated without an internal cap plate; the voids in the conductive fill are typical for this type of material.

**FIGURE 27.20** Micrograph of conductive via fill.

Figure 27.21 is a nonconductive fill with a close-up view of a micrograph illustrating the plating integrity and surface planarization that has maintained the wrap copper requirement. In this example, the full plating requirement was deposited without a separate button plate cycle. The wrap copper demarcation is noted and no separation has occurred at the cap plate.

Some common failure mechanisms, which illustrate the risk associated with fill technology, are shown in Fig. 27.22. Here, micrographs show a via fill with a lack of plating adhesion and wrap copper, allowing interconnect separation.

**FIGURE 27.21** Micrograph of a nonconductive via fill with good plating features.

**27.3.5.3 Via Fill Processing and Flow.** A via fill process flowchart can be used to communicate the modified steps of a typical manufacturing flow. Two process maps are shown to illustrate two typical process flow variables of a plated-cap versus nonplated-cap via fill process. Reliability testing to segregate the performance of via fill materials with the cap-plate and noncap-plate features in the selected application should be performed prior to selecting this design feature.

When a plated-over via is required, plateability of the fill material should be a chief consideration. Fabricators should screen for this compatibility across the various via fill materials

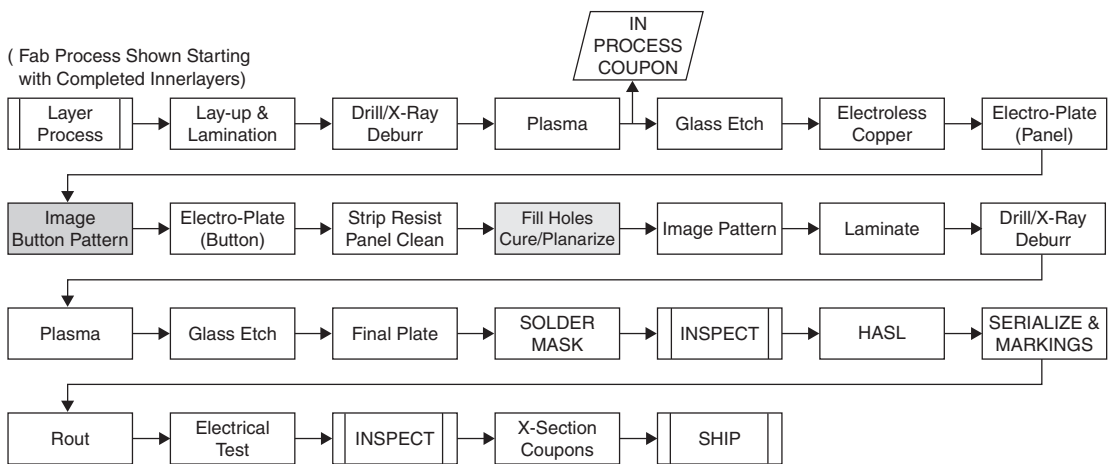

**FIGURE 27.22** Micrograph of a nonconductive via fill with defective features.

within their plating process to determine the integrity of the metalization. The flowcharts illustrate the fabrication methods employing a panel plate scheme. The flow could also be modified for a pattern plate methodology. The two process flows are illustrated in Figs. 27.23 and 27.24. The key via fill process steps are highlighted for clarity.

**27.3.5.3.1 Pre-Via-Fill Processing (Plating Variables).** The plateability of via fill material is an important feature to understand due to industry trends that have shown that plated caps may be problematic in some design constructions. Outgassing of the fill material may separate the metallization during sequential lamination or thermal stress. Poor adhesion can also contribute to a separation but typically can be screened with standard tape testing. Figure 27.25 illustrates a cap-plated buried structure and a micrograph showing a cap-plated via with separation occurring.

When the main design attribute is to limit resin from flowing into to holes at sequential, lamination, the plating over the filled structure may not be required. Here, the filled panel after planarization can be staged for lamination. Figure 27.26 illustrates a noncap-plated buried structure, and the micrograph shows a noncap-plated via with lamination separation occurring.

**FIGURE 27.23** Via fill flow in a noncap plate process (panel plate/button plate).

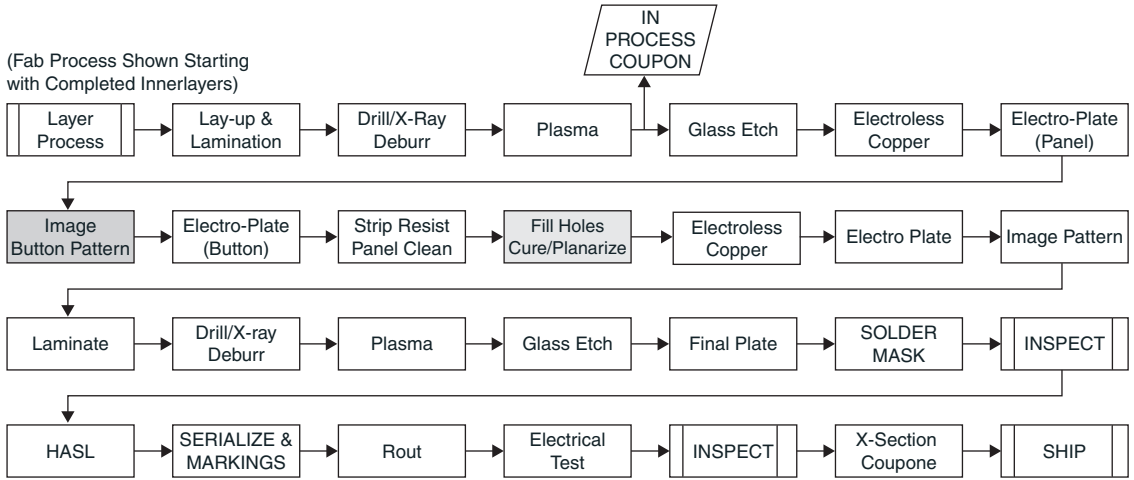

FIGURE 27.24 Via fill flow in a cap-plate process (button plate/panel plate).

FIGURE 27.25 Cap-plated filled structure.

FIGURE 27.26 Noncap-plated filled structure.

Each of these techniques requires the fabricator to understand the fill material compatibility with their base laminate system and plating processes. Typically, process compatibility can be screened with a simple solder-float thermal stress analysis and cross section.

Prior to plating, the fabricator must understand the ability of the fill material to accept the electrolytic process. Some via fill materials have been reported to not be compatible with permanganate chemistry commonly found in electroless copper lines. Some cases of early failure of the via fill cap-plating integrity have been traced to this process. Elimination of the programming step to process the board through permanganate will avoid this incompatibility. Plasma desmear is the generally recommended preplating preparation step. Some resin chemistries that are loaded with ceramic are susceptible to excessive surface roughening if the plasma is too aggressive as is typical in a full etchback cycle. This becomes problematic when secondary nonfilled plated vias are required and are processed with a full etchback cycle. In this instance, it is best to choose a nonceramic filled material or modify the drill sequence so they are protected. Typically, the conductive fill materials may be electroplated directly, omitting the electroless process. If the final surface plate has secondary drilled holes that require metallization, all features may be exposed to the electroless process anyway. If directly plating the material, the fabricator should characterize the material to confirm peel strength because some cases of plating separation have been traced to poor adhesion in direct plate applications. Therefore, when choosing a via fill material, it is best to develop a process map of the required via structure processing and understand the process sequence of when drilling, filling, and plating occur.

Figure 27.27 illustrates a typical manufacturing process targeting plating allowances for the successive plating steps prior to via filling. The first plating step establishes the minimum wrap plating requirement, and deposit thickness should be adjusted for the procurement specification and the balance of final plating. Here the substrate has a panel plate followed by a button plate. One advantage of the button plate is that it serves as a visual guide for the planarization removal process. Acting as a gauge, the button, when completely sanded off, indicates any additional sanding can be assumed to reduce the wrap plating.

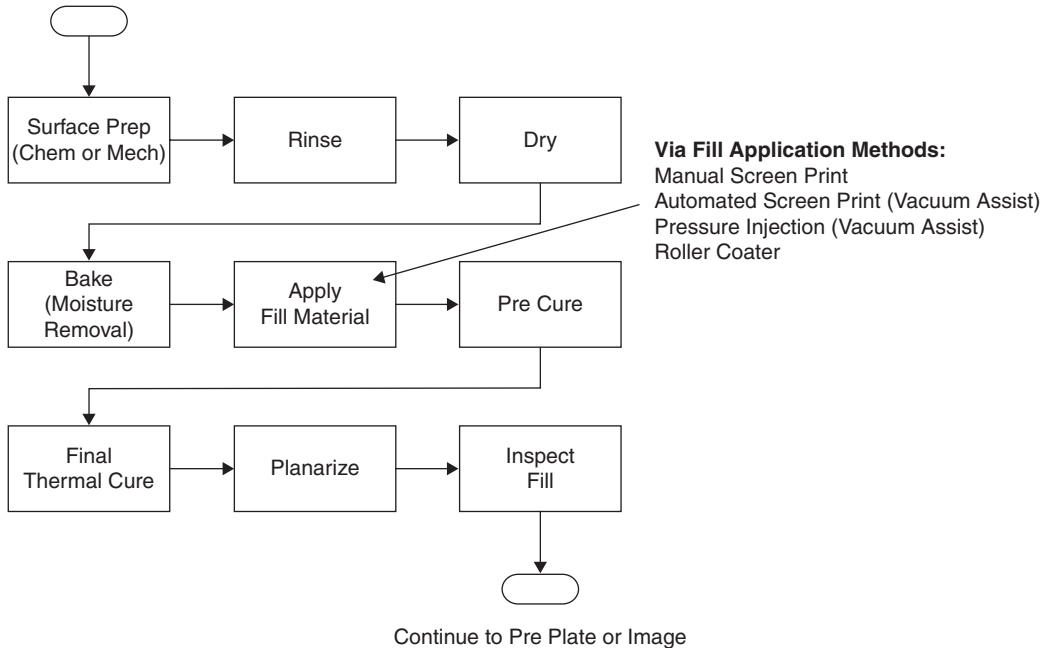

**FIGURE 27.27** Pre-hole-fill plating.

**27.3.5.3.2 Hole-Fill Process.** Once the prefill-plating process is complete, the next major step is the actual hole-fill process. The fill materials can be divided into two major categories: conductive and nonconductive. A generic hole-fill process flow is shown in Fig. 27.28.

The specific equipment and technique can vary by the material type used. The method chosen to apply the material in the holes can be influenced by many variables such as material cost, pot life, viscosity, equipment resources, and the quantity of panels to be processed. Some hole-fill materials lend themselves to a variety of fill methods. Some of the common hole-fill

**PWB VIA FILL APPLICATION**  
(Generic Flow)

(Sample Fab Process Starting from metallization)

**FIGURE 27.28** Generic via fill application flow.

application methods are noted in the flowchart in Fig. 27.28. Application guideline parameters should be followed as noted in the respective material supplier data sheets. Via-hole filling may be considered a finesse process due to its sensitivity to variables that occur from design to design and the availability of support equipment to perform the process. The various application methods each have advantages and disadvantages associated with the technique employed.

When a fabricator is screen printing, a mask sized just over the hole size keeps excess material from being applied to the surface. Screen printing with a dot mask using a back side receiving template with open holes sized just over the plated hole diameter yields a domed fill bump. These bumps can act as a visual indicator similar to a button plate pad to indicate when the planarization is flush to the surface. Other methods include roller coating modified to squeegee excess material off the surface of the panel. Commercially available equipment designed specifically to apply fill material is now available. One such machine uses a pressure-assisted injection method to force material into the holes under a vacuum. The principal advantage of this technique is the ability to reduce the opportunity for void entrapment.

Figure 27.29 illustrates an example of how the filled structure forms with successive steps for a noncap-plated fill process. Note in this example how the surface button plating is mostly removed at the planarization step. Process development should be performed to target the optimum plating build-up method in regard to the process control of available planarization equipment. This means that whatever plating method is employed, both the deposit thickness across the panel and the net removal of deposit thickness as a result of planarization must be

**FIGURE 27.29** Noncap-plated fill and planarization.

understood. Simple eddy current measurements of multiple locations across the panel are recommended prior to and after planarization sanding passes.

Once the planarization is complete, the panels are ready for imaging and etching to allow typical process flow, depending on construction type. The plating method chosen should take into account the surface pattern and construction level of difficulty. Multiple plating cycles are often required if multiple filled structures occur on the same surface plane. Excessive copper plating complicates the imaging, so the starting foil thickness should be kept to a minimum. Figure 27.30 illustrates how the fill method forms from use of a method employing cap plating over the fill material. It should be noted how the copper thickness requiring etch can quickly build up, making pattern definition difficult.

**27.3.5.4 Specifications.** The industry has now released a design guideline document outlining via protection classifications, including the hole fill as described in this chapter. The IPC-4761, “Design Guide for Protection of Printed Board Via Structures,” has established via-protection techniques, creating specific types identified as Types I through VII. IPC-4761 contains many combinations of techniques where an added material is utilized to plug, tent, cover, or fill a via structure. Many of the techniques established are used in Class 1 and 2 hardware or where circuit card assembly consideration is the primary focus. Many of the 4761 via-protection types are of lower cost and lesser complexity than are those used for hole fills. The designer is encouraged to consult the application guide included in Table 5-1 of IPC 4761 to narrow the selection prior to layout and specifying a method. The via fills described in this chapter fall under the Type V and VII classifications. These types have been the focus for developing performance-based requirements as reliability data have become available.

Amendment 1 of the rigid board performance specification IPC-6012B will introduce requirements for maintaining a minimum wrap copper. The specification limit is being established at 0.0005 in. minimum wrap as verified at cross section. This is considered a conservative value resulting from the nonuniformity of the process. Correlation data have revealed that coupons on the panel perimeter rarely match that of the actual product. Uniformity of the planarization across the entire panel is difficult, so a conservative value at cross section was established to ensure that the part maintains wrap copper. The reliability data gathered support this value due to the additional manufacturing risk that can occur from the added fabrication steps. However, some data collected in MRB action and assessment indicate that wrap copper as low as 0.0002 in. is acceptable for some end-use environments. It is likely that future revisions of

FIGURE 27.30 Cap-plated fill and planarization.

IPC 6012 will relax the 0.0005 in. wrap requirement as the industry matures in regard to controlling the planarization process and additional reliability data become available.

**27.3.5.5 Via Fill Summary and Additional Considerations.** The manufacturing of reliably filled vias should not be underestimated. Considerable process development is required to optimize the interaction of maintaining plating wrap to lower the risk associated with via fill planarization. The nature of reported failures due to compromised interconnect integrity have ranged from infant mortality at assembly to latent field failures. These failure mechanisms are very difficult to screen with standard performance verification methods. Even post-assembly environmental stress screening (ESS) may not exercise sufficient stress levels to screen out marginal product effectively. This has directed some users to specify thermal shock temperature cycling at the bare-board production lot level for acceptance testing. This level of lot acceptance becomes more critical for lead-free assembly thermal stress environments, requiring the user to be more cognizant of the fill material selection.

A number of commercially available material choices exist with a wide variety of physical properties. Matching a material to a design type is necessary prior to specifying it on a drawing. Industry dialogue indicates the desire eventually to establish a material performance

specification for fill materials similar to the IPC SM 840 for solder mask. The absence of a material specification requires the user to specify the brand(s) of acceptable fill materials through a user/supplier agreement. The process of specifying a hole-fill material can add considerable cost and difficulty to the PWB manufacturing process. The process labor cost is relatively flat to apply a material, with the most significant cost variable being the material type. Some of the silver-filled conductive materials are roughly twice the cost of nonconductive materials. The added process time and material cost can be roughly estimated at \$25 to \$50 per panel not including setup fees or minimum lot charges.

The impact to reliability is judged to be weighted more toward the suppliers' ability to successfully process the panels without degrading plated interconnects rather than the fill material type. This is followed by the ability of the manufacturer to metallize a specific fill material. The greatest number of failures reported in industry have been related to the planarization process. To this end, commercially available planarization equipment has come to the marketplace. Due to the rapid introduction of hole fill and process immaturity, many suppliers were faced with establishing the sanding processes with modified deburr machines or fully manual methods. Even with automatic planarization equipment, careful consideration should be given when specifying via fill for designs with heavy-weight copper or rigid flex constructions. Any construction that lends itself to circuit pattern imprint at the surface will have difficulty in the planarization process. Panel thickness at via structures can often be several mil. thicker than open circuit areas. This change in height is not easily recognized and is problematic for producing a uniform sanding surface. Additionally, some softer materials or non-glass-reinforced materials may not be able to be planarized without distortion or gouging.

With more designs migrating to higher-density layout schemes, it is expected that the use of via fill will increase. The process of via fill is gaining maturity for Class 3 hardware but this has also been the market segment most affected by reliability issues. Many end users who learned difficult lessons quickly introduced their user-defined specifications for hole fill. User-defined specifications often do not lend themselves to producible limits, so consideration for via fill should be part of the DFM dialogue during the design layout cycle. The user and supplier must work closely together to understand the impact of specifying hole fill for each design construction method employed.

## 27.4 ML-PWB PROCESSING AND FLOWS

---

### 27.4.1 Process Flowcharts

Attempting to visualize the process flow of the manufacture of multilayer printed wiring products can be overwhelming. One way to help picture the multiple paths a board travels is through the use of flowcharts. The flowchart in Fig. 27.31a is a typical process flow for the beginning innerlayer process identified as 1 through 4. Figure 27.31b is a typical finish board flow process after lamination and drill. Three additional diagrams are provided in Fig. 27.32 that represent possible sequential flows for HDI products. They are identified as processes 5, 6, and 7, referring to how the different HDI types might flow. It should be noted that alternative flows and methods are possible in HDI. This discussion is limited to mostly conventional processing. Major aspects of these processes are discussed in detail in the following sections.

### 27.4.2 Innerlayer Materials

The multilayer process begins with the accumulation of the innerlayer clad dielectric laminate.

**27.4.2.1 Documentation and Specifications.** The ML-PWB design documentation should specify the specific material system to be used in the fabrication. Typically materials are identified

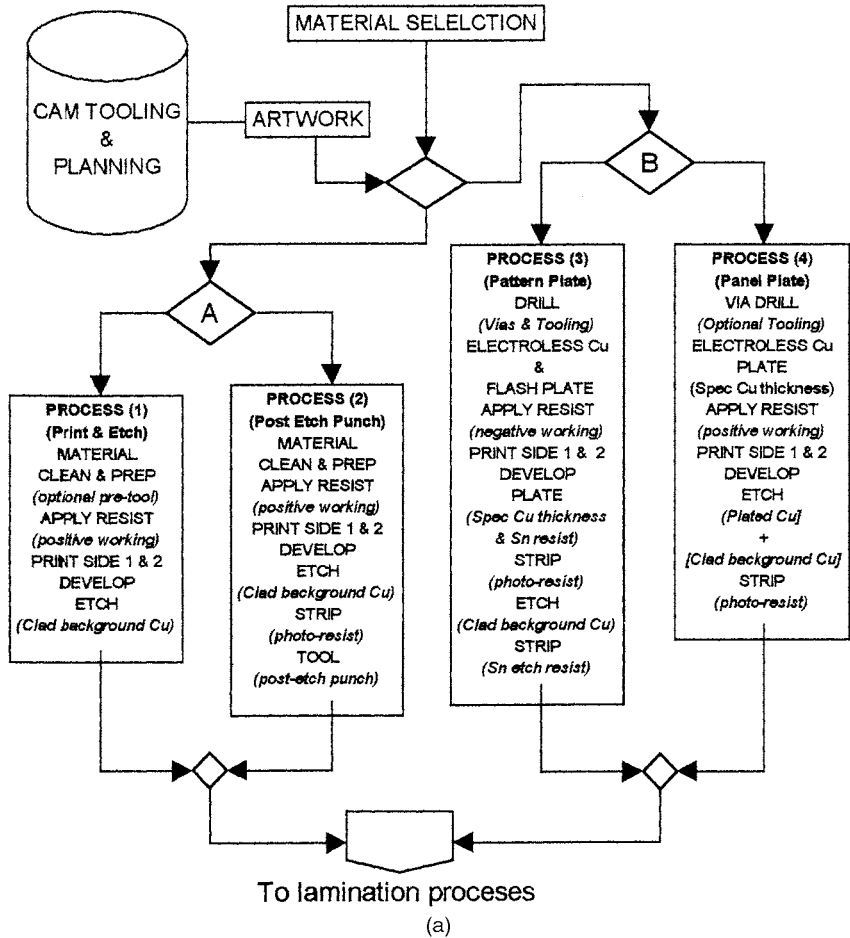

FIGURE 27.31 Process flowcharts: (a) A typical process flow for the beginning innerlayer processes identified as 1 through 4; (b) a typical finished board flow process after lamination and drill.

by IPC-4101 callout or slash sheet designation, for example, IPC-4101/24. Copper weights as well will be specified within the drawing documentation. The specification IPC-4562, “Metal Foil for Printed Wiring Applications,” provides reference to the various weights of copper foils along with an applications use guide. The common terminology refers to foils less than oz./ft.<sup>2</sup> as a metric thickness of micrometers. The most commonly used foil is STD-Type E electrodeposited (IPC-4562/1) with a weight of 1 oz./ft.<sup>2</sup> and a nominal thickness of 1.35 mil. (35.5 μm).

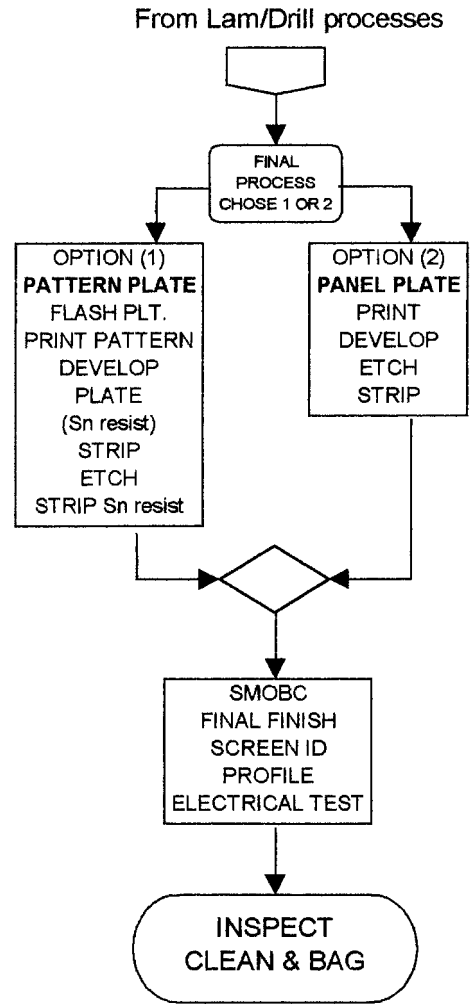

**27.4.2.2 Copper Foil.** High-current applications use heavier (thicker) copper of 2 oz. or above. With copper weights above 3 oz., processing difficulty is increased. High-density circuit designs that have low voltage and that are mainly concerned with passing signals may use thinner copper weight foils, such as 18 μm or less. When sequentially processing clads as buried via pairs, the fabricator must use thin starting foil to promote line definition and image integrity and, where necessary, impedance-controlled tracks.

Copper foil is fabricated in an electroplating process on a rotating drum that produces a coarse-grained columnar copper. The economy of the foil process always yields copper at the minimum thickness tolerance. Due to the speed of the foil process, often a coarse grain structure can yield poor elongation. Elongation is a property of major importance in reducing trace fracturing. Standard copper foils typically fail at elongations around 3 percent. IPC-4562/3 high-temperature elongation (HTE) provides a slight, but important, improvement in elongation from 5 to 8 percent. High-ductility electrodeposited foil, called HD-Type E (IPC-4562/2), is specified to withstand an elongation of 10 percent minimum. Foil vendors also sell special fine-grain-structure, annealed, or wrought foils. The foils with higher elongation are advertised to have superior etch performance for fine-line densities.

Standard foils have a rough surface called *tooth* on one side (drum side out) and a smooth or shiny surface on the opposite side (drum side). The rough side, treated with an adhesion promoter, is laminated against the C-stage dielectric to ensure good adhesion. Since the shiny side of the copper has poor adhesion characteristics, the ML-PWB fabricator must include adhesion promotion steps prior to resist lamination and prior to final board lamination. Double-treated copper foil has an adhesion promoter applied to both sides and is attractive in high-volume applications. Although double-treated foil requires no further adhesion promoting treatments, it has several process disadvantages to overcome:

- Cleanliness and material handling sensitivity is more critical.
- The cost often offsets the savings from the eliminated processes.
- It is somewhat fragile, so it is difficult to rework.
- Complete resist development is difficult, leading to a high incidence of shorts.
- It is not compatible with the plating processes used to make buried and blind vias.

Another foil type offered by laminate suppliers, reverse-treated foil (RTF), offers an advantage for producing fine lines. The RTF copper has adhesion promoter applied to both sides and is classified by 4562 as code R (reverse-treated bond enhancement [cathode side] stain-proofing on both sides). This approach provides advantages to imaging fine lines. When the copper tooth is reversed, the fabricator can improve line definition by allowing the etch chemistry process to stop at the surface of the laminate.

(b)  
**FIGURE 27.31** (b) (Continued)

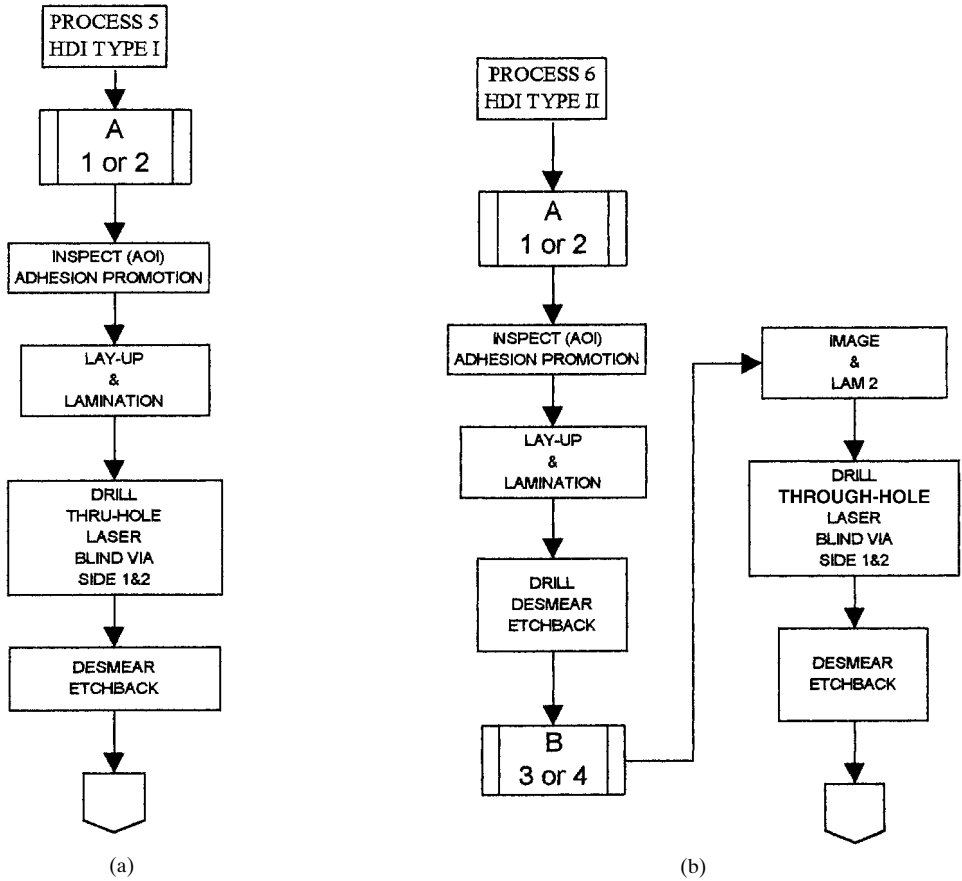

FIGURE 27.32 Diagrams representing possible sequential flows for HDI products. They are identified as processes 5, 6, and 7, referring to how the different HDI types mentioned in the text might flow.

### 27.4.3 Innerlayer Process

An innerlayer detail is essentially a thin double-sided printed circuit. The standard innerlayer process contains no plated holes because it is produced using a print-and-etch process. Blind, buried via layers and laminated cores contain holes that must be plated in either a pattern-plate or a panel-plate process. Figure 27.31a shows a typical flowchart for four innerlayer process options. Processes 1 and 2 support standard innerlayers, and processes 3 and 4 can be used for buried via innerlayers or core subassemblies. All four processes start with a bare copper-clad laminate and end with a patterned double-sided circuit. The patterned circuit must be inspected and treated to enhance adhesion prior to further ML-PWB lamination. All four of these sequences work equally well with any of today's materials systems.

FIGURE 27.32 (C) (Continued)

**27.4.3.1 Process Sequence Flows 1 and 2.** Process sequence flows 1 and 2 are variations of how to produce a standard innerlayer with no plated holes by print-and-etch or post-etch-punch processes:

- Process 1: print and etch** The laminate layers receive an application of photoresist. After photoresist application, the panel tooling holes are punched with the predefined pattern to match the lamination tooling. This is followed by the image printing (exposure) process, where the punched tooling holes align the artwork pattern. After print exposure, the inner panel is ready for development, which clears the non-image area for etching. The artwork is a negative image and produces a retained pattern of “what light sees stays.” The resist that stays behind protects the copper, which becomes the circuit pattern. The etch process then removes the unprotected background copper. The stripping process then removes the resist material and the layer is ready for adhesion promotion.
- Process 2: post-etch-punch** The difference in this sequence is the order in which the laminate material is punched (tooled). The innerlayer detail is resist-coated and placed in the exposure cabinet. The artwork layers have already been pre-aligned as the top and bottom

layer pattern pair within the exposure frame. This is defined as a pinless registration system. The process then is followed by etching and stripping. The final step is to punch the tooling holes, which are aligned optically to etched targets. The advantage of this process is improved innerlayer registration because it compensates for panel in-plane dimensional movement that occurs when stresses are relieved after etching.

**27.4.3.2 Process Sequence Flows 3 and 4.** Process sequence flows 3 and 4, as shown in Fig. 27.31a, are plating processes that may be used for blind and buried via layer pairs or laminated cores. The flows represent two distinctly different plating methods referred to as pattern plate and panel plate. Note that in these processes, the printed image ultimately is registered to tooling holes as well. Depending upon the tooling system, often the tooling holes are drilled at the same time as the via holes. This ensures optimum alignment between drilled holes and printed features due to dimensional movement of the materials.

- **Process 3: pattern plate** The distinguishing factor of this process is that final build-up plating is performed after imaging. Extra processing steps are required in this process to protect the primary metallization. Typically, a deposit of tin metal acts as etch resist, then is stripped after etching. Note that this process is suitable for defining small circuit patterns. The copper plating is selectively built up on the circuit pattern. The etch process need only remove the base-clad copper to define the circuit. Photoresist thickness must be matched with respect to the image resolution of the circuit.
- **Process 4: panel plate** The diagram of process 4 represents the flow for a panel plate substrate. Here the plating deposit covers the entire surface area of the substrate (panel). Photoresist is applied post-plating and provides the only protection to the defined circuit and the plated via holes. The via-hole protection is referred to as tenting. Photoresist materials chosen must have characteristics with tenting properties to avoid resist breakout and voiding of the plated hole. Note that this method places a burden on plating uniformity across the entire surface of the panel due to high current densities at the perimeter of the panel. Imaging of fine features is difficult because the base-clad copper and plated copper are etched together. Additionally, the panel plating of thin-core laminates can induce dimensional shrinkage of the substrate. Process parameters should be optimized through experimentation to applying a low-stress deposit.

## 27.4.4 ML-PWB Tooling

The tooling system employed for ML-PWB fabrication is one of the most critical aspects of the process and requires much forethought. The investment in tooling is significant and not easily changed. Planning is required to determine the degree of flexibility that is needed in a tooling system based on the types of ML-PWBs that will be produced in that facility. The ML-PWB tooling system can be broken down into four aspects: the panel size scheme, the front-end tooling, the method of generating tooling holes, and the hard tooling (plates).

**27.4.4.1 Panel Size Scheme.** The first decision is to choose from essentially three broad approaches to panel size: full sheet, or mass-lamination; standard panel sizes based on cuts from a full sheet; or customized (flexible) panel sizes based on cuts from a full sheet. Any particular facility may also employ more than one approach.

**27.4.4.1.1 Mass-Lamination.** Sheet sizes can be 24 × 48 in.; 36 × 48 in.; 48 × 52 in.; 1.5 meters × 2 meters; or other similar large formats. This approach is well suited to medium or mainstream technology requirements in lines and spaces, and hole-to-pad ratio. It works best with larger sized PWBs since too many small PWBs leave too much blank space between the circuits, wasting the principal advantage of full-sheet lamination. Typically, the copper foils are

standard weights. The cores are .004 in. (1.0 mm) or thicker, although some mass laminators are capable at .002 in. (0.05 mm); and the lamination is a single-resin system, not a mixed dielectric build. The most common construction is from epoxy resin, since most of the enhanced electrical or thermomechanical resin systems are not available in large sheet sizes.

**27.4.4.1.2 Standardized Size Cut Panels.** This approach is dominant in high-end technology PCBs. Some very common panel sizes are 18 × 24 in. and 20 or 21 × 27 in. The facility strives to have the fewest number of standardized panels that will accommodate the majority of the MLB sizes typical of their customer base. Tooling is then either fully fixed or modular based on those panel sizes, but other new panel sizes are not possible without new hard tooling and die. Having four to eight panel sizes is common. These sizes are based on full yield cuts from the laminator's full sheets; for example, the laminator might offer a 36 × 48 or 42 × 54 in. sheet and the fabricator orders (or cuts from full sheets) 14 × 18, 12 × 24, 18 × 24, and 21 × 27 in. panels. This system standardizes tooling into the fewest number of different sizes of hard tooling (e.g., caul plates and separator plates; see section 27.5.1.1). This approach is also best suited to advanced feature sizes, where limiting the panel size to just over the MLB size has the advantage of reducing some degrees of difficulty such as the registration requirement over a larger area. Fixed panel sizes work well for mixed dielectric builds and sequential laminations. Very large cut panel sizes such as 24 × 36 in., approaching mass lamination size, are uncommon but available in very high-volume or backplane fabrication specialty facilities.

**27.4.4.1.3 Custom-Cut Panels.** Asian fabricators have pioneered flexible custom-cut panel sizes to maximize material utilization further and so reduce costs. The difference between standard and flexible cut panels is that standard-cut panels have a limited number of predetermined sizes and consequent hard-tooling configurations, while the flexible cut panels afford a continuous range of size because the tooling isn't fixed but highly configurable. Flexible cut panels are often paired with riveting instead of pinning to hold the details, prepreg, and foil together for lamination. Many Asian facilities will offer both approaches, selecting the best suited to the job at hand.

**27.4.4.2 Front-End Tooling.** The first aspect of the ML-PWB tooling is commonly called front-end tooling or simply computer-automated manufacturing (CAM) tooling. (See IPC-2514A, "GenCAM [BDFAB], Sectional Requirements for Implementation of Printed Board Fabrication Data Description." IPC-2514 is a standard developed by the Computerized Data Format Standardization Subcommittee [2-11] of the Data Generation and Transfer Committee [2-10] of the Institute for Interconnecting and Packaging Electronic Circuits. The GenCAM format is intended to provide CAD-to-CAM, or CAM-to-CAM, data transfer rules and parameters related to manufacturing printed boards and printed board assemblies. IPC-2514 is a section requirement within IPC-2511B, "Generic Requirements for Implementation of Product Manufacturing Description Data and Transfer XML Schema Methodology.") The front end is where manufacturing personnel using a CAM software package generate all phototools, the associated computer numerical control (CNC) electronic files (used by equipment such as drillers and routers), the construction stack-up, and the part manufacturing instructions, or "work order," also called the "traveler." The CAM station mirrors the tooling method chosen for the shop and the job's work order. The CAM software overlays the tooling pattern on each circuit layer to produce the master pattern alignment. The master artwork pattern is then photo-plotted to reproduce the artwork film tools for the imaging operations. Several important manufacturing functions fall within the bounds of the front-end tooling responsibility.

**27.4.4.2.1 Design Rule Check (DRC).** Design rule check (DRC) is where the electronic design data are analyzed against a specific set of fabrication rules, a virtual design for manufacturing (DFM). The capabilities and attributes of these rules are based on sound, industry-proven values that match the technology targeted for construction. The default values embedded into the CAM are input by the manufacturer as technology files. These files should reflect the capability of the fabricator's equipment and processes in light of how they are utilized against the ML-PWB type being produced.

**27.4.4.2.2 Panelization.** To gain economies in the manufacturing process, the individual board design is stepped and repeated within the artwork tooling. *Panelization* is the term used to describe this method. Here the elemental goal is to yield as many parts on one process panel as possible. The CAM software allows manipulation of the single design pattern to place or nest multiples within the confines of the chosen panel dimensions.

**27.4.4.2.3 Artwork Generation (Photo-Plotting).** Once the design has been formatted into the desired panelization, it is ready to be made into a working phototool. The CAM data are output to a server that converts the data into a language recognizable by the plotting equipment. The plotter exposes the circuit pattern on the film tool. Typically, the film tool is polyester-based with a silver emulsion and is exposed by means of a laser or fiber-optic light source. The resolution of the light source directly affects the ability to image the technology type. Note that when the technology type approaches the feature size of HDI, the use of an alternative approach to phototooling may be employed. This is known as laser direct imaging, and, as the name implies, the image is directly exposed onto the production innerlayer, thereby eliminating the use of a phototool.

**27.4.4.2.4 CNC Drilling Routing Tools.** The machine communication method commonly employed in the automation of the drilling and routing process is output from the CAM tooling as CNC programs (from the earliest computer numerical control machines, as differentiated from manual or template positioning systems). The front-end tooling software facilitates the organization and optimization of the CNC routine. The routine must match the flow of the technology process steps being produced. When sequential processing is required, the drilling routing data must be broken out into separate routines. When the technology type involves HDI features that require laser drilling, specific tooling accommodations have to be considered to match the discipline of the laser equipment—for example, the use of special imaged fiducial targets or a special dot mask aligned to the drill locations.

**27.4.4.2.5 Automatic Optical Inspection (AOI).** Another aspect of the tooling set is the data configuration to support the automated optical inspection (AOI) process. AOI is considered part of the detailed inspection process. When the AOI equipment supports what is known as CAD reference, the original design data (which were reproduced in the phototool) are now output as a configured file to compare the imaged circuit layer to the original designed circuit (see Chap. 53 for a complete discussion of inspection).

**27.4.4.2.6 Electrical Testing.** The final aspect of the tooling set is preparation of the electrical design data to support an electrical testing routine. The purpose of the electrical testing within the ML-PWB production process is to verify the integrity of circuit continuity. The electrical data required for the test must be extracted from the circuit pattern unless a separate net list is provided that contains the connectivity. The standard data format for electrical testing is IPC-356. (See also IPC-2515A, “Sectional Requirements for Implementation of Bare Board Product Electrical Testing Data Description [BDTST].”)

Electrical testers can take on many forms, but are generally divided into two major categories, the bed-of-nails and the flying probe. Tooling for a bed-of-nails tester consists of outputting data to manufacture a fixture to accommodate the pins, which make contact with the circuit nets. When a flying probe tester is employed, the net data are fed into the machine, which uses its own software to configure the routine to probe continuity and perform isolation.

The chosen method of test tooling requires an examination of the economics based on the volume and technology of the ML-PWB. For small prototype lots required in short cycle times, flying probe may be more suitable than bed-of-nails testing. Although the throughput of a flying probe unit is less than that of a bed-of-nails tester, the flying probe does not require expensive, and time consuming to construct, fixtures. When the technology type involves HDI features, the only alternative is to use a flying probe due to the limitation of the grid spacing in a bed-of-nails tester. High-density test requirements continue to drive flying probe technology. (See Chaps. 54 and 55 for a complete discussion of electrical testing.)

## 27.4.5 Tooling Hole Formation

The shape, size, and location of tooling holes or slots are dependent on the investment tooling system determined by manufacturing engineering for a given facility, and there a variety of methods to form them. The tooling holes range in size and shape from 0.125 to 0.250 in. diameter to a slotted hole of  $0.187 \times 0.250$  in. The common methods used to produce the mechanical alignment in innerlayers are punch and die or drilling, but the point in the process where they are formed can vary depending on the total tooling scheme.

**27.4.5.1 Prepunch.** A fixed punch and die set is used to generate tooling holes/slots prior to imaging/etching. To avoid having to cut away the photoresist material over the tooling hole, fabricators sometimes perform the punching after resist lamination. In this case, cleanliness has to be significantly refined. If a cut sheet resist laminator is used, it can be adjusted so the resist falls inside the boundary of the tooling locations. The punching occurs in a hydraulic punch press, where alignment is ensured by means of an edge stop on two axes of the panel to square the alignment. The die set penetrates the laminate in one stroke, punching all holes at one time while holding the material flat. Material is punched one piece at a time, yet high throughput can be achieved by this method. Punching of multiple laminates at once is not recommended because the quality and size of the tooling hole/slot are affected. Additionally, thicker laminates (greater than 0.032 in.) require the punch and die set to have a slightly larger tolerance to accommodate the spring-back of the hole within the composite material. Overall, the prepunch method is very accurate and repeatable. Materials with a high degree of movement (low-dimensional stability) are at a significant disadvantage in this method due to the drift of the tooling location after innerlayer processing.

**27.4.5.2 Post-Etch Punch.** An optically aligned punch is used to generate holes/slots after imaging/etching. The fully processed innerlayers are edge-aligned into the punch; a pair of video cameras locates on a diagonal pair of printed fiducials; a servo-system aligns the panel, minimizing alignment errors due to panel distortion; and tooling holes are punched. This process punches an optimized set of tooling holes/slots in the layer just prior to lamination. Post-etch punch can be automated so it has high productivity, but it is slower than a simple punch and die. However, the productivity gain achieved by printing without tooling reduces some of the productivity loss from using post-etch punch.

**27.4.5.3 Drilled Tooling.** When processing follows the process sequence 3 and 4 described earlier, tooling locations may be drilled. This allows the tooling locations to be formed at the same time as the via-drill cycle. To minimize distortion, which affects final registration accuracy, it is recommended that the drill program be scaled. Scaling factors must be characterized through experimentation. Scaling helps minimize the dimensional effect that processing has on the true positions of the holes. Alternatively, extra sets of tooling holes may be produced just for the imaging process, followed by a post-etch punch operation to optimize the lamination registration.

## 27.4.6 Tooling System

There are numerous rationales for innerlayer tooling schemes, and this has resulted in a wide assortment of tooling systems being used across fabricators. Over the years, many tooling systems have evolved, ranging from full-perimeter distribution of holes to as few as four holes located on the midaxis. One low-cost tooling system comprises use of rivets in a flexible layout scheme. The tooling system comprises a substantial investment and therefore merits considerable engineering conceptual judgment. Many shops become trapped with poorly conceived tooling schemes that are difficult to migrate from due to the cost of converting earlier designs.

**FIGURE 27.33** Three different tooling schemes: (a) four-slot tooling; (b) four-slot/four-hole; (c) a tooling system with a full perimeter of holes placed.

Therefore, careful analysis should be given to the product mix and technology types to be manufactured prior to choosing a scheme.

The primary purpose of the tooling system in ML-PWB manufacturing is to facilitate layer-to-layer alignment during the lamination cycle while maintaining a positional reference for subsequent processing. The tooling hole arrangement is mirrored within the front-end tooling routines mentioned earlier. The master alignment of each part keys off the tooling scheme. The primary tooling locations may be used at all process steps or sometimes used to introduce secondary reference holes.

Figure 27.33 shows three different tooling schemes. Figure 27.33a shows a system known as four-slot tooling. This is an excellent system, because the use of four slots allows for growth and shrinkage of the layers during processing. The four slots may be used for printing, inspecting, and lamination, or, if post-etch punch is used, they are used for inspection and lamination only. Figure 27.33b shows a system known as four-slot/four-hole. This is common in a pre-punched system where the slots are used for image printing and the extra holes are engaged at lamination. Alternatively, punched slots can be used for innerlayer image and lamination, while post-lamination holes are drilled for plated holes' drilling and outerlayer imaging. In this method, targets imaged in the details under the outerlayers are exposed by controlled depth boring; a camera then locates the targets and a spindle drills the locating holes for the secondary operations. Figure 27.33c shows a tooling system with a full perimeter of holes placed. This style would be considered overdetermined. It has a disadvantage at lamination because imaged panels typically have to be stretched over the alignment pins. A fourth tooling system not shown uses low-profile rivets to align layers. The rivets can be arranged outside the pattern area and do not penetrate into the caul plate. Rivet height is chosen based on the appropriate panel thickness.

## 27.4.7 Imaging

**27.4.7.1 Surface Preparation.** The first step in the imaging operation is surface preparation to enhance photoresist adhesion. Double-treated foils (DTFs) and foils laminated with the tooth side up (RTFs) require minimum surface preparation. Generally, a process through a tacky roller machine to remove dust and foreign material is adequate. For cores with standard foil with the “shiny side up” (non-tooth or drum side), a more aggressive treatment is needed. Common options include a conveyerized chemical cleaning and/or an abrasive

cleaning. Automated equipment is available to perform this function with pumice or aluminum oxide slurry. Scrubbing the layer by hand is acceptable but labor-intensive, and can provide inconsistent results.

However, acidic 4F grit pumice is required for single-step cleaning. Standard copper foils are coated with a chromate conversion to eliminate formation of heavy copper oxidation during storage. This coating, and any oxides, must be removed to provide a microroughening of the surface. When using any of the mechanical cleaning methods, care must be taken to avoid mechanical deformation (stretching) of the thin laminates. Stresses induced will be relieved after etching of the image, causing positional movement.

**27.4.7.2 Photoresist.** Photoresist is supplied in both dry-film and liquid forms. Dry films are a popular choice because of the simplicity of application. For buried via innerlayers, dry films are preferred because liquids are difficult to use with through holes. The major weakness of dry-film resists is sensitivity to surface flaws and a tendency to lift on poorly prepared surfaces.

**27.4.7.3 Dry Film.** Resist film is typically 1.5 to 2.0 mil. thick. Both thinner and thicker resist is available as a specialty product. Dry-film resist is applied with a hot roll laminator. To aid in production of fine lines and spaces, the use of a wet nip applicator aids in filling surface imperfections. Precision flatness and uniform temperature are equally important as well. Popular resists for high-density applications include films formulated with high-speed sensitivity for laser technology.

**27.4.7.4 Liquid Photoresist.** Liquid resists work well in a print-and-etch process. They have excellent adhesion and a tolerance for surface flaws and are relatively low in cost. The disadvantage of a liquid photoresist is the need to produce a perfect coating. Foreign material, skips, thin spots, and dewetting all cause serious image problems. The use of a wet coating can also cause problems due to resist contamination of the transport system.

**27.4.7.4.1 Roller Coating.** The least expensive and most popular way to coat liquid resists is with a pair of roller coaters consisting of pinch rollers in which one or both rollers is used for coating. The coating roller has a closely spaced, precisely cut spiral groove. Liquid is metered onto this roller and then transferred to the panel. A good roller coater produces an extremely uniform coating. By carefully selecting coater parameters, it is possible to achieve a coating thickness control of 0.1 mil. Some roller coaters use the top roller as a coating roller, allowing the panel to be transported on a clean conveyor system. In these systems, the resist can be dried or the panel can be printed wet. Other roller coaters use both the top and bottom rollers for coating. These roller coaters require a handling system that holds the panel by its edge until the resist is dry. The coating roller is the weak link in a roller coating. Alignment problems result in nonuniform coatings. Flaws produce repeating defects in the coating. Worn or improperly cut grooves result in a low-quality coating.

**27.4.7.4.2 Curtain Coating.** The curtain coater operates by pumping a waterfall of liquid through a narrow slot. By carefully controlling the slot width, pumping pressure, and viscosity, the fabricator can create a well-controlled curtain of liquid. When a panel moves through the curtain, a thin coating is applied to one side. Curtain coaters produce a good-quality coating, but not all photoresists have the proper viscosity for curtain coating.

**27.4.7.4.3 Electrodeposition.** With electrodeposition, a polymer is deposited on a biased metal surface submerged in a liquid medium by a process that is analogous to plating. It gives a well-controlled, high-quality coating. Both curtain coating and electrodeposition are expensive and are not widely used for innerlayer processing.

**27.4.7.5 Photo Print Exposure.** The third step in imaging is photo printing. The three types of photo-printing machines are flood, collimation, and direct image. Most flood printers consist of high-UV (5,000 W) light sources housed within large reflectors to distribute the light uniformly across the imaged surface. Hard contact by means of a vacuum is required between the film and the innerlayer. The silver emulsion side of the polyester film tool makes direct contact with the resist. This allows good image reproduction without collimated light. The drawbacks of contact printing are defects associated with poor contact, poor productivity due to the time required to establish hard contact, and the potential for artwork damage.

The alternative, collimation, an off-contact printing method, holds the film a small distance above the innerlayer surface and prints with collimated light. The collimated machine uses a high-UV lamp with mirrors to reflect intense light straight down on the innerlayer. This method permits a high degree of automation. Off-contact printing is absolutely necessary for printing wet layers. The disadvantage of off-contact printing is a loss of resolution due to incomplete collimation and a great sensitivity to dust and scratches on the artwork.

The other style of printing is referred to as direct imaging, and is the technology of choice where production of high-density line and space features is required. In this process, the electronic data are input into the direct image machine instead of being used to produce a photo-tool. The direct image, typically output through a laser, is used to expose the image by means of a series of on/off pulses manipulated within an x-y axis. The throughput of this process can be limited by the combination of resist speed (sensitivity) and mechanical positioning of the next panel.

### 27.4.8 Develop, Etch, and Strip

**27.4.8.1 Developing.** All modern innerlayer photoresist materials are aqueous-soluble. This means they develop in a mild caustic solution. Note that resists that use solvent developing are no longer in use due to significant health and environmental concerns. The developing process is easily automated by means of conveying the part through a sprayed caustic solution. The developing solution removes the non-imaged resist, which was not polymerized by the light source. Therefore, in effect, "what light sees stays." The quality of the developed image is often quantified by means of a density step chart that was previously exposed. By comparing the step held on both sides of the imaged panel, the fabricator can determine process control.

**27.4.8.2 Etching.** Etching chemistry is determined by the process flow sequence as outlined in Fig. 27.32. Etching can be classified as print and etch when using processes 1, 2, or 4 and using a cured photoresist as an etch resist. Etching is classified as print-plate-etch when using process 3 employing a sacrificial metal layer as an etch resist.

The preferred etch chemistry of the print and etch process is cupric chloride. Cupric chloride is easier to control than the ammoniacal etchant used with finished boards, and it can be easily regenerated. Etching occurs by spray erosion with the highly loaded ( $\leq 25$  oz./gal.) copper-soluble solution. A high degree of automation is possible in the print-and-etch process. Since there is no plating step, it is possible to feed printed innerlayer panels directly into a conveyORIZED inline machine that develops the resist, etches the circuits, and strips the resists. These automated machine lines are called develop, etch, strip (DES) and improve productivity by reducing the defects caused by handling.

The print-plate-etch process follows the same general methods as used in the finished board steps (see Chap. 29). The use of a metal etch resist requires ammoniacal or acid etch. Resist developing is separated from etching by a plating step, so a stand-alone resist developer is required.

### 27.4.9 Inspection

Once innerlayer etching is complete, the innerlayer must be inspected. The innerlayer inspection criteria follow industry-adopted performance limits (IPC-600 and the IPC-6000 series). These limits must be confirmed prior to lamination into an expensive multilayer to prevent decreasing yields. Flaws are categorized to reflect processing defects related to laminate materials and circuit definition. Line width and spacing are of primary importance on dense signal layers. In the case of controlled-impedance layers, it may be necessary to gauge line widths. Power and ground layers are less likely to have defects and are sometimes excluded. Most modern circuitry precludes manual visual inspection due to the inability to accurately

detect flaws and the associated intense labor. AOI is the industry standard for inspecting innerlayers.

AOI has the advantage of being able to detect circuit nicks and protrusions. False errors can be a problem and are time consuming to confirm. AOI technology using CAD reference (the comparison of the circuit image to the design data) has a lower escape rate. Cleanliness and copper oxidation are factors that can influence poor performance in most AOI technologies. Two common methods exist for imaging the circuit. In one, the innerlayer is scanned with a tiny laser spot that causes the substrate to fluoresce. The circuit is seen as a dark image against the light emitted from the substrate. The other method illuminates the circuit with a bright light so that its image appears bright against the dark background of the substrate. Both methods have strengths and weaknesses. The fluorescent method is blind to surface flaws, and substrate flaws can confuse it. The top-light method is oversensitive to the surface appearance of the copper. The AOI inspection of high-density features presents new challenges to the technology related to minimizing false errors. Modern machines employ a combination of image acquisition techniques while performing virtual reasoning against a background scan of design rules that are compared to the design image data.

#### 27.4.10 Adhesion Promotion

Epoxy does not adhere well to untreated copper surfaces. This means that some type of treatment must be applied to the innerlayer before lamination. One option is to use double-treated copper, discussed earlier. Double-treated copper has a rough surface with a treatment supplied by the material vendor. Many ML-PWB fabricators report excellent results with double-treated copper. Others report problems with contamination and difficulty with rework. The alternative to using pretreated copper foil is to use a chemical treatment after etching.

**27.4.10.1 Copper Oxide, Reduced Copper Oxide, and Alternative Oxides.** There are many variations of the copper oxide treatment, but they all work by producing a rough surface topology that enhances adhesion. Depending on the exact nature of the treatment, the color varies from a light brown to a velvet-like black appearance. The differences among the treatments include the density of the oxide and the ratio of cupric oxide to cuprous oxide. To maximize bond strength, the fabricator should avoid oxide formulations that form tall vertical crystalline structures. Low-profile, self-limiting formulations generally provide the most consistent adhesion.

Most copper oxide treatments are applied by dipping the innerlayer in a hot (85 to 95°C) caustic bath for 1 min. or more. The oxide process generally uses a batch process that requires vertical racking of the layers. Rack design is critical to prevent problems with innerlayer damage and contamination. By minimizing the contact points, the fabricator can eliminate this concern. Racks require coating to insulate conductive contact to reduce electromotive effect in the oxide chemistry, which will polarize conductors and prevent oxide from being applied on random isolated traces. Since the oxide treatment is done after inspection and immediately prior to lamination, it can be the source of quality problems if improperly done.

The copper oxide surface treatment is very soluble in acids such as those found in the electroless copper line. If the epoxy-copper interface is fractured during drilling, the dark oxide will dissolve during the plating process, leaving a distinct pink ring around holes. This is not a serious reliability threat; it is generally considered a cosmetic problem but it often causes false concern. One way to minimize pink ring problems is to use an oxide reduction step after oxide formation. This step converts the copper-oxide crystals back to copper metal, preserving their topology. This reduced oxide surface has limited shelf life, so lamination should follow this process within 48 hours. Reduced peel strength should be expected as well.

Copper oxide treatments are not recommended for material systems that require processing temperatures significantly above 180°C. This includes Teflon and some forms of polyimide

film materials. Oxide reduction begins to occur spontaneously above this temperature, reducing adhesion. The use of a thin brown oxide, or a reduced oxide, will reduce the risk of this failure mode. A second problem with polyimide film is that it is soluble in strong caustics, so if the treatment time in the oxidization process is excessive, significant substrate damage can occur. When processing circuits with microfoils having high-density features, the fabricator should reduce processing times because the oxide chemistries can reduce copper thickness.

The LFAC laminates are compatible with current brown oxides and reduced copper oxide treatments. The oxide treatment should be kept thin, not exceeding  $0.4 \text{ mg/cm}^2$ . Alternative oxide treatments, such as peroxy-sulfuric oxide, are strongly preferred for some HF laminates. The cores for ML-PWBs that will be subject to LFA should be post-oxide baked to remove moisture—generally  $120^\circ\text{C}$  for at least 30 minutes for signal layers and 60 minutes for power/ground layers.

**27.4.10.2 Silane-Based Adhesion Promotion (Oxide Alternative Treatments).** The silane-based process is an alternative to the copper oxide process. Silane can be used to bond epoxy to other materials. One end of the silane molecule bonds to the epoxy. If the other end of the molecule is modified to bond to the secondary material, the silane can serve as a bridge, greatly enhancing adhesion. It is commonly used in this mode to enhance the adhesion of epoxy to glass. It can be also used to enhance the adhesion of epoxy to copper.

This silane process attaches a thin silane layer to the copper surface. In lamination, the active epoxy molecules bond to the silane. This causes it to be a binding layer holding the epoxy to the copper. The objective is to achieve a stable coupling between the silane and the copper. This can be done by pre-coating the copper with a metal such as tin that reacts with the silane. When properly applied, the silane treatment is very stable and is resistant to chemical attack and delamination. The silane process has the advantage that it can be conveyORIZED in an inline process system. The major weakness of the process is that silane layers can absorb water and fail in some environments. The proper choice of silane chemistry minimizes the risk.

## 27.4.11 Drilling

The point at which the drilling process occurs is determined by the ML-PWB sequence chosen.

**27.4.11.1 Standard Drilling of Innerlayers.** Standard buried via innerlayers are drilled and plated prior to lamination using the same procedures as a finished ML-PWB. Buried via innerlayers are typically thin, and it is easy to drill very small holes. Whereas an 8 mil. hole is difficult to drill and plate in a 62 mil. thick ML-PWB, it is relatively easy in a 5 or 10 mil. thick innerlayer. Some manufacturers report success with holes as small as 4 mil. However, very small bits are expensive and easy to break. Special handling is required to load the bits and the drill machine must be vibration-free with very low run-out. For most ML-PWB shops, 8 mil. is a practical lower limit for mechanically drilled buried and blind vias. At 8 mil. it is generally possible to drill thin layers in stacks up to 100 mil. thick, greatly increasing drill productivity. However, a 10 mil. bit is less costly than an 8 mil. bit, so cost-sensitive products should try to design around a 10 mil. bit lower limit for buried vias.

LFAC laminates with fillers can be tougher and more brittle than regular FR-4s requiring different drilling parameters. As an example, the standard FR-4 might be drilled at up to 450 surface feet minute (SFM) with a chip load up to 2.0 mil/rev. and a maximum hit count of 1,500 holes; the LFAC epoxy-fiberglass-comparable laminate might be drilled at up to 350 SFM with a chip load up to 1.5 mil/rev. and a maximum hit count of 1,000 holes. Consult your laminate manufacturer's guidelines or applications engineer.

The major challenge in buried via processing is handling. Care must be taken in mechanical operations such as deburring to avoid mechanical damage or distortion. Often a frame is used to stiffen the layer during plating. Blind vias may be fabricated like buried vias and mechanically drilled in a top (or bottom) sub-lamination section prior to full board lamination, or controlled-depth drilling may be used after lamination.

Controlled-depth drilling has the advantage that standard innerlayer processing is used, including foil stacking. Controlled-depth drilling has several limitations:

- Blind holes cannot be stack-drilled, severely limiting drill productivity.
- It is difficult to plate a blind hole whose depth exceeds its diameter; this necessitates limiting the maximum hole depth or increasing the drill diameter such that a maximum aspect ratio of 1:1 is preserved.
- Drill depth tolerances make it easy to under- or overdrill a blind hole, producing a quality or reliability risk.

All of these limitations are avoided when the blind vias are drilled through a two-sided board used for the outerlayer and next innerlayer in a stack-up. These holes are drilled prior to lamination just as a thin two-sided plated through board. In this case, the process sequence for a blind via layer is identical to the sequence for a buried via layer. Such layers can be stack-drilled.

There is no aspect ratio limitation and the need for controlled-depth drilling is completely eliminated. To be able to drill blind vias prior to lamination, a clad outer stack-up is required. One side of the outer component layer is patterned prior to lamination, while the other is patterned after lamination. This means that when the blind via is metallized, the unpatterned side is blanket-metallized. This is true for either pattern plate or panel plate. This outside layer is metallized again when the holes in the finished ML-PWB are metallized. The result can be very thick plating on the exterior of a blind via board. To minimize this problem, the fabricator should plate the blind via innerlayer with the minimum possible current density on the blanket-metallized side.

**27.4.11.2 Drilling Related to Laminated Subcores.** The drilling process for laminated subcores usually follows the rules for finished board drilling and is design-dependent. When designs follow this methodology, they typically push the limits of plating aspect ratio. Density constraint typically drives this requirement due to routing availability. In this case, additional density can be gained through the use of laser blind vias.

**27.4.11.3 Laser Drilling.** Laser-drilled blind vias can be placed on either or both sides of the ML-PWB, and they have inherently accurate depth control. Productivity of the laser is very high. When employing laser blind drilling, it is necessary to use thin insulating dielectrics to produce a thin stack height to the sublayer. Depending on the type of laser employed, it is sometimes necessary to image fiducial targets the next layer down for alignment. This is the case when employing an UV or Nd:YAG laser, which can penetrate copper. Other laser-drilling alignment targets are required when employing a carbon dioxide (CO<sub>2</sub>) laser, which will penetrate only the dielectric. Very high drill rates can be achieved on a scanning CO<sub>2</sub> laser. Here a mask pattern is etched in the copper to allow exposure of the laser beam to the dielectric. The laser removes the dielectric, stopping at the copper pad below. Multiple via stacks can be accomplished with this method by repeating the mask opening at different layer depths. Aspect ratio should always be kept in mind. Most success has been reported when the mask diameter is kept greater than 0.003 in. For best accuracy, a minimum of three etched targets is required and should be referenced to the CNC drill data.

## 27.5 LAMINATION PROCESS

---

The lamination process is an essential step in the fabrication of an ML-PWB. The process is also one of the longest cycle time operations. Therefore, when the process method calls for repeat cycles, or what is called sequential laminations, it can be a significant cost driver. (*Note:* Sequential lamination is often paired with distinct, separate drill and plate processes for the

subcore that further ratchets up pricing, as they are also time-intensive operations.) The lamination process involves two distinct yet linked operations: lay-up and laminating.

**27.5.1 Lay-Up and Materials**

Lay-up occurs in a clean and controlled room environment. The level of environmental control depends on the circuit feature technology being fabricated. The lay-up process for standard multilayer processing is relatively forgiving. However, working with material that is hygroscopic will require additional measures. The innerlayer details require a bake cycle (typically 120°C for 1 hour minimum) to remove moisture. A reduced bake cycle duration is indicated when certain oxide reduction chemistries are employed. Once layers are readied for lay-up, they should be processed as soon as possible. Should extended hold times become necessary, storage in a nitrogen-purged dry box is recommended.

The lay-up operation is often referred to as “building up a book.” The operation follows a guide, often referred to as a stack-up sheet. The guide sheet, which depicts the engineering design of the ML-PWB, is highly recommended to minimize error. The written and illustrated guide to the book build-up process is made a part of the job planning/traveler. Due to the complexity of some products, the operator follows this guide in a recipe-type manner to perform the systematic construction. The lay-up may consist of some four or more PWB material components or other subassemblies. The lay-up operation produces a large assembly when complete that consists of the tooling plates, consumable press materials, and the ML-PWB detail. Refer to Fig. 27.34 and 27.35 for illustrations of the following.

**FIGURE 27.34** Typical ML-PWB stack-up for hydraulic lamination.

FIGURE 27.35 Press stack-up using release sheets and a separator plate.

**27.5.1.1 Tooling Plates.** The outermost item in the stack is termed a caul plate or carrier plate. These are thick, oversized metal plates, generally made of  $\frac{3}{8}$  in. (9,525 mm/0.375 in.) thick steel. The 4130 alloy of steel is often chosen due to its precision machining capability for placement of the holing holes. Sometimes a hardened aluminum alloy is chosen, but is not highly recommended due to its high in-plane expansion. The purpose of the caul plate is to provide a stable base to transport the ML-PWB stack.

**27.5.1.2 Separator Plates.** The multilayer boards in the stack are isolated from each other by metal separator plates. The separator plates provide a mold surface for the laminated ML-PWB. It is extremely important that the separator plates be clean and free of debris. Both aluminum and steel separator plates are used. Separator plates should be cleaned regularly. The surface finish of the plates becomes very critical when laminating against microfoils that will be printed with fine lines. The most common type of steel is one of the 400 series stainless steels that have a very durable surface. Hardened 300 series steels are also occasionally used. Separator plate thicknesses range from as thin as 0.015 in. to as thick as 0.062 in. The thicker plates are more rigid and resist the tendency of internal layer features to print through from one ML-PWB to another. Thin aluminum plates have the advantage of being disposable, eliminating the need for cleaning.

**27.5.1.3 Consumable Press Materials.** The purposes of consumable press materials placed between the tooling plate and the top layer are to ensure that pressure is applied uniformly and to provide thermal lagging to correct heat rise. The purposes of consumable release sheets placed in contact with the foils are to protect the outerlayer foils, keeping them resin-free, and to allow easy separation of the foil from the separator sheet.

Among the materials used to provide for pressure and temperature uniformity are multiple sheets of Kraft paper, silicone rubber pads, expanded mat paper, and composite board. Kraft paper and composite board have the advantage of low cost, but produce an odor that some press operators find objectionable. Silicone rubber pads have the advantage of being reusable, but are limited by the number of heat cycles they can withstand. Silicone rubber pads, when close to the end of their life, go through reversion and leach out silicone oil, which can become a source of contamination. They also have limited success in controlling edge voids. Excellent results are reported with expanded paper mat products that are commercially available. Mat paper press pad materials come in different thicknesses. Some are even produced with a sandwich layer of release material cohered. Other products exist that flow and thus act as a stop for resin during lamination of subcores with predrilled blind vias.

Some form of release material is required against the outer foil surface of the ML-PWB. The release material acts as a nonstick slip sheet to keep the copper surface smooth, minimize the plate cleanup, and catch the resin run-out. Figure 27.35 shows the location of the release sheets. Alternatively, oversized foil can be used to catch the resin run-out. Or, a product called C-A-C (for copper-aluminum-copper) is used that consists of two sheets of foil laminated to either side of an aluminum carrier sheet. In this configuration, the one sheet of C-A-C is between two PCBs with the bottom copper foil over prepreg to form the top side of the bottom PCB, and the top copper foil under prepreg to form the bottom side of the top PCB. Figure 27.36 shows the location of the C-A-C sheet. The aluminum serves to replace the steel or aluminum separator plates and has the added benefits of reducing the stack height (which can sometimes translate to increased productivity by enabling another board to be made in the “book”) and providing excellent protection to the surface of the outerlayer foils. Since they are not handled as foils but as a more rigid composite, there is no propensity to wrinkle, and since they are covered for the entire book-building operation, they are not subject to scratching or having errant debris introduction cause a pit during lamination. Finally, when the book is broken down, the aluminum between the ML-PWBs is easily separated from the foils, leaving the distinct ML-PWBs. The aluminum itself is sometimes sent to the drilling department to be used as an entry material, and then sent to reclamation.

### 27.5.2 Lamination Stack-Up

The lamination process is key to building a reliable ML-PWB. In the lamination process, the board is subjected to heat and pressure that melts the B stage (bonding sheets) and causes it to flow. This encapsulates the circuits and fills any buried vias. The B stage then cures, establishing a good mechanical bond to the inner detail layers. A variety of materials can be utilized in standard laminating press cycles. (Refer to the preceding section 27.3.5 for a detailed discussion of the materials and prefill process.) A typical ML-PWB stack-up is shown in Fig. 27.35. For productivity reasons, multiple stack heights are repeated within each opening of the press. The various components and their placement within the book are shown.

A standard lamination uses tooling pins that go from caul plate to caul plate, passing through each board and all of the separator sheets. Since the CTE of stainless steel roughly matches the in-plane CTE of a multilayer board, a tight fit to the pin is possible. Aluminum has a much higher CTE, so if aluminum is used, a loose fit to the tooling pin is required. Some fabricators use as few as four tooling pins. Others may use 20 or more. In addition to easy stacking, the four-slotted pin system minimizes problems arising from material growth and shrinkage in an overdetermined tooling system. On the other hand, users of systems with a large number of pins believe that firmly anchoring the ML-PWB to stainless steel obtains better dimensional stability.

### 27.5.3 Lamination Breakdown

Once the ML-PWB is fully cured and then cooled to room temperature per the manufacturer’s guidelines, the book is taken apart; this process is called “breakdown.” This is usually a

FIGURE 27.36 Press stack-up using one sheet of C-A-C to replace two sheets of foil, two release sheets, and one separator plate.

manual process which consists of de-pinning the book, then separating the individual ML-PWBs from each other at the separator sheets or C-A-C boundary as shown in Fig. 27.36. The panels are sent to an automatic thickness checker to ensure compliance with requirements, then on to an edge-finishing machine. The edge finisher removes the rough cured prepreg from the edges (called “ooze out”) and any copper foil overhang by routing the four sides. The machine will then bevel and polish the edges so that they are not sharp and there are no protruding glass fibers or copper slivers. The finishing process might also include a bore to remove surface epoxy from around the tooling holes or slots.

## 27.5.4 Lamination Process Methods

**27.5.4.1 Standard Hydraulic Lamination.** A standard hydraulic press generally has a top or bottom ram and several floating platens that create multiple press openings. Typical presses have four to eight openings. The output of the press is based on the stack height in each opening. Low-layer-count designs can yield as many as 96 panels per press cycle based on a stack height of 12 by 8 openings. High-layer-count and thick laminated boards have the stack height reduced to ensure uniform heat rate from the outside to innermost stack. Steam, hot oil, or electrical resistance heaters may heat hydraulic-style presses. The steam and hot oil presses have the advantage of a fast heating rate, but the temperature of the heating fluid limits their maximum temperature. For steam, this is generally below the lamination temperature needed for high-temperature materials. If a steam press must be used, polyimide, PPO, and cyanate esters can be oven-baked to complete their cure. However, the thermal plastic adhesive layers used with Teflon are not compatible with a steam press.

**27.5.4.2 Vacuum-Assisted Hydraulic Lamination.** Many hydraulic presses use a vacuum to eliminate volatiles. Users of vacuum presses report a reduction of edge voiding and the ability

to laminate at a lower pressure. Almost all hydraulic presses sold since 1990 are equipped with a vacuum chamber. In a typical process, the ML-PWB caul plate is loaded onto a carrier sheet, where a spring-loaded rail holds it off the press platen and limits the heat transfer to the ML-PWB stack. Next, the vacuum chamber is closed and a vacuum is drawn and held. A typical vacuum cycle may be from 15 to 60 min., depending on the nature of the materials being laminated. This gives the vacuum time to pull air, moisture, and other volatiles out of the ML-PWB stack. At the completion of this prevacuum process, the press is closed, compressing the spring-loaded rails and establishing good thermal contact with the press platens.

**27.5.4.3 Autoclave.** The autoclave is a popular tool in the composites industry and has found limited use by board fabricators. The autoclave is a sealed cylindrical chamber that subjects the ML-PWB stack to a high-pressure heated gas. The ML-PWB stack is sealed in a vacuum bag, and the hydrostatic pressure from the gas produces the force necessary for lamination. In principle, the autoclave is an excellent machine for producing a void-free lamination. Since the pressure is hydrostatic, it eliminates the problem of low pressure at the panel edge. This results in void-free panel borders and increases the usable area on a panel. In practice, an autoclave requires a long prevacuum cycle and has a slow heatup rate. It is also vulnerable to problems with vacuum bag failures. The result is that autoclaves have not found broad acceptance.

### 27.5.5 Critical Lamination Variables

Since hydraulic presses are by far the most common type of press, the following discussion focuses on that process. The quality of the ML-PWB lamination is affected by both the pressure ramp and the temperature ramp. There are almost as many unique cycles (also known as press recipes) as there are fabricators. However, in general the lamination cycle can be divided into four regions: B-stage melt; B-stage flow; B-stage cure; and cooldown. Figure 27.37 shows a typical lamination cycle with these critical variables identified.

FIGURE 27.37 Typical temperature and pressure cycle for hydraulic lamination.

**27.5.5.1 B-Stage Melt.** During the melt cycle, the B stage is solid and the pressure should be low. Excessive pressure during this portion of the cycle will damage the glass cloth and exacerbate problems with image print-through, also known as “telegraphing.” Most press cycles start with a low pressure known as a kiss pressure. The kiss pressure is high enough to ensure good thermal contact without damaging the ML-PWB. The length of the kiss cycle depends on the heating rates and the cure kinetics of the B stage. In a hot press cycle, the ML-PWB stack is loaded into a preheated press, and the heating rate may approach 20°C/min. In a hot press, the kiss cycle should be limited to a few minutes, or the B stage will begin to cure before flow is complete. At the opposite extreme, the press is loaded cold, and the heating rate is determined by the heating ramp of the press. For a slow heating rate of 5°C/min., a kiss cycle of 15 min. is appropriate.

Some LFAC laminates, however, have process guidelines where a best practice is to have a kiss cycle with 0 psi with a slow heat rise on the order of not more than 15°C/min. until approximately a 90°C internal temperature. This step is held for 30–40 min. to drive out moisture before pressure is applied and the flow stage initiates.

**27.5.5.2 B-Stage Flow.** The second portion of the cycle begins when the B stage liquefies, but before its viscosity begins to rise due to curing. In this region of the cycle, the liquid B-stage flows and encapsulates the circuitry. As long as the internal features are surrounded by liquid B stage, print-through is not an issue. The key to good results is to select a pressure that will allow reproducible resin flow but that does not squeeze out all available resin before the progressing cure stops the flow. Once again, the exact pressure depends on the temperature cycle, the B-stage viscosity characteristics, and the B-stage cure kinetics. For a fast-curing B stage and a fast temperature ramp, pressures as high as 600 psi may be needed to ensure complete circuit encapsulation. On the other hand, with a slow ramp and a long B-stage working time, high pressures give excessive flow and best results are obtained at 200 psi. Improper melt staging can result in “footballing,” a term used to describe a panel whose center is significantly thicker than its outside. To determine proper melt, it is recommended to install a thermocouple in the center stack edge to chart the actual heat rise through the flow.

A typical dicy-cured FR-4 multifunctional epoxy has a flow range, called the critical range, at the temperatures between 70–130°C. HF and LFAC laminates have a critical range typically between 80–140°C. During the critical range, the heat rate input and pressure are critical variables. A typical dicy-cured FR-4 press recipe would be 4–8°C/min. rise at 200 to 300 psi pressure. HF and LFAC laminates’ recipes are usually lower in the rate of rise and higher in pressure, such as 2–4°C/min. and 225–360 psi pressure.

Table 27.5 shows some press recipes from the processing guidelines posted on the laminators’ web pages. This table is intended to illustrate that moving from standard FR-4 to other HF or LFAC laminates will require the development of new press recipes.

**TABLE 27.5** Press Recipes for Selected Materials

	T <sub>g</sub> °C (DSC)	Rise (°C/min.)	Critical range (°C)	Pressure (psi)	Cure time (min.)/Temp (°C)
Standard Dicy-Cured FR-4	175	4–7	70–130	200–300	60/182
Non-Dicy FR-4 Laminate	155	2–4	80–140	275–360	90/193
HF Laminate	160	2.3–5.6	>100	380	90/200
LFAC Laminate A	185	4.4–7	70–130	200–300	75/185
LFAC Laminate B	190	2.3–5.6	83–139	225–325	75/193
LFAC Laminate C	210	2–4	80–140	275–360	90/193
LFAC Laminate D	190	2–4.5	80–135	200–300	120/200
LFAC Laminate E	215	2	80–135	300	120/200
Polyimide	250	2–4	80–138	225–275	200/218

**27.5.5.3 B-Stage Cure.** In the third part of the cycle, flow has stopped and the resin cure is proceeding. The temperature is held at its maximum value to minimize the time to obtain full cure. For a typical epoxy system, this usually is approximately 180°C for 60 min. LFAC laminates, however, tend to require longer and hotter cure stages: up to 200°C internal temperature for 120 min., and longer for thicker boards. Some materials, such as polyimide, require a significantly higher cure temperature for even longer.

**27.5.5.4 Cooldown.** The last part of the cycle is the cooldown cycle. In Fig. 27.37, it is suggested that the pressure is released after some cooling has occurred, but before the stack reaches room temperature. In many modern systems, the ML-PWB stack is transferred hot to a low-pressure cooling press. It is important to control the cooling rate to minimize warpage. It is generally desirable to cool through  $T_g$  in a stress-free state without any significant thermal gradients present. A properly designed cooling press will meet these conditions.

## 27.5.6 Critical B-Stage Variables

During a typical lamination cycle, the B stage undergoes several significant changes. At the beginning of the cycle, the B stage is a solid with a low cross-link density and a melt temperature near 90°C. As the temperature rises, the B stage melts and becomes a high-viscosity liquid. As the press heats further, the viscosity of the liquid drops. When the B stage begins to cure, viscosity reaches a minimum and begins to rise. The region around the viscosity minimum is called the region of maximum flow. The wider this region and the lower the minimum viscosity, the more flow occurs. Figure 27.38 shows a schematic viscosity curve for a typical cure cycle. In a high-flow B stage, the initial cure level is low. This results in a longer time at temperature before the B-stage viscosity rises due to cure. This is often described as a long gel time. In terms of Fig. 27.38, a high-flow B stage has a low minimum viscosity and a wide region of maximum flow. A low-flow B stage has a higher degree of initial cure and may include flow restrictors to increase the minimum viscosity. High-flow B stages are useful

FIGURE 27.38 Typical viscosity curve for B stage during lamination.

in presses with a high-heating rate where the resin may begin to cure before flow is complete. They give excessive flow if used in a press cycle with a very slow heating rate.

### 27.5.7 Single-Ply versus Multiple-Ply B-Stage Fill Considerations

For dielectric separations that could be filled by either one “thick” ply of B stage—for instance, style 7628—or by two thinner plies of B stage—for instance, style 1080—the fabricator and engineer need to determine which approach is best on a product-by-product basis.

Building ML-PCBs with single-ply B-stage fill is common and has the following advantages:

- Costs are reduced significantly when sheets of prepreg are eliminated—the main advantage.
- Z-axis expansion is easier to control since there is usually less resin with a thicker style.
- Overall thickness has less variation since there are fewer elements in the construction.
- Single-ply fill allows for overall thickness reduction when two plies of any style are replaced by one ply of the same style or thinner.

Building with two plies is usually either preferred or required with the following conditions:

- The separation to be filled is between two planes generating a large voltage bias and additional dielectric separation is required to minimize the potential of dielectric withstanding breakdown.
- The separation to be filled is between two layers having thicker (70 micron) copper foil. In this case, there is frequently insufficient resin in a single ply to encapsulate the features and prevent air bubbles in etched-out regions.

## 27.6 LAMINATION PROCESS CONTROL AND TROUBLESHOOTING

A good lamination cycle produces a flat ML-PWB that is free of moisture or voids and has a fully cured substrate. All layers must be well registered. The ML-PWB must be free of warp and the thickness must be within the specification. Any controlled impedance layers must have the correct pressed dielectric separations above and below the signal layer. Each of these requirements puts special demands on the lamination process. To assist in setting control measures, the following process indicators (see Table 27.6) should be monitored with a Statistical Process Control (SPC) method.

**TABLE 27.6** Process Variables and Limits

Process indicator	Specification limit	Gauge type or method
Thickness control	Per engineering drawing or internal spec requirement	Over-arm micrometer
Heat rise %/min. through melt	Per resin system requirement	Chart recorder
Cure	$T_g$ of resin system	TMA
Post cure	Dwell time/temp per resin system requirement	Chart recorder
Registration	Per engineering drawing or internal spec requirement	Appropriate coupons or x-ray inspection equipment
Dielectric separation	Per engineering drawing	Cross section

## 27.6.1 Common Problems

**27.6.1.1 Voids and Moisture.** Substrate voids are a serious problem in many lamination processes. One source of these problems is moisture. B stage is very hygroscopic and must be stored in a low-humidity environment to preclude serious void problems. C-stage components also have a tendency to absorb water, and many fabricators use a bake to dry layers prior to lamination. However, for a fast innerlayer line with a good dryer in the oxide line, an innerlayer bake may not be necessary. Voids generally cluster in the low-pressure regions near the edge of the panel. This effect is minimized by the use of vacuum lamination. Increasing the lamination pressure can also reduce voids. However, the use of high pressures with high-flow materials can result in excessive flow, which leads to other substrate flaws such as resin starvation.

**27.6.1.2 Blisters and Delamination.** Blisters and delamination are also caused by trapped volatiles that collect in the low-pressure regions associated with print-through. If a board has wide copper borders on every layer, blisters are often found in the lower-pressure circuit areas adjacent to the borders. The best solution to this problem is to avoid areas of heavy copper adjacent to low-density circuit areas by replacing solid borders with a dot or stripe pattern. Also, the glass style and resin content of the prepreg should be matched to the weight of copper thickness adjacent to the prepreg.

**27.6.1.3 Under Cure.** The requirement of full cure is relatively easy to obtain if proper cure time and temperature are used. One measure of the cure level is  $T_g$ . Periodic measurements of  $T_g$  are an excellent check for material and process consistency. Another way to check cure is to make two consecutive measurements of  $T_g$ : If the epoxy is only partially cured, it will continue to cure during the first measurement and a higher  $T_g$  will be detected on the second measurement. A shift in  $T_g$  of more than  $5^\circ\text{C}$  is an indication of under cure. This measurement is typically performed on a TMA. Figure 27.39 shows an example of an epoxy TMA run; note that the second TMA run has a delta of  $3^\circ\text{C}$ .

**27.5.1.4 Post-Lamination Bake.** Many fabricators bake the ML-PWB at  $150^\circ\text{C}$  for up to four hours after lamination. One purpose of this baking is to ensure a complete cure.

FIGURE 27.39 TMA analysis of epoxy with woven fiberglass. (Courtesy of Microtek Labs, Anaheim, CA.)

Although a bake will advance the cure, it is unnecessary if a proper lamination cycle is used (although polyimide is an exception; check the recommended processing guidelines). As discussed earlier, this can be verified by  $T_g$  measurements. However, additional baking beyond full cure degrades the material and reduces  $T_g$ .

A second purpose of the bake is to reduce the warpage often seen in the outer boards of a stack-up. Although a post-lamination bake will flatten the boards, it is more of a repair than a root solution. If the panels are cured in the press in a way that ensures they go through  $T_g$  in an isothermal stress-free state, warpage should not occur. The warpage seen in the outer boards of a stack is generally a symptom of nonuniform cooling.

The third purpose of a bake is to relax internal stress and improve registration. Internal stresses are a symptom of an overdetermined tooling system. If such a system is used, a bake may improve registration. If the more popular four-pin system is used, a bake is unnecessary. Always confirm the need of a post cure with the recommendations of the material supplier.

### 27.6.2 Special Consideration for Non-Dicy, Non-Bromine, and LFAC Laminates

For decades, the majority of PCBs have been built with epoxy resins, dicy-cured, and with bromine flame retardant. The industry has developed around this paradigm. Drills and drilling, chemistry, lamination, and circuit card assembly are all well understood with reference to standard FR-4. Although there are fabricators with processes developed to manufacture PCBs using laminates other than standard FR-4, this knowledgebase is not distributed industrywide. Especially problematic is the intersection of requirements for HF and/or LFAC with high thermal resistance and improved electrical characteristics, such as low attenuation in the material.

Many laminators recognized that the heart of their product line would need to be revamped from the entry-level cost-conscious material all the way through to the highest performance material. This was a large undertaking, requiring many different trials to find the right ingredients, in the right combinations, with the desired properties, especially the response to the new elevated reflow temperatures. As is frequently the case, there are trade-offs. For instance, reducing CTE by increasing filler is desirable to a point; the increase of filler increases the dielectric constant and loss tangent properties of the material, making it less suitable for high-speed digital products. The line-up from the bottom to the top of the performance ladder, with and without bromine, capable of withstanding high-temperature reflow, isn't complete in all cases.

These materials have not been in manufacturing and the field as long as the time-honed standard epoxy systems. Also, as they have been used, they have also been continuously refined—which has caused processes to be continuously redefined. The major processes that need to be developed and optimized specifically for nonstandard FR-4 laminates are inner-layer adhesion promotion, lamination, drilling, and hole wall preparation. The fabricator must work closely with its laminate and chemistry providers to develop the specific process parameters that will work with their lamination equipment and chemistries.

The major problems have been delamination (both adhesive and cohesive failures), voiding, and hole wall pull-away. Some of these quality problems can be discovered prior to shipment by cross-section analyses, but some do not manifest until after high-temperature reflow. Since laminators test laminates rather than finished PCBs, and fabrication and design features both effect the final product, a cautious fabricator will test completed PCB parts for quality and reliability, simulating the intended assembly soldering profile. Accordingly, submitting an actual final ML-PWB to multiple cycles through a production reflow oven with a lead-free soldering profile can be advantageous. After reflow exposure, the parts are visually inspected for blisters, then cross sections are taken at both high and low hole density areas to look for internal delamination or laminate cracks, voiding, and hole wall pull-away. Figures 27.40 through 27.43 show examples of these defects.

**FIGURE 27.40** Blistering.

**FIGURE 27.41** Laminate crack.

**FIGURE 27.42** Void.

**FIGURE 27.43** Hole wall pull-away.

## 27.7 LAMINATION OVERVIEW

---

The standard hydraulic vacuum press cycle is flexible and has very high output. Through the use of multiple openings and stacked lamination, high productivity is obtainable. Hydraulic lamination works effectively with all modern materials systems.

ML-PWB fabricators use many different laminate systems, press cycles, and B-stage formulations. The most significant differences among press cycles are in the heating rate, cure temperature, and cure time. At one extreme, the ML-PWBs are loaded into a cold press. This gives a very slow heating rate, and a B stage with a low flow is needed to avoid excessive flow. This material works well at low pressures, minimizing print-through and innerlayer distortion. A vacuum cycle is recommended to minimize voiding in low-pressure regions near the panel edge. The other extreme is a hot-loaded press with a very fast temperature rise. This cycle needs a high-flow material a high pressure to complete the resin flow cycle before the onset of cure. Although a vacuum is less important with this cycle, it will minimize edge voids. Some materials require a moisture drive-off prior to heat using a 0 psi low temperature hold.

Some fabricators use bakes both before and after lamination. The bake before lamination is designed to ensure moisture removal from cores after the application of the adhesion promotion chemistry; follow the recommendations of the laminate manufacturer carefully. The bake is also needed if innerlayers are stored at high humidity prior to lamination, or as a standard process for hygroscopic materials such as some of the LFAC laminates or polyimide. Other fabricators use a bake after lamination to complete the cure, reduce warp, and relieve stress. Although a post bake will achieve these goals, it is usually unnecessary in a controlled lamination process. In the case of high-temperature materials such as polyimide, cyanate ester, and PPO, a post bake is a useful way to achieve a full cure in a process where the maximum press temperature is limited.

## 27.8 ML-PWB SUMMARY

---

The printed wiring board manufacturing industry continues to be challenged with a high rate of change. Today's global market and added environmental considerations are driving investments and innovation in research and development of integrated components (e.g., laminates), subcomponents (e.g., resins and glass), and process consumables (e.g., oxide chemistry) for PCB fabrication. The manufacturing flow has only a backbone of standard methodologies, with many optional branches and staging through some process sequences multiple times (as in sequential lamination and HDI technologies). PCB fabrication has become much more complex, interactions between processes and components are compounded, and the user requirements are more formidable. A successful implementation of any of the high-density constructs or high-temperature-resistant materials should always be complemented with sound statistical process verification and testing appropriate to the end use.

# CHAPTER 28

---

# PREPARING BOARDS FOR PLATING

---

**Jim Watkowski**

*MacDermid Incorporated, Waterbury, Connecticut*

---

## 28.1 INTRODUCTION

---

A major part of manufacturing printed circuit boards involves *wet process* chemistry. The plating aspects of wet chemistry include deposition of metals by electroless (metallization) and electrolytic (electroplating) processes. Topics to be described here are multilayer processing, electroless copper, direct metallization, electroplating of copper and resist metals, nickel and gold for edge connector (tips), tin-lead fusing, and alternative coatings. Specific operating conditions, process controls, and problems in each area will be reviewed in detail. The effects of plating on image transfer, strip, and etching are also described in this chapter. See the printed circuit plating flowchart in Fig. 28.1.

Two driving forces have had major influence on plating practices: the precise technical requirements of electronic products and the demands of environmental and safety compliance.

Recent technical achievements in plating are evident in the capability to produce complex, high-resolution multilayer boards. These boards show narrow lines (3 to 6 mil), small holes (12 mil), surface-mount density, and high reliability. In plating, such precision has been made possible by the use of improved automatic, computer-controlled plating machines, instrumental techniques for analysis of organic and metallic additives, and the availability of controllable chemical processes. Military-specification-quality boards are produced when the procedures given here are closely followed.

---

## 28.2 PROCESS DECISIONS

---

Process and equipment needs dictate the physical aspect of the facility and the character of the process, and vice versa. Some important items to consider are the following.

### 28.2.1 Facility Considerations

1. *Multilayer and two-sided product mix:* Lamination presses and innerlayer processes are required.
2. *Circuit complexity:* Dry film, photoimageable resist, and a clean room are needed.

3. *Level of reliability (application of product):* Extra controls and testing are required.
4. *Volume output:* Equipment sizing and building space are needed.
5. *Use of automatic versus manual line:* Productivity, consistency, and a workforce are required.
6. *Wastewater treatment system:* Water and process control capability must be available.<sup>1</sup>
7. *Environmental and personnel safety; compliance with laws.*
8. *Costs.*

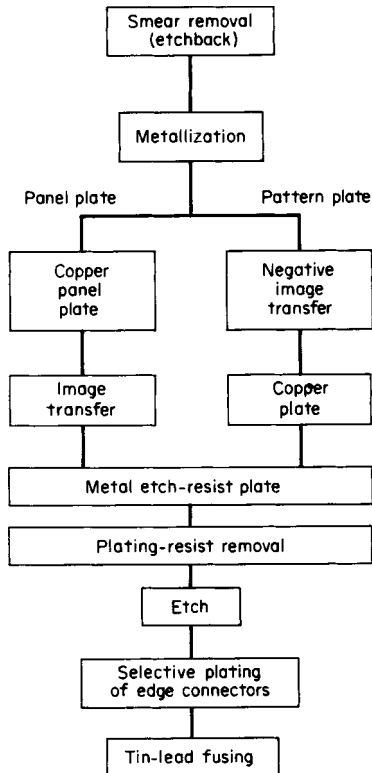

FIGURE 28.1 Printed wiring board plating flowchart.

minated the electroless copper step and converted to DMT. Developed in the 1980s, DMT methods produce a conductive surface on the nonconductive through-hole surfaces (see Chap. 30 for a detailed discussion). Electroless copper baths contain formaldehyde and chelators. In addition, the baths use large volumes of water, are difficult to control, and make it difficult to treat waste. DMT claims include increased productivity, ease of control, and lower hazardous material involvement. Because of these characteristics, DMT will probably gain significant acceptance as a primary hole metallization method.<sup>2</sup> Acceptance of the DMT process has been delayed by the high cost of conveyORIZED equipment and chemicals.

DMT primary technologies include:

- a. Palladium
- b. Carbon-graphite
- c. Conductive polymer
- d. Other methods (see Chap. 30 for further information)

### 28.2.2 Process Considerations

1. *Material:* The principal printed board material discussed will be NEMA grade FR-4 or G-10, that is, epoxyfiber-glass clad with 1.2-, 1-, or 2-oz. copper. Other materials will be briefly mentioned because they can significantly alter plating and related processes.
2. *Standard:* Plated through hole (PTH) is the current standard of the industry. The following purposes, objectives, and requirements apply to both multilayer and two-sided boards:
  - a. *Purposes:* Circuit density; double-sided circuitry
  - b. *Objectives:* Side-to-side electrical connection; ease of component attachment; high reliability
  - c. *Requirements:* Complete coverage; even thickness; a hole-to-surface ratio of 0.001 in. minimum; no cracks; no voids, nodules, or inclusions; no pull-away; no epoxy smear; minor resin recession; optimum metallurgical structure; M/L compatibility
3. *Image transfer:* Photoimageable, dry film, or screening of plating resists will depend on board complexity, volume, and labor skills.
4. *Electroless copper:* The type chosen will depend on the method of image transfer as well as on the need for panel plating. These processes are readily automated. The largest percentage (estimates are as high as 95 percent) of printed circuit board manufacturers worldwide rely on the electroless copper method for hole metallization.
5. *Direct metallization technology (DMT):* Some of the remaining printed circuit board manufacturers have eliminated the electroless copper step and converted to DMT. Developed in the 1980s, DMT methods produce a conductive surface on the nonconductive through-hole surfaces (see Chap. 30 for a detailed discussion). Electroless copper baths contain formaldehyde and chelators. In addition, the baths use large volumes of water, are difficult to control, and make it difficult to treat waste. DMT claims include increased productivity, ease of control, and lower hazardous material involvement. Because of these characteristics, DMT will probably gain significant acceptance as a primary hole metallization method.<sup>2</sup> Acceptance of the DMT process has been delayed by the high cost of conveyORIZED equipment and chemicals.

6. *Electroplating processes.* Deposit requirements are as follows:

- Electrical conductivity
- Mechanical strength
- Ductility and elongation
- Solderability
- Tarnish and corrosion resistance
- Etchant resistance
- Compliance with military specification (mil-spec)

Details emphasizing operation, control, and mil-spec plating practices are given elsewhere. Metal-plated structures of completed PC boards are as follows:

- Copper/tin-lead alloy
- Copper/tin (SMOBC)
- Copper/tin-nickel (nickel)/tin-lead
- Copper/nickel/tin-nickel/silver

7. *Strip, etching, and tin-lead fusing:* Methods required by these steps are determined by the preceding processes and by the need for automation.

## 28.3 PROCESS FEEDWATER

---

### 28.3.1 Water Supply

Printed circuit board fabrication and electronic processes require process feedwater with low levels of impurities. Large volumes of raw water must be readily available, either of suitable quality or treatable at reasonable cost. New facilities must consider water at an early stage of the site selection and planning process. Zero discharge, although a desirable goal, is very costly and difficult to achieve.

### 28.3.2 Water Quality

Highly variable mineral content causes board rejects and equipment downtime, as well as reduced bath life, burdened waste treatment, and difficult rinse water recovery. Many water supplies contain high levels of dissolved ionic minerals and possible colloids that can cause rejects in board production. Some of these impurities are calcium, silica, magnesium, iron, and chloride. Typical problems caused by these impurities are copper oxidation, residues in the PTH, copper-copper peelers, staining, roughness, and ionic contamination. Problems in the equipment include water- and spray-line clogging, corrosion, and breakdown. The best plating practices suggest good-quality water for high yields. The need for water low in total dissolved solids (TDS), calcium hardness, and conductivity is well known. Good water eliminates the concern that the water supply may be responsible for rejects. Although water quality is not well defined for plating and PC board manufacturing, for general usage, some guidelines can be assigned as follows. Where high-purity water is required, see Sec. 28.3.3.

Typical quantities are:

TDS:	4 to 20 ppm
Conductivity:	8 to 30 $\mu\text{S}/\text{cm}$
Specific resistance:	0.12 to 0.03 M
Carbonate hardness ( $\text{CaCO}_3$ ):	3 to 15 ppm

Somewhat higher values are acceptable for less-critical processes and rinses.

### 28.3.3 Water Purification

Two processes widely used for water purification are reverse osmosis and ion exchange. In the reverse osmosis technique, raw water under pressure (1.4 to 4.2 MPa or 200 to 600 lb./in.<sup>2</sup>) is forced through a semipermeable membrane. The membrane has a controlled porosity that allows rejection of dissolved salts, organic matter, and particulate matter, while allowing the passage of water through the membrane. When pure water and a saline solution are on opposite sides of a semipermeable membrane, pure water diffuses through the membrane and dilutes the saline water on the other side (osmosis). The effective driving force of the saline solution is called its *osmotic pressure*. In contrast, if pressure is exerted on the saline solution, the osmosis process can be reversed. This is called the *reverse osmosis* (RO) process, and involves applying pressure to the saline solution in excess of its osmotic pressure. Fresh water permeates the membrane and collects on the opposite side, where it is drawn off as product.

Reverse osmosis removes 90 to 98 percent of dissolved minerals and 100 percent of organics with molecular weights over 200, as shown in Table 28.1.

A small quantity of dissolved substances also facilitates deionized (DI) water production, wastewater treatment, and process rinse water recovery, since it makes recycling less costly and more feasible. An RO system will result in lower costs for DI water preparation and for process water recycling. The setup for recycling requires additional equipment for polymer addition, filtration, and activated carbon treatment.

**TABLE 28.1** Purified Water Supply Values  
*Typical in/out RO values*

TDS, ppm	SiO <sub>2</sub> , ppm	Conductivity, $\mu$ S	Hardness-CaCO <sub>3</sub> , ppm
170/4	30/1	130/8	24/1
240/7	45/2	200/14	35/2
300/10	60/2	250/20	45/3

DI water purification is used when high-purity water is required, for example, in bath makeups, rinses before plating steps, and final rinses necessary to maintain low ionic residues on board surfaces. Mil-spec PC boards must pass the MIL-P-28809 test for ionic cleanliness. This is done by final rinsing in DI water. Deionized water is made by the ion exchange technique. This involves passing water containing dissolved ionics through a bed of solid organic resins. These convert the ionic water contents to H<sup>+</sup> and OH<sup>-</sup>. Deionized water systems are more practical when using feedwater low in ionic and organic content.

Other requirements are as follows:

pH: 6.5–8.0

Total organic carbon: 2.0 ppm

Turbidity: 1.0 NTU

Chloride: 2.0 ppm

## 28.4 MULTILAYER PTH PREPROCESSING

Two-sided printed circuit boards are usually processed by first drilling and deburring, then metallizing the through hole. Multilayers require treatment prior to any metallization process. Resin smear must be removed from the innerlayers, and texturing of the epoxy surface enhances hole wall adhesion. The preprocessing can be categorized as either smear removal or etchback.

Fresh solution replenishment is crucial for effectively attacking smear and achieving uniformity through the holes. Circulation pumps and 90°C work piece movement are required to prevent temperature stratification of the heated baths as well as assist in forcing fresh chemistry through the holes. Higher-aspect-ratio holes may require vibration to dislodge air bubbles from the holes and enhance uniformity of attack (see Chap. 29).

**28.4.1 Smear Removal**

High-speed drilling machines are used to drill holes into the PWB dielectric. During the drilling operation, sufficient heat is generated, causing the epoxy to melt. As the drill is withdrawn, the melted epoxy smears across and coats the innerlayer copper surfaces, causing a condition commonly known as *drill smear* (see Figs. 28.2 to 28.6).

**28.4.2 Etchback**

Etchback refers to the aggressive removal of the epoxy and glass that results in the protrusion of the innerlayer copper. When two surfaces of the innerlayer are exposed, it is referred to as two-point connection, and when three surfaces of the innerlayer are exposed, it is referred to as three-point connection. Physically, the innerlayer copper will protrude from the drilled-hole three-point connection for copper bonding, which is required on some mil-spec boards (see Fig. 28.7).

**28.4.3 Smear Removal/Etchback Methods**

The four methods commonly used utilize hole wall epoxy or dielectric oxidation, neutralization-reduction, and glass etching. Three of the four common methods employ technology that

**FIGURE 28.2** PTH vertical and horizontal cross sections illustrating optimum innerlayer connection and smear removal.

**FIGURE 28.3** Drill smear example (note smear on the innerlayer).

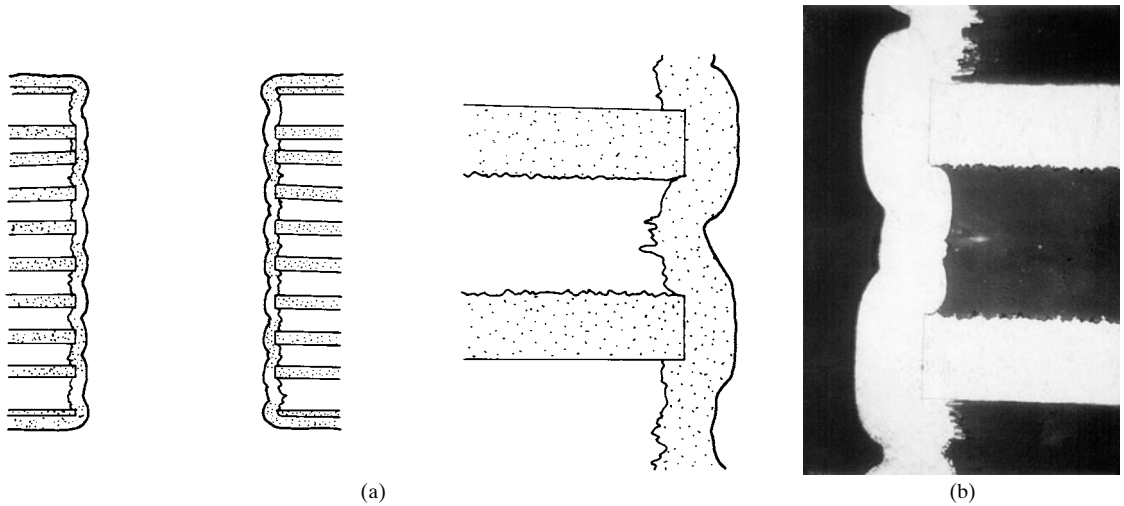

**FIGURE 28.4** Scanning electron microscope (SEM) view of topography after desmear.

oxidizes resin or dielectric, followed by a neutralization-reduction step. The fourth method—sulfuric acid—solvates or dissolves resin or dielectric. All methods remove smear, but the resultant surface of the epoxy affects hole wall pull-away and adhesion.

**28.4.3.1 Sulfuric Acid.** This process has been used extensively for many years because of its ease of operation and reliability of results. Disadvantages are lack of control, inability to attack certain resin systems, and the inability to create significant topography resulting in poor hole wall adhesion. Operator safety is crucial since concentrated sulfuric must be used.

**28.4.3.2 Chromic Acid.** Chromic acid is a more controllable method that imparts some topography for enhanced hole wall adhesion and has a longer bath life. However, insufficient neutralization of the  $\text{Cr}^{+6}$  leads to copper voids. The line cost of using chromic acid is appealing. However, the Restriction of Hazardous Substances (RoHS) and waste treatment regulations of chromic acid add substantial costs that make this method a nonviable option. Etchback is possible by double processing.

**28.4.3.3 Permanganate.** Permanganate is the most widely used and preferred method in the industry. This easy-to-control process incorporates electrolytic regeneration, which adds to consistency and increases bath lives. Permanganate effectively removes drill smear from most materials and imparts some texturing to the resin that increases hole wall adhesion.<sup>3</sup> (See Fig. 28.2) for an example of hole wall topography after etchback. Problems result from lack of chemical control or inconsistent cure of the multilayer package.

Permanganate is also used as a second step in conjunction with the other methods to enhance hole quality.<sup>4</sup>

**28.4.3.4 Plasma.** Plasma utilizes electrical current to generate a plasma from fluorocarbon gases. This plasma oxidizes the epoxy resin and removes drill smear. Longer cycles or double cycling will generate etchback. Plasma works on any material and is especially effective when processing polytetrafluoroethylene (PTFE)-based dielectrics. This process has few

steps and does not require the use of large quantities of chemicals. Disadvantages of plasma are nonuniformity of the treatment across the batch and across the panel. The texture generated on the epoxy is minimal, and an ash is commonly left behind that leads to poorer hole wall adhesion. A secondary cleanup, such as permanganate, is commonly used after plasma to remove the ash. The cost of the equipment and its maintenance is high. Controls must be provided to prevent air pollution.

#### 28.4.4 Process Outline: Smear Removal and Etchback

The four common methods for smear removal and etchback are given in Table 28.2. Combinations of these methods are also in use because of added reliability they offer to both process and product.

Polyimide and polyimide-acrylic systems are processed in chromic acid or plasma. Teflon™, and R T Duroid™ materials are treated (before operations) in sodium-naphthalene mixtures to yield void-free, high-bond-strength copper in the PTH. The introduction of lead-free material and halogen-free material has challenged the desmear processes. The new materials are more chemically resistant, and thus more aggressive desmear cycles are required to remove any smear. These more chemically resistant resin systems are more difficult to texture. Alternative solvents, higher temperatures, and cycle optimization may be required to process these newer materials effectively.

## 28.5 ELECTROLESS COPPER<sup>5,6,7,8,9,10</sup>

### 28.5.1 Purpose

This second series of chemical steps (after smear removal) is used to make panel side-to-side and innerlayer connections by metallizing with copper. The process steps required include

racking, cleaning, copper microetching, and hole and surface catalyzing with palladium and electroless copper. Typical steps are as follows:

1. *Cleaner-conditioner.* Alkaline cleaning is used to remove soils and condition holes.
2. *Microetch.* This slow acid etching is used for removal of copper surface pretreatments, oxidation, and presentation of uniformly active copper. Persulfates and sulfuric acid hydrogen peroxide solutions are commonly used.
3. *Sulfuric acid.* This acid removes persulfate residues.
4. *Predip.* This process maintains the balance of the next step.
5. *Catalyst (activator).* Neutral or acid solutions of palladium and tin are used to deposit a thin layer of the catalytic metal on the nonconductive surfaces. Some palladium is unintentionally absorbed onto the foil surface and innerlayers.
6. *Accelerator (postactivator).* This process removes colloidal tin on board surfaces and holes or change the charge of the palladium tin colloid.
7. *Electroless copper.* This alkaline-chelated copper-reducing solution deposits thin copper in the holes (20 to 100  $\mu\text{in}$ ) and surfaces.
8. *Antitarnish.* This neutral solution prevents oxidation of active copper surfaces by forming a copper conversion coating.

### 28.5.2 Mechanism

Equations 28.1 and 28.2 illustrate the process.

However, Eq. 28.2 is an old two-step catalyzation sequence that is no longer in use in the industry.

### 28.5.3 Electroless Copper Processes

New materials and increased reliability criteria have precipitated a newer generation of electroless copper baths. Lead-free assembly forces the PWB to undergo higher thermal excursions, thus increasing the stress on the plated through holes. Proprietary additives (which are not listed in Table 28.3) affect the integrity of the electroless copper-plated deposit. Selection from the several types available depends on the type of image transfer desired. Operation and control of three bath types and the function of constituents are given in Tables 28.3 and 28.4.

The problems encountered with this system are as follows:

1. *Uncoppered holes or voids.* Voided holes appear as black or dark color in the holes. Corrective actions: Ensure that the process is functioning correctly by verifying the times, temperatures and concentrations of all preceding process tanks, including the desmear process as specified. The electroless copper bath components should be verified as well as the dwell time. Low loading factor, low temperature, or high air agitation lead to low bath activity and poor plating characteristics. Voids may also be caused by an overaggressive electrolytic preclean line.
2. *Hole wall pull-away.* This is the separation of the copper pulling away from the dielectric. The defect is usually detected during the cross-sectioning inspection. If the hole wall pull-away is severe, large blisters can be seen in the hole with the naked eye. Hole wall

**TABLE 28.3** Electroless Copper Processes  
*Operation and control*

	Low deposition	Medium deposition	Heavy deposition
Copper	3 g/l	2.8 g/l	2.0 g/l
HCHO	6–9 g/l	3.5 g/l	3.3 g/l
NaOH	6–9 g/l	10–11 g/l	8 g/l
Temperature	65°–85°F	115° ± 5°F	115° ± 5°F

Deposition time	20 min	20 min	20–30 min
Thickness	20 μin	40–60 μin	60–100 μin

pull-away can be caused by insufficient texturing of the epoxy dielectric during the desmear process, overconditioning, overcatalyzation, or insufficient acceleration. The electroless copper bath may become overactive and plate a stressed deposit. Ensuring that the process is functioning as specified with regard to dwell times, chemical concentrations, and bath temperature are the corrective actions.

- 3. Bath decomposition.** This is rapid plating out of the copper. Common causes are bath imbalance, overloading, overheating, lack of use, tank wall initiation, and contamination.
- 4. Electroless copper-to-copper-clad bond failure.** Copper-to-copper adhesion failures can occur on the surface or on the innerlayers. Surface copper adhesion failures arise from unclean copper. Dry-film and/or developing residues, overconditioning, insufficient rinsing, insufficient microetch, and overcatalyzation are common causes. Innerlayer copper-to-copper adhesion failures, commonly referred as ICD, may be due to all the items mentioned. Further causes may be related to the electroless copper bath itself. A stressed deposit due to high bath activity or decomposition has poor integrity and may fail under reliability testing. Specific additives in supplier formulations may contribute to ICDs as well.
- 5. Staining.** Copper oxidation is due to moisture or contamination on the copper surface. Corrective action involves dipping boards in antitarnish or hard rinsing in DI water.

**TABLE 28.4** Electroless Copper  
*Function of constituents*

	Constituent	Function
Copper salt	CuSO <sub>4</sub> · 5 H <sub>2</sub> O	Supplies copper
Reducing agent	HCHO	Cu <sup>+2</sup> + 2e → Cu <sup>0</sup>
Complexer	EDTA, tartrates, Rochelle salts	Holds Cu <sup>+2</sup> in solution at high pH; controls rate
pH controller	NaOH	Controls pH (rate) 11.5–12.5 optimum for HCHO reduction
Additives	NaCN, metals, S, N, CN organics	Stabilize, brighten, speed rate, strengthen

### 28.5.4 Process Outline

This outline presents the typical steps in an electroless copper process:

1. Rack
2. Clean and condition
3. Water rinse
4. Surface copper etch (microtech)
5. Water rinse
6. Sulfuric acid (optional)
7. Water rinse
8. Preactivator
9. Activator (catalyst)
10. Water rinse
11. Postactivator (accelerator)
12. Water rinse
13. Electroless copper
14. Rinse
15. Sulfuric acid or antitarnish
16. Rinse
17. Scrub (optional)
18. Rinse
19. Copper flash plate (optional)
20. Dry
21. Release to image transfer

## 29.1 INTRODUCTION

---

The reality in printed circuit evolution is that the parts are continuing to increase in degree of difficulty and complexity. A new genre of high-density interconnect (HDI) boards is making the transition from leading edge to mainstream. These boards are characterized by a combination of a series of complex features that include buried and blind vias, high-aspect ratio plating, small-hole plating (as low as 6 mil diameter holes), and fine lines and spaces side by side with ground plane areas of different sizes.

The industry, however, still has a need to produce simpler products, such as single-sided and double-sided boards; these are still in demand. Multilayer boards with lower layer counts (four to eight) fall in this category also.

This chapter focuses on all aspects of electroplating. Emphasis will be on acid copper plating as the main process for providing interconnection. Tin, tin-lead, nickel, and gold electroplating will also be covered as important plated materials. In addition, the latest innovations in technology for meeting the challenges of product complexity, such as pulse plating and horizontal conveyORIZED plating, are discussed in detail.

---

## 29.2 ELECTROPLATING BASICS

---

Electroplating is the production of adherent deposition of conductive surfaces by the passage of electric current through a conductive metal-bearing solution. The rate of plating depends on current and time and is expressed by Faraday's law (Eq. 29.1):

$$W = (ItA)/(nF) \quad (29.1)$$

where  $W$  = metal, g  
 $I$  = current, A  
 $t$  = time, s  
 $A$  = atomic weight of the metal  
 $n$  = number of electrons involved in metal ion reduction  
 $F$  = Faraday's constant (96,485°C/mol)

Plating occurs at the cathode (the negative electrode). Accordingly, deposition thickness is determined by time and by the current that is impressed on the surface being plated; for example, by using the preceding formula, one can readily calculate the weight of the deposited metal. The weight can then be converted to a specific thickness over a known area. The rate of deposition of the most common metals is shown in Table 29.1.

**TABLE 29.1** Rate of Deposition of the Most Common Metals Grams

Metal	Grams deposited per amp.hr	Amp. hr. per sq.ft. to deposit 0.001 in	Amp. hr. per sq.dm. to deposit 25 $\mu\text{m}$
Copper	1.186	17.8	1.88
Tin	2.214	7.8	0.82
Lead	3.865	6.9	0.73
Nickel	1.095	19.0	2.00
Gold	7.348	6.2	0.65

To plate 1.0 mil of copper, one would need 17.8 amperes per square foot (ASF) or 1.88 amperes per decimeter (ASD) for 1 hour (60 min.). Properties of electrodeposits are shown in Table 29.2.

**TABLE 29.2** Properties of Electrodeposits

Property	Cu	Ni	Au	SnPb	Sn
Melting point, °F	1980	2600	1945	361	450
Hardness, VHN	150	250	150	12	4
CTE X $10^{-6}/^{\circ}\text{F}$	9.4	8.0	8.2	12.2	12.8
Conductivity, %IACS	101	25	73	11.9	15.6
Electrical resistivity, $\mu\Omega/\text{cm}$	1.67	6.8	2.19	14.5	11.1
Thermal conductivity, CGS°C	0.97	0.25	0.71	0.12	0.15

## 29.3 HIGH-ASPECT RATIO HOLE AND MICROVIA PLATING

The combination of increasing layer counts (panel thickness) and decreasing hole size results in higher aspect ratios.

### 29.3.1 Aspect Ratios

Aspect ratios are calculated by dividing panel thickness by the hole size. (See Fig. 29.1 for example of a high-aspect hole with a 15:1 ratio.) Standard direct current (DC) plating bath formulations are not sufficient to plate these geometries. Modifying the concentrations of the electrolyte components is required. In general, lowering the copper concentration and increasing the acid concentration improves through-hole distribution, as indicated in Table 29.3. Proprietary additives play a role maximizing through-hole distribution as well.

Solution agitation is an integral part of successfully plating high-aspect ratio through holes. Ninety degree work rod agitation with a  $1/2$  in. stroke is the most common method of replenishing

**FIGURE 29.1** A 15:1 aspect ratio plated with MacDermid PPR 100.

solution in the holes. Other adjuncts such as high-flow circulation pumps or e-ductor systems aid in solution turnover and replenishment of solution inside the holes. A decrease in corresponding current density is required to achieve improved throwing power and to prevent copper burning. For aspect ratios above 10:1, pulse plating yields the best microdistribution.

**TABLE 29.3** Plating Solutions for Different Aspect Ratios

	High aspect ratio formulation	Medium aspect ratio formulation	Low aspect ratio formulation
Aspect ratio	>8:1	3:1 – 8:1	<3:1
Copper sulfate ( $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ )	45 g/l	60 g/l	75 g/l
Free sulfuric acid	300 g/l	260 g/l	225 g/l
$^{66}\text{Fe}$ electronic grade			
Chloride ion ( $\text{Cl}^-$ )	50 ppm	50 ppm	50 ppm

### 29.3.2 Blind Microvia Plating

Smaller holes and increasing circuit density are drivers that push technology for “via-in-pad” and “stacked microvia” designs that help minimize PWB real estate. It has been established that via-in-pad designs, where the via is not filled, can lead to voids in the BGA solder joint that can negatively affect reliability.

Stacked vias, or the sequential build-up process, is a technology where vias (either blind or through hole) are metallized, plated to required thickness, then circuitized. Another layer of dielectric is applied and the process repeated.

Electrodeposited copper (see Fig. 29.2) has become an effective method of filling microvias, replacing the alternative via filling techniques, especially as the conductor patterns become finer and the pitch density of the component packaging increases. Resin or conductive pastes have been used for via filling, but the reliability problems associated with these materials include subsequent polishing, entrapped air within the blind micro via, and void formation during the reflow process.

All major suppliers to the PWB industry have developed processes for filling blind microvias.

**FIGURE 29.2** Example of a plated filled blind microvia.

The electrolyte compositions for via filling baths typically run with high concentrations of copper (up to 50 g/l as metal) and lower concentrations of acid (approximately 100 g/l). These concentrations are juxtaposed to high-aspect ratio plating. Thus, these process usually are utilized in a panel plating mode for filling vias only. This type of process usually requires some type of planarization step post-filling to decrease the amount of copper plated on the surface.

Proprietary additives are key for consistent filling and for filling vias of various diameters and depths. Typical systems will contain carriers, brighteners, and levelers.

Further developed processes are capable of plating through holes and filling vias simultaneously, although aspect ratio capability is limited and should be tested before committing to production.

## 29.4 HORIZONTAL ELECTROPLATING

---

As the degree of part complexity continues to increase, new innovative plating solutions are being put into place. Periodic pulse reverse (PPR) is an example of this, and another major development is the advent of horizontal acid copper plating.

Here, the panel is transported in a horizontal mode through the plating equipment with stationary anodes below and above it. The panel continues to plate as it travels, interfacing with one anode after the other. The panel comes off the end of the line plated.

The plating thickness is a function of time and current density. The dwell time is determined by the length of the plating module and the conveyor speed. Plating at 20 ASF for 60 min. in horizontal equipment running at 1 m/min. would require a plating module that is 60 m long. This length is not practical. Current density has to be increased to 40, 60, 80, and higher ASF. At 80 ASF, the equipment length needs to be only 15 m.

New chemical additives were formulated to accommodate high-current-density plating.

However, this current density offered new challenges: at high-current densities, most plating solutions lose throwing power. Another problem that was encountered early on was that the anode film particulates would land on the top side of the panel and eventually create nodulation. This did not occur on the bottom side.

Two major developments helped make horizontal processing popular:

- Pulse plating, coupled with solution impingement, resolved the throwing power problem of plating at high current densities.
- Nodulation was resolved by taking the copper dissolution out of the module and replacing the standard anode with an inert or insoluble anode. Copper dissolution or oxidation was achieved by different means, such as the use of rectification, the use of ozone, or the dissolution of copper oxide.

### 29.4.1 Advantages of Horizontal Processing

The most dramatic advantage of horizontal plating is the uniformity from panel to panel. All panels go through the equipment in an identical fashion. They all see the entire bank of anodes, and they are in a single plating solution. All panels coming off a horizontal line are alike. If for some reason one edge of the panel has higher plating, then all panels will have the same edge equally high. In vertical plating, different panels are plated in different parts of the cell, in different positions in the rack, and even in different tanks or baths. Although vertically plated panels may all be within specifications, there will always be inherent variability that the shop has to contend with in downstream processing beyond the plating line.

Horizontal plating machines can be easily automated. Loaders and unloaders are usually integrated in the system. Automation of chemical analysis and dosing is incorporated with minimum cost increase. The equipment is easily linked to pre- and post-processes. Horizontal processing lends itself well to continuous production flow and reduced cycle time.

**Horizontal DC**

Via Diameter	90 $\mu\text{m}$
Via Depth	72 $\mu\text{m}$
Surface Thickness	19 $\mu\text{m}$
Base Thickness	4 $\mu\text{m}$
Throwing Power	25%
Current Density	7 ASD

**FIGURE 29.3** Horizontal plated through hole(PTH)/DC-plated resin-coated copper.**Horizontal Pulse**

Via Diameter	90 $\mu\text{m}$
Via Depth	72 $\mu\text{m}$
Surface Thickness	17 $\mu\text{m}$
Base Thickness	15 $\mu\text{m}$
Throwing Power	88%
Current Density	7 ASD

**FIGURE 29.4** Horizontal PTH/pulse-plated resin-coated copper.

Anode uniformity is a major advantage in horizontal plating. The size and geometry of an insoluble inert anode do not change. Anode variability and maintenance are eliminated. The latter is a very labor-intensive and hazardous activity associated with vertical plating.

Horizontal equipment is completely enclosed. This minimizes the operator and shop personnel's exposure to acid and chemical fumes and creates a better and safer working environment.

Horizontal plating gives superior surface thickness distribution. Variation of less than 10 percent across a panel-plated surface is normal. This is due to the anode's close proximity to the cathode; usually, the anode-to-cathode spacing is between 8 and 10 mm, or 0.3 and 0.4 in.

In addition, surface-to-hole thickness variation is minimized. Excellent throwing power (80 to 100 percent) is achievable in blind vias (aspect ratios greater than 1:1 [i.e., with depth exceeding hole diameter]) and in through holes (with aspect ratios of 10:1). This is the result of solution dynamics coupled with periodic pulse reverse rectification. This feature makes horizontal pulse plating an enabling technology for HDI applications. Figures 29.3 and 29.4 show the difference in throwing power of DC and PPR plating in a 1:1 via hole. Figure 29.5 shows an example of horizontal PPR plating of a via with an aspect ratio greater than 1, that is, the depth is greater than the diameter of the via.

**Copper Gleam PPR-H**

Via Diameter	120 $\mu\text{m}$
Via Depth	160 $\mu\text{m}$
Surface Thickness	17 $\mu\text{m}$
Base Thickness	17 $\mu\text{m}$
Throwing Power	100%
Current Density	8 ASD

**FIGURE 29.5** Horizontal PTH/pulse-plated microvia.

Horizontal equipment is capable of handling thin material (as thin as 10 mil). In the vertical mode, thin parts are a challenge to rack and to transport. Core plating requires the use of a metal frame to add rigidity to the part so that it can be handled and agitated in the bath during the plating cycle. This adds labor and creates handling defects.

#### 29.4.2 Drawbacks of Horizontal Processing

To date, most horizontal equipment is designed around panel plating. Pattern plating has its advantages and is being worked on by a series of equipment suppliers and could be available in the near future.

The equipment requires a substantial investment and is a major deviation from standard vertical processing. There is both a learning curve and engineering know-how that will be needed to run this equipment smoothly. The equipment is integrated, and either it all works or it all doesn't. It requires a large parts inventory and trained equipment maintenance crew to ensure uninterrupted operation.

### 29.5 COPPER ELECTROPLATING GENERAL ISSUES

---

Copper is the most commonly used metal in the structure of a printed circuit board. Copper has high electrical conductivity, strength, and ductility, and low cost. It is readily plated from simple solutions, and it is readily etched. MIL-STD-275 states that electrodeposited copper shall be in accordance with MIL-C-104550, and shall have a minimum purity of 99.5 percent as determined by ASTM-E-53, and shall be 0.001 in. (1.0 mil). Requirements for good soldering also indicate the need for 1.0 mil of copper and smooth holes. Copper plating is generally regarded as the slow step in manufacturing PC boards.

Copper electrolytic plating of printed circuit boards is a key process step in circuit manufacturing. After all, it forms the traces that carry the signal. The physical properties of the deposit, specifically tensile strength and elongation, have to be controlled so the product can withstand, without cracking, the temperature excursions of assembly and of use. A successful copper-plating system must be able to provide a copper deposit with tensile strength between 40 and 50 kpsi and percent elongation between 10 and 25 percent. As demands for speed and impedance control continue to increase, the thickness uniformity of the plated copper becomes extremely critical.

In the late 1990s, significant developments occurred in HDI boards, usually for portable products. HDI has traditionally focused on the high-end telecommunications, imaging, and computing markets. Handheld electronics products present unique challenges in terms of size, weight, functionality, and cost. This poses a series of challenges to the board manufacturer in every processing area. Acid copper electroplating is quickly becoming the limiting factor in most board shops today. High-aspect ratio plating, 3 mil lines and spaces, laser-drilled microvias, as well as buried vias, are forcing the industry to look for innovative approaches to the traditional methods of plating.

#### 29.5.1 Pattern Plating versus Panel Plating

Panel plating does not involve any patterning or imaging before plating and hence has a uniform surface geometry; with good plating practice, less than 10 percent thickness variation across the panel and from panel to panel is achievable. The challenge here is to get good throwing power so as not to overplate the surface to achieve 1.0 mil in the hole. An overplated surface limits the line width and spaces that can be circuitized by subsequent etching.

Pattern plating, as the name implies, occurs after pattern or image transfer and, accordingly, is the real challenge for the plating process. Here, the surface geometry is not uniform and may have extremes of isolated traces and pads, as well as ground plane areas. This gives rise to great disparity in primary current distribution, which can result in two to four times thicker copper in the isolated areas, compared with the ground plane areas.

### 29.5.2 Thickness Distribution

A formidable challenge facing acid copper plating of printed circuit boards is thickness distribution on the surface of the panel (whether pattern or panel plated) and thickness distribution in the barrel of the hole or the via, namely throwing power. If the throwing power is 100 percent, then plating 1 mil of copper in the hole would result in plating 1 mil on the surface.

At 50 percent throwing power, to achieve 1.0 mil in the hole would result in 2.0 mils on the surface, which would limit the etching capabilities in the panel plate and increase the thickness variation in pattern plate.

HDI compounds the plating challenges with microvias, small holes, and fine lines. Different approaches are being practiced to resolve the following four plating issues:

- Low-current-density plating
- Chemically mediated process
- Electrically mediated process
- Horizontal conveyORIZED systems

### 29.5.3 Additives in Acid Copper Plating

Additives used for bright acid copper plating are divided into three categories: (1) the carrier or suppressor, (2) the additive or brightener, and (3) a leveling component. Each component has a specific role in controlling the quality of the deposit. Polarization curves that show the ensuing current as the voltage is increased are used to study the effects of the various components on the plating system and how they affect the deposit.

Figure 29.6 shows a polarization curve where the current is plotted against the voltage. The data can be obtained from a potentiostat setup, shown in Fig. 29.7. Here, we have three electrodes in the plating solution. The first is a counter electrode and is usually made of copper or platinum; the second is the working electrode and is a rotating platinum disk; and the third is the reference electrode, like a double-junction calomel. Voltage is applied between the working and the reference electrodes, and the ensuing current is measured between the working and the counter electrodes. This is the principle upon which cyclic voltametric stripping (CVS)

FIGURE 29.6 Acid copper: cathodic polarization curve.

FIGURE 29.7 Acid copper: polarization study: three-electrode cell.

is based. CVS equipment is commonly used to assay the additives in the plating solution. A closer look at the polarization curve shows four distinct areas:

- **Low-current area** Here, there is a minimum increase in current as the voltage is increased.
- **Metal deposition area** This is an area where there is a significant increase of current with applied voltage.
- **Limiting-current-density area** This area is marked by a plateau, where there is no increase of current as the applied voltage continues to rise.
- **“Hydrogen evolution” part of the curve** This is the last area.

The area of most interest when plating, of course, is the area of metal deposition. The slope of this part of the polarization curve can be altered (suppressed or accelerated) by the addition of organic additives to the plating bath.

#### 29.5.4 Carrier/Suppressor

Carriers are large-molecular-weight poly-oxyalkyl-type compounds. Figure 29.8 shows the effect of the carrier on the polarization curve. The addition of a carrier alone did not alter the

FIGURE 29.8 Effect of chloride concentration in a copper stock solution with carrier.

polarization curve; however, when this is done in the presence of 10 ppm of the chloride ion, a marked suppression is observed initially but is not sustained as voltage continues to increase.

At 60 ppm of chloride, the suppression is sustained; the result is that it now takes more voltage to produce the desired current.

The suppression is a result of the effect of the carrier on the diffusion layer (also referred to as the Helmholtz double layer). The carrier is adsorbed to the surface of the cathode; this results in increasing the thickness of the diffusion layer. The result is better organization.

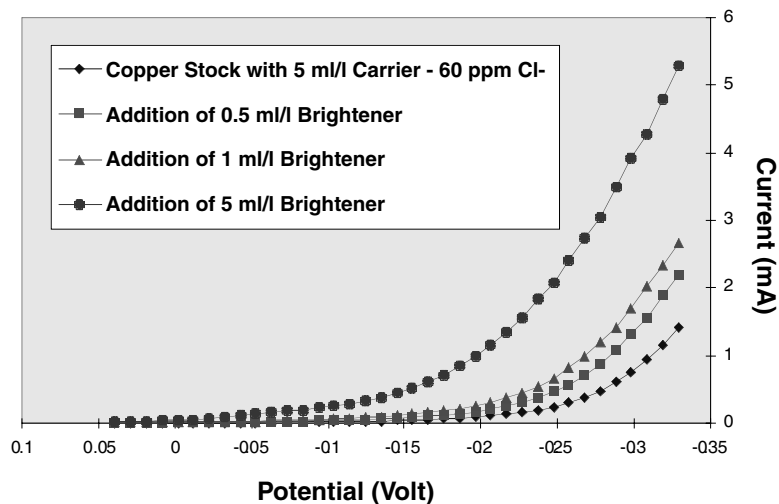

This gives rise to a deposit with a tighter grain structure (see Fig. 29.9). The carrier-modified diffusion layer also improves plating distribution and throwing power, without burning the deposit.

**FIGURE 29.9** The effect of a carrier on the grain structure of the deposited copper.

### 29.5.5 Additive/Brightener

These are typically small-molecular-weight disulfide compounds, with the general structure R-S-S-R. The R groups are organic functional groups and vary from one brightener system to the other. Figure 29.10 shows the effect of a brightener on a suppressed polarization curve.

**FIGURE 29.10** Effect of brightener concentration in a copper stock solution with carrier.

Basically, the brightener increases the current and reduces the suppression. The brightener plays a key role in determining the physical properties of the deposit. It is a grain refiner and, as such, it has a direct enhancing effect on the physical properties of the deposit, such as tensile strength and percent elongation.

### 29.5.6 Levelers

Levelers are used to offset localized high-current-density areas that result from high points or sharp edges in the plating surface. An example would be the dog-bone effect, occasionally seen at the knee of the hole.

Levelers are a class of compounds, typically aromatic, that adsorb preferentially at high points in the plating topography due to the increased mass transport possible at these sites.

The adsorption of the leveler at these sights creates localized suppression, allowing plating in the lower-current-density areas to catch up with high areas—hence, the leveling effect.

### 29.5.7 Low-Current-Density Plating

One way to achieve good distribution is the use of a low-current acid copper-plating system, which is designed specifically to produce a deposit with the required physical properties at reduced current density. Some shops are presently plating HDI boards at 6 to 8 ASF for a period of 4 to 6 hours. This will give excellent plating distribution, due to the increased suppression at these low plating voltages.

Low-current-density plating baths or electrolytes are characterized by lower copper concentration and increased sulfuric acid concentrations (refer to Table 29.4). The additive package of carrier and brightener is specifically formulated to operate at these low-current densities.

**TABLE 29.4** Operation and Control

Operating variable plating	Low-current density plating	Conventional CD* plating	High-speed plating
Copper	1–2 oz./gal	2–3 oz./gal	7–8 oz./gal
Copper sulfate	4–8 oz./gal	8–12 oz./gal	28–32 oz./gal
Sulfuric acid	25–32 oz./gal	22–28 oz./gal	5–8 oz./gal
Chloride	40–80 ppm	40–80 ppm	40–80 ppm
Additives	As required	As required	As required
Temperature	75–85°F	70–85°F	75–100°F
Cathode CD	5–15 ASF	20–40 ASF	40–150 ASF
<b>Anodes</b>			
Type	Bars or baskets		
Composition	Phosphorized 0.04–0.06% P		
Bags	Closed-napped polypropylene		
Hooks	Titanium or Monel		
Length	2 in. shorter than rack		
Anode CD	25–50% of cathode CD		
<b>Properties</b>			
Composition	99.8% (99.5% min., ASTM-E-53)		
Elongation	10–25% (6% min., ASTM-E-8 or ASTM-E-345)		
Tensile strength	40–50 kpsi (36 kpsi min, ASTM-E-8 or ASTM-E-345)		

\*CD, current density.

These types of products are in use throughout the industry and are tolerated as long as the numbers of HDI boards are a small percentage of the overall production. This practice, however, dramatically reduces the output of the plating line and increases the cost of the part. As the percentage of HDI boards increased, the need for a different answer became apparent.

### 29.5.8 Chemically Mediated Process

Here, the carrier is engineered for maximum chemical suppression, even at a high-current density.

This is demonstrated by the shift in the Tafel slope (see Fig. 29.11). These baths are capable of good throwing power and surface distribution while plating at relatively high-current densities. “Super-throw” baths are capable of 85 percent throw in a 5:1 aspect ratio board while plating at 30 and at 35 ASF. This kind of bath contrasts with the low-current bath and can improve productivity significantly, while still operating under conventional DC plating.

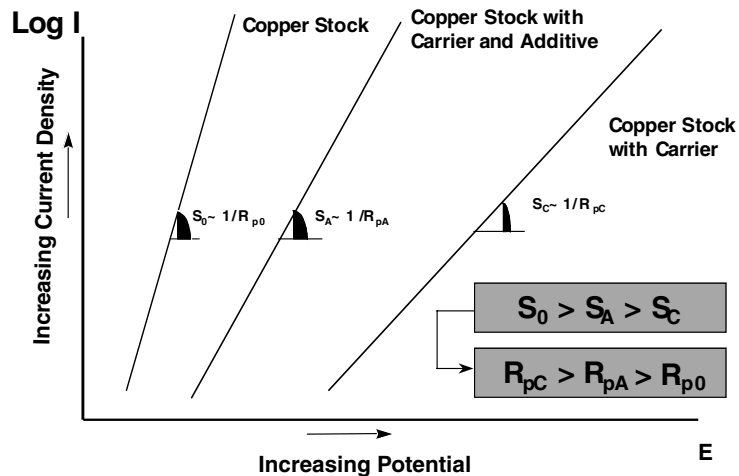

FIGURE 29.11 Tafel plots: direct current.

The system fits readily into existing in-house equipment and in-house know-how. Figure 29.12 shows an example of a blind via that is 5.0 mil in diameter and 3.0 mil deep, plated with this type of bath at 20 ASF for 90 min.

### 29.5.9 Pulse Plating (Electrically Mediated Process)

In this plating system, the bath is engineered to respond to a periodically pulsed reverse current. The required Tafel slope shift is accomplished through rectification (see Fig. 29.13). The rectifier produces a pulsed wave with a forward cathodic current that is perturbed by short anodic pulses. The forward current at 1X (e.g., 30 ASF) is maintained for 10 ms and the reversed at 3X (e.g., 90 ASF) for 0.5 ms, for example. The duty cycle may vary (e.g., 20 ms forward with 1.0 ms reverse).

FIGURE 29.12 Example of a blind via that is 5.0 mil in diameter and 3.0 mil deep, plated with chemically mediated bath.

FIGURE 29.13 The pulse periodic reverse effect.

There is also room to optimize the forward-to-reverse current ratio; 1:3 is only one example. The shape of the wave is very important here, also. A square wave with minimum rise time gives the best results (see Fig. 29.14).

FIGURE 29.14 Periodic pulse reverse rectifier output wave.

Chemical suppliers have designed specific additive packages that ensure maximum response to the periodic pulse reverse wave. During the reverse cycle, the additive is preferentially desorbed from the high-current-density areas. This results in less plating acceleration due to the additive, and more suppression due to the carrier. Since the low-current-density areas of the panel will also receive a lower reverse pulse, the acceleration is reduced to a lesser degree than in the high-current-density areas. This leads to greatly improved plating thickness distribution.

Often, the difference in plating thickness between isolated surface features and ground planes will be no greater than 0.5 mil. This effect is so powerful that throwing power greater than 100 percent is commonplace.

Figure 29.15 shows the plating in a hole that is 0.013 in. in diameter in a 0.100 in. thick board (8:1 aspect ratio). The board was plated using Copper Gleam PPR (a proprietary additive) under the following conditions: forward current density, 30 ASF forward-to-reverse (F:R) CD ratio, 1:2.67 duty cycle, 20:1 ms plating time, and 60 min.

The results are an average thickness on the surface of 1.1 mil and an average thickness in the hole of 1.4 mil. Reverse pulse plating gives dramatic improvements in copper thickness distribution beyond the capabilities of the chemically mediated process. It is clearly the wave of the future as the HDI boards become more and more complex. However, it involves capital investment for the pulse rectifier, which may be five to six times the cost of an equivalent DC rectifier. It also involves a learning curve for matching the new parameters (F:R ratio, duty cycle, ASF, and the shape of the wave) to meet the specifications of the part number being plated.

**FIGURE 29.15** One hundred mil board with 13 mil diameter hole plated with Copper Gleam PPR for 60 min. Surface-to-hole ratio is 0.75.

### 29.5.10 Key Factors for Uniform Plating

To have day-to-day control and achieve ductile, strong deposits, and uniform copper thickness, you need the following controls:

1. Maintain equipment following best practices, such as uniform air agitation or e-ductors (also known as “ser-ductors”) in the tank, equal anode/cathode distances, rectifier connection on both ends of tank, and low resistance between rack and cathode.
2. Maintain narrow-range control of all chemical constituents, including organic additives and contaminants.
3. Conduct batch carbon treatment as needed.
4. Control temperature at 70° to 85°F, or as specified by supplier.
5. Eliminate contaminants in the tank from preplate cleaners, microetchants, and impure chemicals.

The plating thickness distribution of your plating bath can be readily evaluated. Use noncopper-clad or bare epoxy laminate. First, plate 80 to 100  $\mu\text{in}$  of electroless copper, then rack the panels and plate at the specified ASF to plate 80 to 100  $\mu\text{in}$  of plated copper (usually 1/10 of the plating cycle time). Place the rack in a microetch solution until 60 to 80 percent of the copper is etched away. Remove and examine. The remaining copper is where the high-current density is. This is a useful tool in optimizing bath geometry, especially anode placement and panel placement on the rack. It is also useful in designing thieving and shielding for the best thickness distribution.

The plated-copper thickness distribution for a specific pattern can also be studied the same way. After plating the electroless copper on non-copper-clad bare laminate, image the pattern.

Plate for a limited time to get approximately 80 to 100  $\mu\text{in}$ , or 0.2 to 0.3  $\mu\text{m}$ . Strip the resist off the panel and place in microetch until 80 percent of all copper is removed. The remaining copper is where the high-current density is.

## 29.6 ACID COPPER SULFATE SOLUTIONS AND OPERATION

---

The preferred industrial process uses an acid copper sulfate solution containing copper sulfate, sulfuric acid, chloride ion, and organic additives.

### 29.6.1 Solution Makeup by Current Density

Using the proper additives, the resultant copper is fine-grained with tensile strengths of 50,000 lb/in.<sup>2</sup> (345 MPa), a minimum of 10 percent elongation, and a 1.2 surface-to-hole thickness ratio (see Table 29.4).

### 29.6.2 Operation and Control

- **Agitation** Air (vigorous) is agitated from an oil-free source at 70° to 80°F. Or e-ductors (airless high-volume, low-pressure circulation).
- **Filtration** The operation is continuous through a 3 to 10  $\mu$ m filter to control solution clarity and deposit smoothness.
- **Carbon treatment** New baths do not require activated carbon purification. Circulation through a carbon-packed filter tube is recommended to control organic contamination; for design and number, consult with supplier. The need for batch carbon treatment is indicated by corner cracking after reflow; dull, pink deposits; and haze, haloing, or comet trails around the PTH. Carbon-treat about every 1,500 (Ah) per gal. The following is the procedure for batch carbon treatment.
  1. Pump to the storage tank.
  2. Clean out the plating tank.
  3. Rinse and clean the tank.
  4. Leach with 10 percent H<sub>2</sub>SO<sub>4</sub>.
  5. Adjust the agitators.
  6. Clean the anodes.
  7. Heat the solution to 120°F.
  8. Add 1 or 2 qt of hydrogen peroxide (35 percent per 100 gal of solution). Dilute with 2 pt water, using low-stabilized peroxide.
  9. Air-agitate or mix for 1 hour.
  10. Maintain heat at 120° or 140°F.
  11. Add 3 or 5 lb. powdered or granular carbon per 100 gal. of solution. For a specific carbon source, seek recommendations from your supplier. Mix for 1 to 2 hour.
  12. Pump back to plating tank promptly or within 4 hours.
  13. Analyze and adjust.
  14. Dummy plate at 10 A/ft<sup>2</sup> for 6 hours. Panels should be matte and dull. Replenish with additive.
  15. Follow supplier instructions for electrolyzing and start-up.
- **Contaminants** In general, acid copper tolerates both organic and metallic contaminants. Organic residues may come from cleaners, resists, and certain sulfur compounds. Dye systems usually are more resistant than dye-free systems with respect to certain cleaner constituents.

Metals should be kept at these maximums: chromium, 25 ppm; tin, 300 ppm; antimony, 25 ppm. Nickel, lead, and arsenic may also cause roughness and other problems.

### 29.6.3 Process Controls

#### 29.6.3.1 Bath Composition

- Copper sulfate is the source of metal. Low copper will cause deposit burning; high copper will cause roughness and decreased hole-to-surface thickness ratios or throwing power.
- Sulfuric acid increases the solution conductivity, allowing the use of high currents at low voltages.
- However, an excess of sulfuric acid lowers the plating rate, whereas low acid reduces hole-to-surface ratio (throwing power).
- Chloride ion ( $\text{Cl}^-$ ) should be controlled at 60 to 80 ppm. Below 30 ppm, deposits will be dull, striated, coarse, and step-plated. Above 120 ppm, deposits will be coarse-grained and dull. The anodes will become polarized, causing plating to stop. Excess chloride is reduced by bath dilution or by dragout.
- Additive components analysis and control are critical for consistent product quality. The primary analytical tool is CVS, and the Hull cell continues to be a useful complementary tool. Excessive or insufficient additive will cause deposit burning and corner cracking. This condition can be judged by metallographic cross-sectioning and etching. Optimum-quality plated metal is fine-grained and equiaxed (nondirectional) and shows no laminations or columnar patterns.
- Concerning water quality, the use of DI water and contamination-free materials such as low chloride and iron will give added control and improved deposit quality.

**29.6.3.2 Temperature.** Optimum throwing power and surface-to-hole ratios are obtained by operating at room temperature (i.e., 70° to 80°F). Lower temperatures cause brittleness, burning, and thin plating. Higher temperatures cause haze in low-current-density areas and reduced throwing power. Cooling coils may be necessary during a hot summer or under heavy operation.

**29.6.3.3 Deposition Rate.** A thickness of 0.001 in. (1.0 mil) of copper deposits in 54 min. at 20 A/ft<sup>2</sup>, in 21 min. at 50 A/ft<sup>2</sup>.

**29.6.3.4 Hull Cell.** Operation at 2 A will show the presence of organic contamination, chloride concentration, and overall bath condition. However, an optimum Hull cell panel is only a small indication that the bath is in good operating condition, since test results are not always related to production problems. More reliable results are obtained by adjusting the bath before Hull cell testing. See Sec. 29.12.4 for procedures on Hull cell.

### 29.6.4 Cross-Sectioning Results—Troubleshooting

Sectioning with etching provides information on the plated copper that explains PTH quality in terms of processing factors. Besides showing the overall quality, cross-sectioning gives information on thickness and on possible problems, such as drilling, cracking, blowholes, and multilayer smear. Copper deposits with columnar or laminar patterns indicate inferior copper properties. Cross sections of optimum copper deposits are fine-grained and equiaxed (structureless) upon etching.

### 29.6.5 Inferior Copper Deposits

These may be caused by any of the following:

- Either low or excess additives
- Chloride out of range (i.e., too high or too low)
- Organic, metal, or sulfur (thiourea) contamination
- Excess DC rectifier ripple (greater than 10 percent)
- Low copper content with bath out of balance
- Roughness in drilling, voids in electroless steps, or other problems introduced in earlier processing

**29.6.5.1 Cracking and Ductility.** Resistance to cracking is tested by the following:

- **Solder reflow** Wave soldering and cross-sectioning are acceptable alternatives.
- **Elongation** Two mil copper foil should exceed 10 percent elongation. Acid copper elongation should range between 10 and 25 percent. Frequent testing gives more meaningful results.
- **Float solder test** This test includes prebaking and flux, using a 5 to 20 sec. float in a solder pot (60:40) at 550°F, followed by cross-sectioning for evaluation.
- **Copper foil bulge test** This test measures tensile strength by puncturing copper at high pressure.
- **DC ripple** High values of rectifier ripple (8 to 12 percent) may cause inferior copper deposits and poor distribution of thickness.

**29.6.5.2 Visual Appearance.** When plated, copper has a semibright appearance at all current densities. Unevenness, hazy or dull deposits, cracking, haloing around the PTH, and low-current-density areas indicate organic contamination. Carbon treatment is required if these conditions persist. Burned, dull deposits at high-current densities indicate low additive content, contamination, solution imbalance, or low bath temperatures. If dull, coarse deposits result at low-current densities, the chloride ion is not in balance.

When chloride is high or bath temperature too low, anodes may become heavily coated and polarized (the current drops). Decreased throwing power (surface-to-hole ratio), reduced bath conductivity, or poor-quality plating may also indicate contamination and are corrected as follows:

- Maintaining solution balance and chloride content at 60 to 80 ppm
- Circulating solution through filter continuously, passing through a carbon canister periodically, or by batch carbon treatment
- Analyzing organic additives by CVS or Hull cell
- Checking metal contaminations every three months
- Keeping the temperature between 70° and 85°F
- Checking anodes daily and replacing bags and filters (rinsed in hot water) every three to four weeks

**29.6.5.3 Problems.** Table 29.5 lists problems that appear after copper plating. Two groups are listed, with the first group readily correlated to the copper-plating process. Thin, rough copper plating in the PTH may also be exhibited by outgassing and blowholes during wave soldering. Figures 29.16 through 29.25 illustrate some of these effects.

**TABLE 29.5** Printed Wiring Board Copper-Plating Defects

Defect in copper process	Cause
Corner cracking	Excess additive, organic contamination in solution
Nodules	Particulate matter in solution; also drilling, deburring residues
Thickness distribution	See Sec. 29.5.2
Dullness	Off-balance solution, organic contamination
Uneven thickness in PTH	Organic sulfur (thiourea) contamination
Pitting	Additive malfunction, defective electroless, or preplate preparation
Columnar deposits	Low additive, rectifier malfunction
Step plating, whiskers	Excess or defective additive
Defect, overall manufacturing process	Cause
Voids etching	Malfunction of electroless copper steps, also preplate cleaner
Inner-layer smear	Drilling or malfunction in smear removal
Roughness	Drilling or drilling residues
Hole-wall pullaway	Malfunction of smear removal or electroless copper steps
Copper-copper peeling	Surface residues from electroless and/or image transfer
Soldering blowholes	Drilling roughness, voids, and thin plating

**FIGURE 29.16** PTH vertical cross section illustrating corner cracking.**FIGURE 29.17** PTH vertical cross section illustrating uneven, thick/thin copper plating.**FIGURE 29.18** PTH vertical cross section illustrating columnar copper deposit structure.**FIGURE 29.19** PTH vertical cross section illustrating copper voids.

## 29.7 SOLDER (TIN-LEAD) ELECTROPLATING

Solder plate (60 percent tin, 40 percent lead) is widely used as a finish plate on printed circuit boards. This process features excellent etch resistance to alkaline ammonia, good solderability after storage, and good corrosion resistance. Tin-lead plating is used for several types of boards, including tin-lead/copper, tin-lead/tin-nickel/copper, solder mask over bare copper (SMOBC), and surface-mount (SM). Fusing is required on all tin-lead-plated surfaces. Thickness minimums are not specified.

The preferred composition contains a minimum of 55 percent and a maximum of 70 percent tin. This alloy is near the tin-lead eutectic, which fuses at a temperature lower than the melting point of either tin or lead and, thus, makes it easy to reflow (fuse) and solder. (The composition of the eutectic is 60 percent tin, 37 percent lead, with a melting point of 361°F.)

Fusing processes include infrared (IR), hot oil, vapor phase, and hot-air leveling for SMOBC.

Plating solutions currently available include the high-concentration fluoboric acid-peptone system as well as low-fluoboric, nonpeptone, and a nonfluoboric organic aryl sulfonic acid process. These processes are formulated to have high throwing power and give uniform alloy composition.<sup>1</sup> The sulfonic acid process has the advantage of using ball-shaped tin-lead anodes. Table 29.6 gives details of operation and control of two high-throw tin-lead (solder) baths.

**TABLE 29.6** Tin-Lead Fluoborate: Operation and Control High

	HBF <sub>4</sub> /peptone	Low HBF <sub>4</sub> /proprietary
Operating conditions		
Lead	1.07–1.88 oz./gal	1.4–3.0 oz./gal
Stannous tin (SN <sup>+2</sup> )	1.61–2.68 oz./gal	3.0–4.5 oz./gal
Free fluoboric acid	47–67 oz./gal	15–25 oz./gal
Boric acid	Hang bag in tank	Same
Additive	Use as needed by Hull cell and Ah usage.	Use as needed by Hull cell and Ah usage.
Temperature	60–80°F	70–85°F
Cathode current density	15–18 A/ft <sup>2</sup>	10–30 A/ft <sup>2</sup>
Agitation	Solution circulation	Mechanical and solution circulation
Anodes		
Type	Bar	
Composition	60% tin-40% lead	
Purity	Federal Specification QQ-S-571 <sup>30</sup>	
Bags	Polypro	
Hooks	Monel	
Length	Rack length minus 2 in	
Current density	10–20 A/ft <sup>2</sup>	

### 29.7.1 Agitation

The solution is circulated by a filter pump, without allowing air to be introduced.

### 29.7.2 Filtration

A 3 to 10  $\mu\text{m}$  polypro filter is needed to control solution cloudiness and deposit roughness.

### 29.7.3 Carbon Treatment

The solution is batch-treated at room temperature every 4 to 12 months. If the solution is clear and colorless, additive is added based on Hull cell and analysis. Do not use Supercarb or hydrogen peroxide.

### 29.7.4 Contaminations

Several classifications of contaminations are possible:

- **Organic** Such contamination results from peptone or additive breakdown and plating resists. Periodic carbon treatment is needed.
- **Metallic** Copper is the most serious of these contaminations. It causes dark deposits at low-current densities (in the plated through hole) and may coat the anodes. The maximum levels of metallic contaminants allowable are copper, 15 ppm; iron, 400 ppm; and nickel, 100 ppm.
- **Nonmetallic** The maximum levels allowed are chloride, 2 ppm; and sulfate, 2 ppm.
- **Dummy** Copper is removed by dummy plating at 3 to 5 A/ft<sup>2</sup> several hours each week. (Dummy plating is plating at a low-current density, using corrugated metal sheets or scrap panels.) Other metals such as iron and nickel in high concentrations may contribute to dewetting and cannot be easily removed. Ensure that the copper is covered by a tin-lead coating before reducing the current density for dummifying.

### 29.7.5 Solution Controls

Stannous and lead fluoborates are the source of metal. Their concentrations and ratio must be strictly maintained, as they will directly affect alloy composition. Fluoboric acid increases the conductivity and throwing power of the solutions. Boric acid prevents the formation of lead fluoride. Additives promote smooth, fine-grained, tree-free deposits. Excess peptone (three to four times too much) may cause pinholes (volcanoes) in deposit when reflowed. Testing by Hull cell and periodic carbon treatments is indicated. The peptone add rate is about 1 to 2 qt per week for a 400 gal tank. Only DI water and contamination-free chemicals should be used—for example, <10 ppm iron-free and <100 ppm sulfate-free fluoboric acid. A clear solution is maintained by constant filtration.

### 29.7.6 Deposition Rate

A layer of 0.5 mil tin-lead is deposited in 15 to 17 min. at 15 to 17 A/ft<sup>2</sup>. The best practice is to plate at 10 to 25 A/ft<sup>2</sup> (2.3 copper current). Higher currents lead to coarse deposits and more tin in the alloy. Excessive current causes treeing and sludge formation.

### 29.7.7 Deposit Composition

The composition should be 60 percent tin to 40 percent lead. The composition should be confirmed with a deposit assay. Alloy composition is determined by the ratio of tin and lead in the solution; thus  $\text{Sn (oz./gal)} + [\text{total Sn} + \text{Pb (oz./gal)}] \times 100 = \% \text{Sn}$  (29.2).

### 29.7.8 Hull Cell

This test shows overall plating quality and the need for peptone, additives, or carbon treatment, as well as the presence of dissolved copper in the solution.

### 29.7.9 Visual Observation of Plating

When plated, solder has a uniform matte finish. The deposit should be smooth to the touch. A coarse, crystalline deposit usually indicates the need for additives or peptone or a current density that is too high. Peeling from copper is generally related to the procedure. The fluoboric acid predip should not be used as a holding tank (for more than 5 min.) prior to solder plating.

Acid strength and cleanliness are also important in this case. Load the tank with some residual current (5 to 10 percent). Rough, dark, thin, or smudged deposits may be due to organic contamination and may require carbon treatment. Dark deposits, especially in low-current-density areas and in the plated through hole, are due to copper contamination or to thin plating.

A Hull cell test will confirm deposit, and a dummy plate will remove copper.

### 29.7.10 Corrective Actions

- Keep the bath composition in balance.
- Use contaminant-free chemicals.
- Dummy-plate once a week at 3 to 5 A/ft<sup>2</sup>.
- Circulate the solution through a filter continuously.
- Maintain additives by Hull cell and by analysis.
- Analyze for copper, iron, and nickel at least once a month.
- Carbon-treat on schedule.

## 29.8 TIN ELECTROPLATING

---

Tin is used extensively for plating electronic components and PC boards due to its solderability, corrosion resistance, and metal etch-resist properties. The current MIL-STD-275 does not include tin plating, although earlier versions stated a required thickness of 0.0003 in. Specifications covering tin plating are MIL-T-10727 and MIL-P-38510, which say that tin must be fused on component leads.

### 29.8.1 Acid Tin Sulfate

This is the most widely used system. Among the many processes available, some produce bright deposits for appearance and corrosion resistance; others give matte deposits, which can be fused as well as soldered after long-term heating. Tin sulfate baths are somewhat difficult to control, especially after prolonged use.<sup>2,3</sup> Table 29.7 describes their operation and control.

#### 29.8.1.1 Process Controls

- **Agitation** A filter pump circulates the solution without allowing air to be introduced. Cathode rod agitation is also useful for a wider range of plating current densities.
- **Filtration** A 3 to 10  $\mu\text{m}$  polypropylene filter is needed to control excess cloudiness and sludge formation.
- **Temperature** The preferred temperature for deposit luster and visual appearance is 60 to 65°F. Use cooling coils. Baths can operate up to 85°F, but may result in smoky, hazy deposits.
- **Carbon treatment** Light carbon filtration at room temperature removes organic contaminations. New baths are also made up if problems continue with deposit quality, solderability, thickness control, and cost-effectiveness.

**TABLE 29.7** Acid Tin Sulfate: Operation and Control

Operating conditions:	
Tin	2 oz./gal
Sulfuric acid	10–12% by volume
Carrier, additives	Replenish by Ah usage and spectrophotometry
Temperature	60–65°F for bright, 65–85°F for matte
Cathode current density	10–30
Current efficiency	100%
Plating rates	0.3 mil @25 A/ft <sup>2</sup>
Anodes:	
Type	Bars
Composition	Pure tin
Bags	Polypropylene
Hooks	Monel or titanium
Length	Rack length minus 2 in
Current density	5–20 A/ft <sup>2</sup>

- **Contaminations** These include three groups of contaminants.
  - **Organics** These come from additives and breakdown of resist.
  - **Metallic** The effects of metallic contaminants on the plated deposits and the maximum levels allowable are as follows: copper darkness, 5 to 10 ppm; cadmium dullness, 50 ppm; zinc dullness, 50 ppm; nickel streaks, 50 ppm; iron dullness, 50 to 120 ppm; and chromium dullness, 5 ppm.
  - **Nonmetallic** The maximum level allowable is 75 ppm of chloride.
- **Anodes** To maintain tin content, remove anodes when the bath is idle.

#### 29.8.1.2 Solution Controls

- **Bath constituents** Stannous sulfate and sulfuric acid are maintained by analysis, additives by spectrophotometry, Ah usage, Hull cell, and the percentage of sulfuric acid additions.
- **Electronic-grade chemicals** Such chemicals must be used to control metallic contaminations of cadmium, zinc, iron, and so on.
- **Control additive** Low levels of additives must be maintained.
- **Hull cell** This test is useful for control of additive levels and plating quality. See Sec. 29.12.4 for the procedure.
- **Rinsing after plating** Adequate rinsing after plating is important to control white or black spots on tin surfaces.
- **Visual observation** When plated, tin has a uniform lustrous finish. The deposit should be smooth to the touch.

### 29.8.2 Problems with Tin Electroplating

- **Dull deposits** These are due to an out-of-balance condition of the main solution constituents, that is, low acid (<10 percent), high tin (>3 oz./gal), improper additive levels, contamination by metals or chlorides, or high temperatures (>65°F).

- **Peeling tin** Tin comes off due to low acid (<10 percent) or organic contamination.
- **Slivers** These are caused by overetching. A review of etching practice is indicated, as well as the use of 1.2 oz. copper foil.
- **Pitting** If substrate is not the cause, check precleaning, solution balance and contaminants, current efficiency, and current densities. High-current densities may cause pitting.
- **Strip and etching residues** Tin is attacked by strong alkaline solutions. To control residues and spotting, use mild room temperature stripping and alkaline-ammonia etching.
- **Poor solderability** This may be caused by excess additives or contaminations in the bath, poor rinsing, bath age, or excessive thicknesses (>0.3 mil).

## 29.9 NICKEL ELECTROPLATING

Nickel plating is used as an undercoat for precious and nonprecious metals. For surfaces such as contacts or tips that normally receive heavy wear, the uses of nickel under a gold or rhodium plate will greatly increase wear resistance. When used as a barrier layer, nickel is effective in preventing diffusion between copper and other plated metals. Nickel-gold combinations are frequently used as metal etch resists. Nickel alone will function as an etch resist against the ammoniacal etchants.<sup>4</sup> MIL-STD-275 calls for a low-stress nickel with a minimum thickness of 0.0002 in. Low-stress nickel deposits are generally obtained using nickel sulfamate baths in conjunction with wetting (antipit) agents. Additives are also used to reduce stress and to improve surface appearance.

### 29.9.1 Nickel Sulfamate

Nickel sulfamate is commonly used both as an undercoat for through-hole plating and on tips. Conditions given in Table 29.8 are applicable for through-hole and full-board plating.

**TABLE 29.8** Nickel Sulfamate: Operation and Control

Operating conditions:	
pH	3.5–4.5 (3.8)
Nickel	10–12 oz./gal
As nickel sulfamate	43 oz./gal
Nickel chloride	4 oz./gal
Boric acid	4–6 oz./gal
Additives	As required
Antipit	As required
Temperature	130 ± 5°F
Cathode current density	20–40 ASF
Anodes:	
Type	Bars or chunks
Composition	Nickel
Purity	Rolled depolarized, cast, or electrolytic; SD chips in titanium basket
Hooks, baskets	Titanium
Bags	Polypro, Dynel, or cotton
Length	Rack length minus 2 in.

### 29.9.1.1 Process Controls

- **pH** With normal operation, pH increases. To lower pH, use sulfamic acid (not sulfuric acid). A decrease in pH signals a problem; anodes should be checked.
- **Temperature** The preferred temperature is 125°F. Low temperature causes stress and high-current-density (CD) burning. Higher temperatures increase softness of nickel deposit.
- **Agitation** Solution circulation between panels is done by filter pump and/or cathode rod agitation.
- **Filtration** This is done continuously through 5 to 10  $\mu\text{m}$  polypro filter, which is changed weekly.
- **Deposition rate** For 0.5 mil, plate 25 to 30 min. at 25 A/ft<sup>2</sup>. For 0.2 to 0.3 mil, plate 15 min. at 25 A/ft<sup>2</sup>.
- **Contaminations** These include three groups of contaminants:
  - **Metals** The following are the maximum allowable metal content by atomic absorption: iron, 250 ppm; copper, 10 ppm; chromium, 20 ppm; aluminum, 60 ppm; lead, 3 ppm; zinc, 10 ppm; tin, 10 ppm; and calcium, 0 ppm. These metal contaminants lower the deposition rates and cause nonuniform plating. Cooper and lead cause dark, brittle deposits at low CD. Dummy-plate at 3 to 5 A/ft<sup>2</sup>. Iron, tin, lead, and calcium cause deposit roughness and stress.
  - **Organics** These cause pitting, brittleness, step plating, and lesser ductility.
  - **Sulfates** These cause solution breakdown and should not be added.
- **Carbon treatment** Circulate through a carbon canister for 4 hours (more than one canister may be required) or batch-treat to remove organics. The basic six steps to batch-carbon-treat are as follows:
  1. Heat to 140°F.
  2. Transfer to the treatment tank. Do not adjust pH.
  3. Add 3 to 5 lb. carbon per 100 gal of solution. Premix outdoors.
  4. Stir 4 hours at temperature.
  5. Let the solution settle 1 to 2 hour.
  6. Filter the solution back to cleaned tank.

**29.9.1.2 Common Problems.** Pitting, stress (cracking), and burned deposits are common problems:

- **Pitting** This is caused by low antipit, poor agitation or circulation, boric acid imbalance, or the presence of organics. In testing for antipit, the solution should hold bubble for 5 sec. in a 3 in. wire ring and for less than 5 sec. in a 5 in. ring. In the case of severe pitting, cool to room temperature, add 1 pt/200 gal hydrogen peroxide (35 percent), bubble air, and reheat to 140°F. Carbon-treat as described in Sec. 29.9.1.1. Adjust pH before restarting.
- **Stress** This refers to the cause of deposit cracking. Although low nickel chloride causes poor anode corrosion (a rapid decrease in nickel content), high chloride causes excess stress. To prevent this, maintain pH, current density, and boric acid for control below 10 kpsi.
- **Burns** A low level of nickel sulfamate causes high-current-density “burns.”

Common treatment includes the following:

- **Hull cell** Plate at 2 A for 10 min. with gentle agitation. This test is useful for bath condition and contaminants.

- **Visual observation** The plated metal has a matte, dull finish. Burned deposits are caused by low temperature, high-current density, bath imbalance, and poor agitation. Rough deposits are due to poor filtration, pH out of spec, contamination, or high-current density.

Pitting is due to low antipit, poor agitation, bath imbalance, or organic contamination. Low plating rates are due to low pH, low-current density, or impurities. Gassing at the cathode is a sign of low plating rates.

### 29.9.2 Nickel Sulfate

This is typically plated with an automatic edge connector (tip) plating machine. Table 29.9 gives the operating conditions that apply to these systems. For additional instruction, follow the details in Sec. 29.9.1.

**TABLE 29.9** Nickel Sulfate: Operation and Control

Operating conditions:	
pH	1.5–4.5
Nickel	15–17 oz./gal
Nickel chloride	2–4 oz./gal (with soluble anodes)
Boric acid	5–7 oz./gal
Stress reducer	As required
Antipit	As required
Temperature	130 ± 5°F
Cathode current density	100–600 A/ft <sup>2</sup>
Current efficiency	65%
Anodes:	
Composition	Nickel or platinized titanium

Nickel anodes are preferred in tip machines because the pH and the metal content remain stable. The pH will decrease rapidly when insoluble anodes are used. The pH should be maintained at 1.5 or higher with additions of nickel carbonate. Stress values are higher than in sulfamate baths, with values of about 20 kpsi.

## 29.10 GOLD ELECTROPLATING

Early printed circuit board technology used gold extensively. In addition to being an excellent resist for etching, gold has good electrical conductivity, tarnish resistance, and solderability after storage. Gold can produce contact surfaces with low electrical resistance. In spite of its continued advantages, the high cost of gold has restricted its major application to edge connectors (tips) and selected areas, with occasional plating on pads, holes, and traces (body gold). Both hard-alloy and soft, pure gold are currently used. Plating solutions are acid (pH 3.5 to 5.0) and neutral (pH 6 to 8.5). Both automatic plating machines for edge connectors and manual lines are in use.

### 29.10.1 Acid Hard Gold

To a large extent, acid golds are used for compliance to MIL-STD-275, which states that gold shall be in accordance with MIL-G-45204, Type II, Class 1. The minimum thickness shall be

0.000050 in (50  $\mu\text{in}$ ); the maximum shall be 0.000100 in. Nonmilitary applications require 25 to 50  $\mu\text{in}$ . A low-stress nickel shall be used between gold overplating and copper. Type II hard gold is not suited for wire bonding. These systems use potassium gold cyanide in an organic acid electrolyte. Deposit hardness and wear resistance are made possible by adding complexes of cobalt, nickel, or iron to the bath makeup. Automatic plating machines are being used increasingly because of the enhanced thickness (distribution) control, efficient gold usage, productivity, and quality. A comparison of automatic versus manual plating methods for edge connectors is given in Table 29.10.

**TABLE 29.10** Acid Gold-Cobalt Alloy: Operation and control

	Manual	Automatic
Gold content, troy oz./gal	0.9–1.1	1–3
pH	4.2–4.6	4.5–5.0
Cobalt content	800–1000 ppm	800–1200 ppm
Temperature	90–110°F	100–125°F
Solution density	8–15 Be	12–18 Be
Replenishment per troy oz. gold	8 Ah	6.5 Ah
Current efficiency	50%	60%
Agitation	5 gal/min.	50 gal/min.
Anode-to-cathode distance	2–3 in.	1.4 in.
Anodes, composition	Platinized titanium	Platinized titanium
Cathode current density	1–10 A/ft <sup>2</sup>	50–100 A/ft <sup>2</sup>
Thickness	40 $\pm$ 10 $\mu\text{in}$ .	40 $\pm$ 2 $\mu\text{in}$ .
Deposition rate for 40 $\mu\text{in}$ .	3–6 min.	0.3–0.6 min.
Deposition composition	99.8% gold, 0.2% cobalt	99.8% gold, 0.2% cobalt
Hardness	150 Knoop	150 Knoop

Gold solution contaminants			
Metal	Maximum ppm	Metal	Maximum ppm
Lead	10	Iron	100
Silver	5	Tin	300
Chromium	5	Nickel	300–3000
Copper	50		

Organics: Tape residues, mold growth, and cyanide breakdowns.

### 29.10.1.1 Process Controls

- **Analysis** Gold content, pH, and density should be maintained at optimum values. Operation at very low gold content causes early bath breakdowns with loss of properties, less current efficiency, and less cost savings. The pH is raised by using potassium hydroxide and is lowered with acid salts. Solution conductivity is controlled by density, which is adjusted with conductivity salts. Hull cell is not recommended for this purpose.
- **Anodes** Platinized titanium should be replaced when operating voltages are excessive or when thick coatings develop on the anode surfaces.
- **Recovery** Plating solutions should be replaced when contaminated, when plating rates decrease, or after about 10 total gold content turnovers.

**29.10.1.2 Problems.** Difficulties can be controlled by proper gold bath and equipment maintenance. Some typical situations follow:

- **Discolored deposit** This may be due to low brightener; to metal contaminants such as lead, low pH, low density, or organic contaminations; or to leaking from tape. Gold plate is stripped to evaluate nickel. For these problems, first try to lower the pH, raise the density, or increase the brightener before replacing the bath or using decreased current densities.
- **Gold peeling from nickel** This is generally due to inadequate solder stripping, leaky tape, or poor activation. Methods to increase nickel activation include increasing acid strength after nickel plating and using a fluoride activator, cathodic acid, or gold strike. A gold strike that is compatible with gold plate and has low metal content and low pH is available. Its main purpose is to maintain adhesion to the nickel substrate.
- **Wide thickness range** To narrow the thickness range, improve the solution movement between panels; clean, adjust, or replace anodes; and adjust or replace the solution.
- **Low deposition rate** This is characterized by excessive gassing and low efficiencies. To correct this condition, adjust solution parameters and check for contaminants such as chromium.
- **Pitting** Strip gold and evaluate nickel and copper by cross-sectioning.
- **Resist breakdown** Low current efficiencies cause this condition. Use solvent-soluble screened or dry film for best results.

### 29.10.2 Pure 24-Karat Gold

High-purity 99.99 percent gold processes are used for boards designed for semiconductor chip (die) attachment, wire bonding, and plating solder (lead) glass devices, for their solderability and weldability. These qualities comply with Types I and III of MIL-G-45204. The processes are neutral (pH 6 to 8.5) or acid (pH 3 to 6). Pulse plating is frequently used. Table 29.11 gives typical conditions for a neutral bath.

**TABLE 29.11** Neutral Pure Gold: Operation and Control

Gold content	0.9–1.5 troy oz./gal
pH	6.0–7.0
Temperature	150°F
Agitation	Vigorous
Solution density	12–15 Be
Replenishment	4 Ah/troy oz.
Current efficient	90–95%
Cathode current density	1–10 A/ft <sup>2</sup>
Deposition rate for 100 $\mu$ in., @5 A/ft <sup>2</sup>	8 min.
Deposition composition	99.99% + gold
Hardness	60–90 Knoop

### 29.10.3 Alkaline, Noncyanide Gold

Various processes for alloy and pure gold deposits are available. Solutions are based on sulfite-gold complexes and arsenic additives and operate at a pH of 8.5 to 10.0. A decision to use this process is based primarily on the need for uniformity (leveling), hardness (180 Knoop), purity, reflectivity, and ductility. PC board use is limited to body plating, since wear characteristics of

the sulfite-gold are not suitable for edge connector applications. The microelectronics industry uses these processes for reasons of safety and gold purity. Semiconductor chip attachment, wire bonding, and gold plating on semiconductors are possible applications and are enhanced by using pulse plating without metallic additives.

#### 29.10.4 Gold Plate Tests

Several routine in-process and final quality control tests are performed on gold:

- **Thickness** Techniques are based on beta-ray backscattering and x-ray fluorescence. Thickness and area sensitivity are as low as 1  $\mu\text{in.}$  with 5 mil pads.
- **Adhesion** Standard testing involves a tape pull test.
- **Porosity** Tests involve nitric acid vapor and electrographics.
- **Purity** Lead is a common impurity that must be controlled to <0.1 percent. Other tests included discoloration by heating, electrical contact, and wear resistance.

### 29.11 PLATINUM METALS

---

Interest in platinum systems usually soars in a climate of high gold prices, even though plating results are not always as dependable as those obtained when using gold.

#### 29.11.1 Rhodium

Deposits from the sulfate or phosphate are hard (900 to 1000 Knoop), highly reflective, extremely corrosion-resistant, and highly conductive (resistivity is 4.51  $\mu\text{/cm}$ ). Rhodium plate is used where a low-resistance, long-wear, oxide-free contact is required. In addition, rhodium as a deposit on nickel for edge connectors has been replaced by gold. This is due to difficulty in bath control problems with organic and metallic contaminants, as well as cost. Table 29.12 shows details of rhodium plating.

**TABLE 29.12** Rhodium Sulfate: Operation and Control

Rhodium	4–10g/L
Sulfuric acid	25–35 mL/L
Temperature	110–130°F
Agitation	Cathode rod
Anodes	Platinized titanium
Anode-to-cathode ratio	2:1
Cathode current density	10–30 A/ft <sup>2</sup>
Plating rate	At 20 A/ft <sup>2</sup> , 10 $\mu\text{in.}$ will deposit in 1.4 min., based on 70% cathode current efficiency

#### 29.11.2 Palladium and Palladium-Nickel Alloys

Deposits of 100 percent palladium, 80 percent palladium with 20 percent nickel, and 50 percent palladium with 50 percent nickel find use as suitable deposits for edge connectors. Deposits are hard (200 to 300 Knoop), ductile, and corrosion-resistant. A palladium-nickel undercoat for gold shows good wear and electrical properties.

### 29.11.3 Ruthenium

Deposits of ruthenium are similar to rhodium but are plated with easier control, greater bath stability, and high-current efficiency at lower cost. Deposits are usually stressed.

## 29.12 SILVER ELECTROPLATING

Silver is not widely used in the printed circuit industry, although it finds applications in optical devices and switch contacts. Thicknesses of 0.0001 to 0.0002 in. (0.1 to 0.2 mil) with a thin overlay of precious metal are specified.

Silver plating should not be used when boards are to meet military specifications. The reason for this is that, under certain conditions or electrical potential and humidity, silver will migrate along the surface of the deposit and through the body of insulation to produce low-resistance leakage paths. Tarnishing of silver-gold in moist sulfide atmospheres also produces electrical problems on contact surfaces due to diffusion of the silver to the surface.

Another reason for the lack of acceptance of silver is that silver is plated from an alkaline cyanide bath, which is highly toxic. Bright plating solutions that produce deposits with improved tarnish are usually related to black anodes and are due chiefly to solution imbalance, impurities in anodes, or solution roughness and pitting. Most metals to be plated, particularly the less noble metals, require a silver strike prior to silver plating to ensure deposit adhesion.

## 29.13 LABORATORY PROCESS CONTROL

Laboratory processes available for electroplating control include conventional wet chemical analysis, advanced instrumental techniques, metallographic cross-sectioning, and Hull cell.

### 29.13.1 Conventional Wet Chemical Analysis

The traditional wet chemical methods for metals and nonmetal plating solution constituents are available from suppliers and in the literature.<sup>5,6</sup> These methods also make use of pH meters, ion electrodes, spectrophotometers, and atomic absorption. The composition of liquid concentrates for plating solutions is shown in Table 29.13.

**TABLE 29.13** Composition of Liquid Concentrates

Chemical	Formula	Weight, lb./gal	Percent	Metal, oz./gal
Acids				
Sulfuric	H <sub>2</sub> SO <sub>4</sub>	15.0	96	—
Hydrochloric	HCl	9.8	36	—
Fluoboric	HBF <sub>4</sub>	11.2	49	—
Alkaline				
Sodium hydroxide	NaOH	12.8	50	—
Ammonium hydroxide	NH <sub>4</sub> OH	7.5	28	—
Metals				
Copper sulfate	CuSO <sub>4</sub> ·5H <sub>2</sub> O	9.7	27	9
Copper fluoborate	Cu(BF <sub>4</sub> ) <sub>2</sub>	12.9	46	25.4
Stannous fluoborate	Sn(BF <sub>4</sub> ) <sub>2</sub>	13.3	51	44.3
Lead fluoborate	Pb(BF <sub>4</sub> ) <sub>2</sub>	14.4	51	65.0
Nickel sulfate	NiSO <sub>4</sub> ·6H <sub>2</sub> O	11.0	44	17.8
Nickel sulfamate	Ni(NH <sub>2</sub> SO <sub>3</sub> ) <sub>2</sub>	12.9	50	24
Nickel sulfamate	Ni(NH <sub>2</sub> SO <sub>3</sub> ) <sub>2</sub>	12.3	43	20
Nickel chloride	NiCl <sub>2</sub> ·5H <sub>2</sub> O	11.2	54	23.7

### 29.13.2 Advanced Instrumental Techniques

New techniques have been developed for the control of organic additives in copper plating. Continued development is in progress in the area of measurement of such additives in nickel, gold, and tin solutions. Methods used include liquid chromatography, ultraviolet/visible (UV/VIS) spectrophotometry, CVS, ion chromatography, UV persulfate oxidation, and polarography. These techniques can detect contaminations in various processes, and they show the need for an effectiveness of carbon treatment. Table 29.14 lists and references these techniques, which are having a major influence on plating process capabilities. Literature references list 136 entries on these techniques.<sup>7</sup>

**TABLE 29.14** Advanced Instrumental Analysis Techniques

Technique	Constituent
Cyclic voltammetry stripping	Organics and inorganics
Liquid chromatography with UV/VIS	Organics and inorganics
Ion chromatography	Ionic species
Polarography	Organics and inorganics
Ion selective electrode	Ionic metals, nonmetals
Atomic absorption (AA)	Metals, nonmetals
UV oxidation	Total carbon

### 29.13.3 Metallographic Cross-Sectioning<sup>8,9</sup>

A method for cross-sectioning PC boards is as follows:

- 1. Bulk cutting.** Remove a manageable-sized piece of board or assembly by shearing or abrasive cutting.
- 2. Precision cutting.** Perform low-speed sawing with a diamond wafer blade to produce vertical sections about 1 × 1.2 in., and cut a horizontal section next to PTH pads.
- 3. Mounting.** Encapsulate sections vertically and horizontally in epoxy resin.
- 4. Fine grinding.** Hand-grind using 240-, 320-, 400-, and 600-grit silicon carbide papers.
- 5. Rinsing.** Rinse the sample between grits.
- 6. Polishing.** Diamond-polish (6 μm) on nylon cloth and alumina polishing (0.3 μm) on nap cloth using a rotating wheel. To polish the sample, place it on the rotating-wheel polisher and move it slowly in the opposite direction. Polish for 4 min. if using a 6 μm diamond on nylon, and 1 min. on 0.3 μm alumina on nap cloth. Clean and dry between polishing compounds.
- 7. Etching.** Apply a cotton swab for 2 to 5 sec., soaked in a solution of equal parts of ammonium hydroxide and 3 percent hydrogen peroxide. Rinse in water and dry carefully.
- 8. Documenting.** Observe and photograph the sample with a microscope at 30 to 1500 × magnification.

### 29.13.4 Hull Cell

Although the advanced techniques discussed previously provide precise control of plating solutions, Hull cell testing is still widely used in the industry. Its advantages are low cost, simplicity of operation, and its actual correlation with plating production. Its main disadvantage

is that defects in copper plating frequently are not shown by this method. For example, Hull cell testing will not help in detecting dull plating, roughness, or pitting. The procedure starts with brass panel preparation, in the following order:

1. Remove the plastic film.
2. Treat with cathodic alkaline cleaner.
3. Soak in 10 percent sulfuric acid.
4. Rinse.

Repeat these steps until the panel is water-break free. Proceed with the Hull cell as follows:

1. Rinse with test solution.
2. Fill to mark.
3. Adjust temperature and agitation.
4. Attach panel to negative terminal.
5. Plate.

Agitation should be similar to tank operation—that is, vigorous air bubbling for copper, gentle stirring for tin and tin-lead, and none for tin-nickel. Plate copper and nickel at 2 A and other metals at 1 A. The effects of bath adjustment, carbon treatment, dummy plating, and so on, are readily translated from the Hull cell to actual tank operations. See previous sections on metal plating for Hull cell results, and consult the supplier for test equipment.

## 30.1 DIRECT METALLIZATION TECHNOLOGY\*

---

For 40 years the PTH process of choice has been palladium followed by electroless copper, but there have been at least 12 DMT processes challenging that established process, with several hundred installations, a significant percentage of the total number of PCB shops. The basic idea for the palladium systems dates back to the Radovsky patent of 1963,<sup>1</sup> which claimed a method of using an electrically nonconductive film of palladium in a semicolloidal form to directly metallize through holes in printed circuit boards. Radovsky's invention was never commercialized. The basic idea for the carbon/graphite systems dates back to the very early days of eyelet boards when Photocircuits was experimenting with graphite, silver, and other media to turn their single-sided PCBs into reliable double-sided boards.

### 30.1.1 Direct Metallization Technologies Overview

From the many media and technical variations, some common elements have evolved.

**30.1.1.1 Direct Metallization Technologies Common Elements.** There are two elements common to all DMT:

1. Holes must be conditioned more specifically and thoroughly than for electroless copper.
2. Conductive media must be removed from the copper foil in a majority of the techniques (an exception is DMS-E).

It is understood that additional desmear steps are necessary or advisable when processing multilayer PCBs. Common elements to all horizontal conveyORIZED DMT systems are:

- Throughput is typically 6 to 15 min for a panel, with the next panel following 1 in behind
- Tremendous economies in rinse water use
- Lower consumption of chemicals

---

\* All proprietary names are trademarked by their respective owners.

- Fewer steps than in its vertical mode
- Panel-to-panel uniformity

Many DMT processes work better than electroless copper on substrates with “difficult” resin systems such as PTFE, cyanate ester, or polyimide.

**30.1.1.2 Direct Metallization Categories.** DMT falls into four broad categories:

1. Palladium-based systems
2. Carbon or graphite systems
3. Conductive polymer systems
4. Other methods

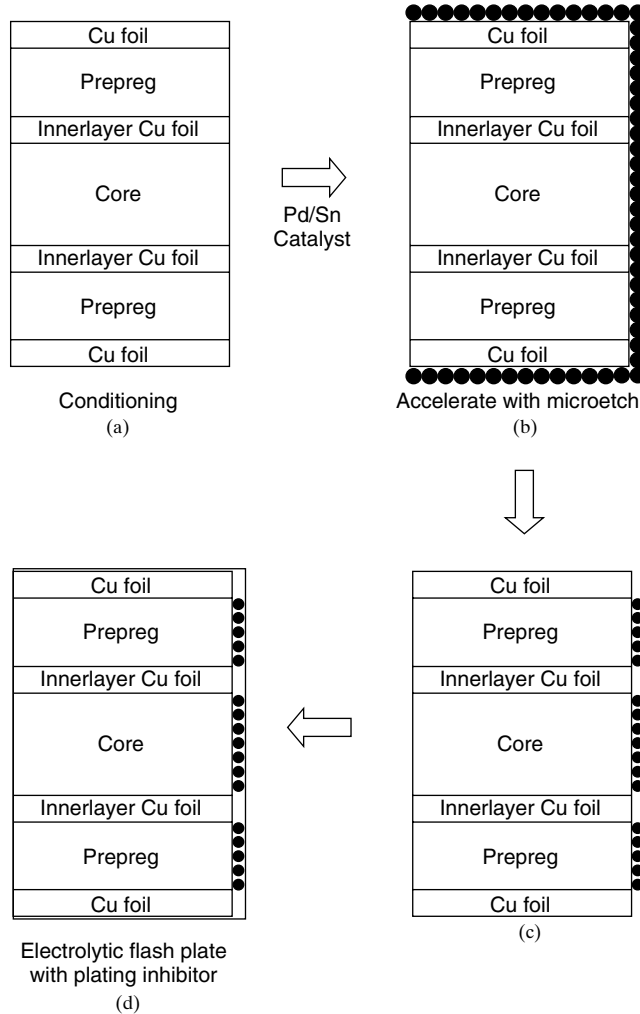

### 30.1.2 Palladium-based Systems

**30.1.2.1 Palladium/Tin Activator with Flash Electroplating.** EE-1,<sup>2</sup> the first commercialized direct metallization technique was invented in 1982 at Photocircuits and PCK. It uses a palladium/tin activator followed by mandatory flash electroplating. The flash-plating bath contains a polyoxyethylene compound to inhibit the deposition of copper on the foil surface without inhibiting deposition on palladium sites on nonconductive surfaces (holes, edges, substrate). Deposition occurs by propagation from the copper foil and grows epitaxially along the activated surface of the hole. Coverage takes about 5 to 6 min. This flash is pattern- or panel-plated subsequently to full thickness in any electroplating bath. Microetching is incorporated in the accelerator to remove palladium sites and nail heads from innerlayers. A special cleaner/conditioner is used. This process has never been adapted to horizontal equipment. (See Fig. 30.1.)

**30.1.2.2 Palladium/Tin Activator with Vanillin.** DPS<sup>3</sup> was invented in Japan in the late '80s. This method uses a palladium/tin activator with vanillin, followed by pattern or panel electroplating. It employs a special cleaner/conditioner and a carbonate accelerator. The three key solutions—cleaner/conditioner, activator, and accelerator—all operate at elevated temperatures. DPS has recently been adapted to horizontal equipment, but works well in the vertical mode, both manual and automatic. Following the last step, the *Setter*, DPS yields a stable, grayish conductive palladium film in the holes. It is believed that the cleaner/conditioner slightly solubilizes the activator, attracting it to the nonconductive surface, and that the vanillin lines up the palladium molecules, and directs them towards the work, hence giving lower electrical resistance and better adhesion to nonconductive surfaces. It is also claimed that there is little palladium/tin left on the copper foil, so it is easily soft-etched away in the normal electroplating preplate cycle. (See Fig. 30.2.) DPS was the first DMT process to suggest an  $\Omega$  meter as the standard quality assurance (QA) tool.

**30.1.2.3 Converting Palladium to Palladium Sulfide.** Crimson,<sup>4</sup> invented by Shipley, employs a conversion step after the activator where palladium is changed to palladium sulfide, which is claimed to be more conductive for subsequent electrolytic copper plating. The *enhancer* stabilizes the conductive film so that it is chemically resistant to imaging steps. The *stabilizer* neutralizes residues from the enhancer, thereby preventing contamination of subsequent steps. The *microetch* selectively removes activator from copper surfaces to achieve optimum copper-to-copper bond and reliable dry film adhesion. The process works best in conveyORIZED horizontal equipment and can be followed by pattern or panel electroplating. (See Fig. 30.3.)

**30.1.2.4 Process Variations.** ABC,<sup>5</sup> invented in Israel by Holtzman et al., is similar to EE-1. It has been adapted to conveyORIZED horizontal equipment, but must be followed by a flash electroplating in a proprietary bath.

**FIGURE 30.1** Principle of EE-1 process: (a) conditioning—making glass and epoxy surfaces receptive of Pd catalyst sites; (b) palladium catalyst sites; (c) acceleration removes excess tin and microetch removes catalysts from the surface of Cu foil; (d) flush Cu plate coppers enter surface in drilling hole walls.

Conductron, from LeaRonal, is similar to DPS with the addition of a special cleaner/conditioner and a glass-etch step. It has been adapted to conveyorized horizontal equipment and can be followed by pattern or panel electroplating.

Envision DPS, from Enthone-OMI, and Connect, from M & T (now Atotech), are fairly similar to each other, and to DPS, though each has a specific cleaner/conditioner and modified accelerator. No adaptation has been made to horizontal processing. Both processes can be followed by pattern or panel electroplating.

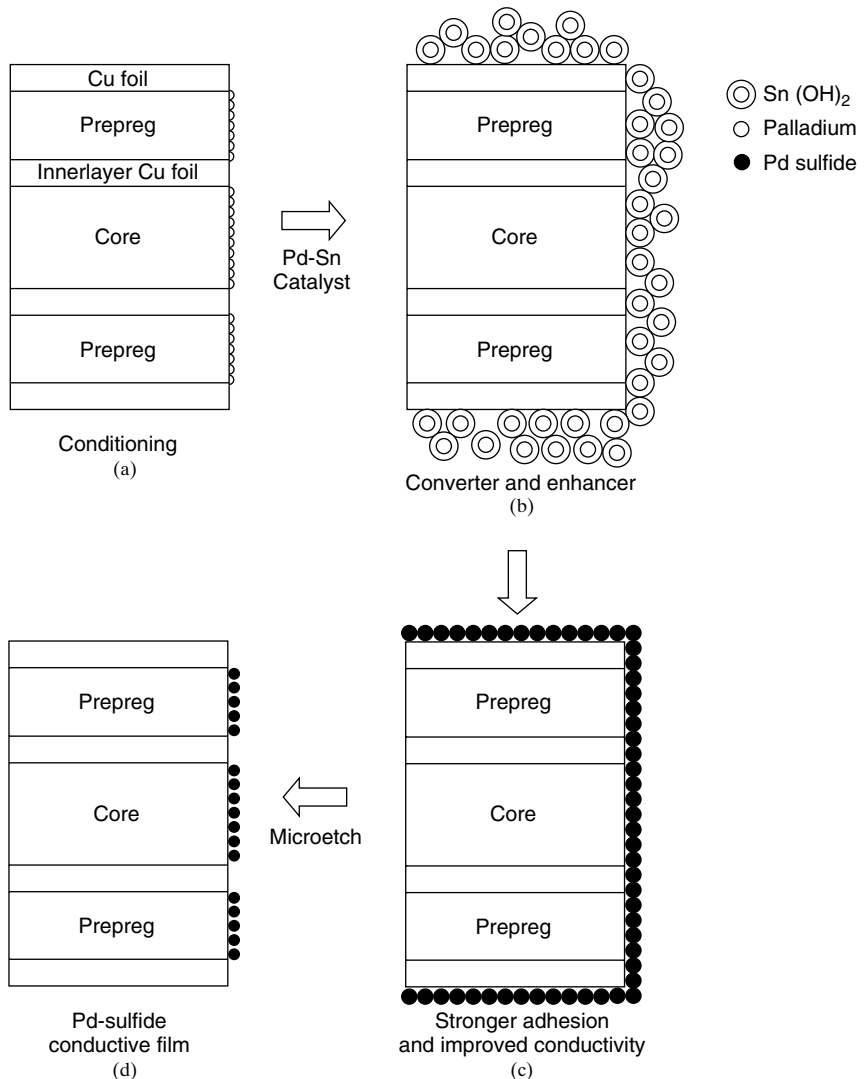

Neopact,<sup>6</sup> from Atotech, uses a tin-free palladium activator in colloidal form. The subsequent postdip removes the protective organic polymer from the palladium, leaving it exposed and with increased conductivity. It has been adapted to conveyorized horizontal equipment, works well in vertical, and can be followed by pattern or panel electroplating. (See Fig. 30.4.)

**FIGURE 30.2** Principle of the DPS process: (a) conditioning for receptive surface; (b) catalysts adhering to the surface; (c) stronger adhesion; (d) ready to plate.

### 30.1.3 Carbon/Graphite Systems

**30.1.3.1 Carbon Suspensions.** Black Hole,<sup>7</sup> the second direct metallization technique, was patented by Dr. Carl Minten in 1988 and pioneered by Olin Hunt, who sold their technology to MacDermid in 1991. MacDermid improved the process considerably and called it Black Hole II. Instead of palladium activator, Black Hole II uses carbon suspensions as its conductive medium. Polyelectrolyte conditioned nonconductive surfaces absorb carbon sites, and they “line up” after heating. To ensure sufficient conductivity, the carbon treatment is performed twice. Residues of carbon sites must be removed from the copper foil surface by a

**FIGURE 30.3** Principle of Crimson process: (a) conditioning; (b) colloidal Pd sites adhered to the surface; (c) Pd-sulfide (stronger adhesion of Pd catalysts); (d) microetch to remove Pd from Cu surface for better Cu-Cu adhesion.

microcleaning step. Black Hole II has been well adapted to conveyORIZED horizontal equipment and can be followed by pattern or panel electroplating. (See Fig. 30.5.)

**30.1.3.2 Graphite.** Shadow<sup>8</sup> is from Electrochemicals (division of LaPorte Industries, UK) and uses graphite as its conductive medium. The process sequence of Shadow is very simple and involves fewer steps than most DMTs. Electrochemicals and one of their fabricators, Eidschun Engineering, made the breakthrough in inexpensive, compact, conveyORIZED horizontal equipment, and the Shadow process is well adapted to this mode. It can be followed by pattern or panel electroplating.

**FIGURE 30.4** Principle of Neopact process: (a) conditioning surface; (b) metal cluster in colloidal suspension adhered to the hole wall; (c) stripped Pd adhering to the hole wall; (d) Cu reduced.

### 30.1.4 Conductive Polymer Systems

**30.1.4.1 DMS-E.** DMS-E<sup>9</sup> from Blasberg is a second-generation DMS-2 process with which they pioneered in this field. DMS-1 was similar to EE-1. After microetch and conditioning, a potassium permanganate solution forms a manganese dioxide coating in the holes which acts as an oxidizing agent during subsequent synthesis reaction. In the catalyzing step, an EDT\* monomer bath wets the manganese dioxide surfaces especially well. During the sulfuric acid fixation step, a spontaneous oxidative polarization takes place, forming a black conductive poly-EDT film on the nonconductive areas of the PCB. This technique is very suitable for use in conveyorized, horizontal equipment, since the oxidative conditioning step is very hot (80 to 90°C), and there are solvents involved. It can be followed by pattern or panel electroplating. (See Fig. 30.6.)

\* EDT = 3,4 Ethylenedioxythiophene.

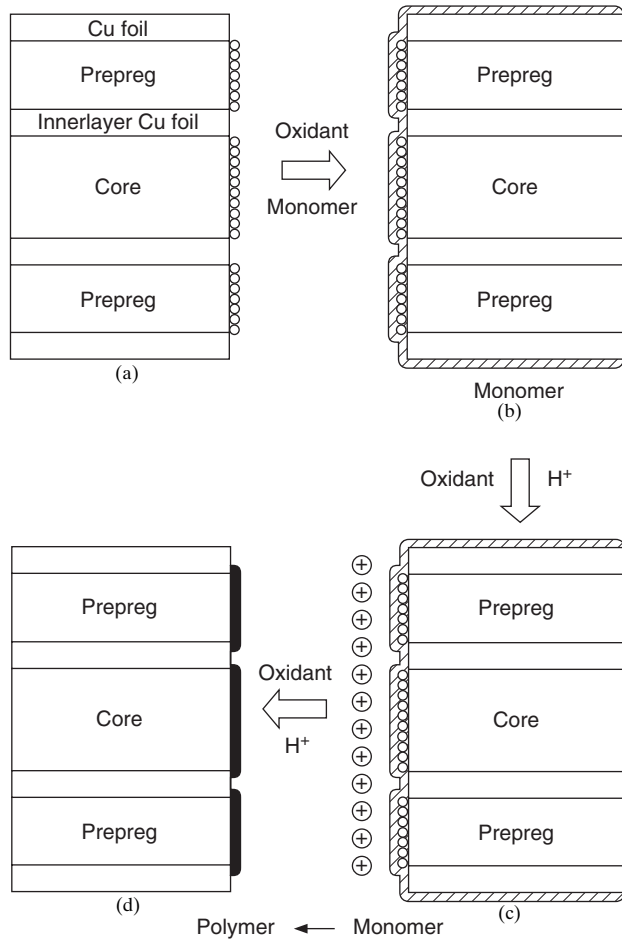

**FIGURE 30.5** Principle of carbon/graphite process: (a) conditioning; (b) carbon particles adhered to the surface; (c) dense more conductive carbon conducting film; (d) removal of conduction film from Cu surface resulting in stronger Cu-Cu interface.

**30.1.4.2 Compact CP.** Compact CP<sup>10</sup> was developed by Atotech in 1987 and is essentially similar to DMS-E, except that it combines the catalyzing and fixation steps, it uses an acid permanganate, and the conductive film is a polypyrrole. The technique is very suitable for use in conveyerized, horizontal equipment. It can be followed by pattern or panel electroplating.

### 30.1.5 Other Methods

There are several other novel ways to metallize holes in PCBs, such as Phoenix and EBP from MacDermid, Schlötposit from Schlötter. There are conductive ink and laser scribing/filling techniques; there are sputtering and sequential plating, to name a few, but they do not fall within the scope of this chapter.

**FIGURE 30.6** Principle of conductive polymer process: (a) conditioning; (b) monomer created on the surface; (c) oxidant reduces monomer to polymer yielding highly conductive surface; (d) further improved conductive surface.

### 30.1.6 Comparative Steps of DMT Process

**30.1.6.1 DMT.1: Palladium-based Systems.** All vertical modes only, for comparison purposes, are shown in Table 30.1.

**30.1.6.2 DMT.2: Carbon/Graphite Systems—Conveyorized Horizontal.** Conveyorized horizontal systems are shown in Table 30.2.

**30.1.6.3 DMT.3: Conductive Polymer Systems.** Conveyorized, horizontal systems with optional electrolytic flash are shown in Table 30.3.

### 30.1.7 Horizontal Process Equipment for DMT

Although many DMTs fit easily into existing electroless copper lines, whether manual or automatic, and perform well in a vertical mode, DMT is becoming inextricably linked to horizontal processing in a conveyorized machine. Like so many inventions, necessity was its mother. Certain DMT processes are marginal in the vertical/basket mode, and handling each panel individually was the only solution. The advent of compact and inexpensive horizontal DMT equipment has been a catalyst. Although Atotech pioneered horizontal electroplating equipment with their Uniplate system, until the development of horizontal DMT machines it was not feasible to engineer a horizontal PTH machine. Now, however, for those who want only flash plating, or even full electroplating, the entire process—both PTH and galvanic—may be horizontal, conveyorized, and automated with the advantages of reduced chemical consumption; radically reduced use of rinse water; panel-to-panel uniformity, reliability, and quality; reduction in operating personnel; reduction of handling; a fully enclosed operating environment; and JIT delivery. Stackers/accumulators further minimize handling and optimize efficiency.

### 30.1.8 DMT Process Issues

Anything brand new experiences some “teething problems” at the beginning, and DMT is no different. But most of the processes referred to in this chapter are in at least their second generation and some are already in their third, so there are no serious contraindications to the use of DMT. However, there are a few caveats:

1. Esoteric base material does not run well with all DMT.
2. Not all DMT performs as well in the vertical mode as in the horizontal.
3. Certain DMT is better suited to the rigors of multilayer production.
4. Some perform better than others with very small holes.
5. Some processes are cleaner than others.
6. Certain DMT is more sensitive than electroless copper to organic contamination in electrolytic copper plating.

7. Rinsing is important, and some DMT needs special rinsing.
8. Rework is simple in most DMT, but it can be abused, i.e., it changes the cost structure.
9. Quality assurance tools for DMT (how do you know that holes will plate void-free?) are being developed, but at the moment, the only absolutely certain method is to flash electroplate, because, unlike electroless copper, there is not much to see in the hole after DMT.
10. Some DMT analyses and operating controls are rudimentary.

### 30.1.9 DMT Process Summary

Strong ecological and health reasons will drive the use of DMT for the manufacture of PTH boards. Since the cost of PTH metallization constitutes only 2 to 3 percent, at most, of the total process cost of a PCB, the direct saving resulting from DMT is very small. However, the fringe benefits of this technology are rather significant: water conservation, no noxious chemicals, minimal panel handling, reduced waste treatment, lower labor costs, fewer rejects, etc.

## CHAPTER 31

---

# PWB MANUFACTURE USING FULLY ELECTROLESS COPPER

---

**Dr. Hayao Nakahara**

*N.T. Information Ltd., Huntington, New York*

---

### 31.1 FULLY ELECTROLESS PLATING

---

Fully electroless plating has been recognized as a viable technology for some time. It is especially useful for the formation of fineline conductors and considered excellent for plating small, high-aspect-ratio holes because of its high throwing power when compared with that of galvanic plating (see Fig. 31.1). However, its use was limited to the manufacture of double-sided and simple multilayer printed wiring boards (PWBs) for some time after the commercial introduction of the additive process called CC-4 began at Photocircuits Corporation in 1964. This was due to some relatively poor physical properties of electrolessly deposited copper, such as elongation of 2 to 4 percent, compared to 10 to 15 percent achieved by galvanically deposited copper.

The view on electroless plating technology began to change in the mid-1970s when IBM decided to utilize the technology for the fabrication of multilayer boards (MLBs) to package its then top-of-the-line mainframe computers.<sup>1</sup> IBM and other PWB makers using fully electroless copper plating have continuously improved the properties of electrolessly deposited copper since the early 1980s. IBM has continued to use the technology for the fabrication of more advanced MLBs for mainframe and supercomputers.<sup>2,3</sup> Stimulated by IBM's work, and because of technical necessity, NEC Corporation and Hitachi Ltd. of Japan also applied electroless plating technology for the fabrication of MLBs for their mainframe and supercomputers.<sup>4,5</sup>

Today, electrolessly deposited copper is considered as reliable as galvanically deposited copper, and fully electroless plating technology is finding its way to many applications.<sup>6-20</sup> In this chapter, we will discuss various methods of PWB fabrication by means of fully electroless copper-plating technology.

PWB fabrication technology using electroless plating is often referred to as *additive technology*. Therefore, throughout this chapter, the words *electroless* and *additive* will be used interchangeably. Electroless copper plating for through-hole metallization, which deposits a thin film of copper on the wall of plated-through-holes (PTHs), typically from 0.3 to 3  $\mu\text{m}$  thick, is a technology different from the one under consideration and will not be discussed in this chapter (see Chap. 29, "Electroplating").

**FIGURE 31.1** Ability of electroless bath to plate hole of high aspect ratio without reducing throwing power.

## 31.2 THE ADDITIVE PROCESS AND ITS VARIATIONS

There have been many variations to additive processes,<sup>20,21</sup> but there are three basic additive processes commercially practiced, as illustrated in Fig. 31.2:

1. Pattern-plating additive
2. Panel-plate additive
3. Partly additive methods

## 31.3 PATTERN-PLATING ADDITIVE

Pattern-plating additive methods can be classified further into three different approaches, as described in the following sections, depending on the base substrates used.

### 31.3.1 Catalytic Laminate with CC-4<sup>®22</sup>

CC-4 stands for *copper complexer number 4*, EDTA, the fourth complexing agent successfully tried by Photocircuits in the early 1960s for full-build electroless copper-plating solution. Over time, the term CC-4 has been used frequently as an adjective, such as in “CC-4 process” or “CC-4 bath.”

**31.3.1.1 Process Steps.** The CC-4 process starts with catalytic laminates coated with catalytic adhesive. The process sequence is as follows:

1. Catalytic base laminate coated with catalytic adhesive (both sides)
2. Hole formation

\* CC-4 is a registered trademark of AMP-AKZO Corporation.

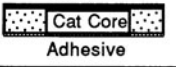

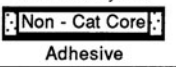

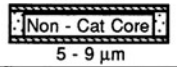

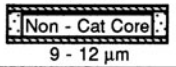

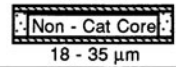

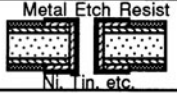

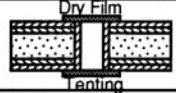

BASIC PROCESS STEPS \ VARIATION OF ADDITIVE PROCESS	PATTERN PLATE ADDITIVE			PANEL PLATE ADDITIVE	PARTLY ADDITIVE
	CC - 4	AP - II	FOIL PROCESS

ETCH & STRIP	↓	↓			↓
SOLDER MASK					

FIGURE 31.2 Variation of additive process.

3. Mechanical abrasion of the adhesive surfaces for better adhesion of plating resist
4. Application of plating resists (screening ink or dry film resist)
5. Formation of microporous structure of exposed adhesive surfaces by chemical etching in acid solution ( $\text{CrO}_3/\text{H}_2\text{SO}_4$  or  $\text{CrO}_3/\text{HBF}$ )
6. Fully electroless copper deposition on the conductor tracks and hole walls
7. Panel baking
8. Application of solder mask and legends
9. Final fabrication and test

**31.3.1.2 Resist Issues.** When the conductor width is 8 mil (0.2 mm) or wider, image transfer (step 4) for a majority of CC-4 boards is still done by screen printing with thermally curable or UV-curable ink, since the cost of imaging by screening method is less than one-third that of dry film imaging. The plating resist is permanent; that is, it stays permanently as an integral part of the board. UV-curable ink is preferred because of its shorter curing time that tends to minimize lateral ink flow while being cured. Lateral ink flow narrows the conductor width since the conductor is formed in the trench between plating resists. See Fig. 31.3.

**FIGURE 31.3** Narrowing of conductor due to lateral flow of plating resist after application.

**31.3.1.3 Typical Plating Conditions.** Although the practical limitation of screen printing conductor pattern is 8 mil (0.2 mm), in a mass production environment, 6-mil (0.15 mm) conductor patterns have been successfully screened, but such a pattern is confined to a limited area of the panel. Therefore, a conductor pattern which is less than 6 to 7 mil is normally formed by dry film resist. E.I. du Pont de Nemours & Co. and Hitachi Chemical Co., Ltd., are two major suppliers of permanent dry film plating resists which withstand the hostile plating bath environment. Typically, additive bath temperatures range from 68 to 80°C and pH from 11.8 to 12.3, and panels must stay in the bath for more than 10 h with plating speed of typically 2.0 to 2.5  $\mu\text{m}/\text{h}$ .

Since the use of solvent such as 1-1 trichloroethane is being banned, semiaqueous-developable permanent dry film resist has been developed by Hitachi Chemical to withstand the plating condition as previously described and is used extensively in Japan.

Since paper-based laminates are still the dominant materials in Japan (although CEM-3 and FR-4 laminates have been used increasingly in recent years), some allowance for this material in the plating solution is made. Therefore, plating baths for paper-based laminates are usually maintained at the lower end of the operating temperature (68 to 72°C) in order not to delaminate them.

**31.3.1.4 Permanent Plating Resist.** The use of a permanent plating resist creates a flush surface, where the copper and resist are at the same height from the base laminate. This offers two distinct benefits. In the board fabrication process, after the conductors are formed, the

**FIGURE 31.4** Flush surface resulting from additive plating with permanent plating resist. (Photo courtesy of Ibiden Co. Ltd.)

chance of their destruction due to scratch is minimized. (See Fig. 31.4.) In addition, the flush surface makes the application of solder mask easier and reduces the consumption of solder resist by as much as 30 percent when compared to that incurred in a conventional subtractive, etched foil process. In the board assembly process, a permanent plating resist acts as the solder resist and tends to minimize solder bridges during the soldering operation, particularly for fine-pitch devices.

### 31.3.2 Noncatalytic Laminate with AP-II<sup>22</sup>

AP-II is an abbreviation of Additive Process II developed by Hitachi Ltd. This process also makes use of permanent plating resist. However, unlike the CC-4 process, it starts with noncatalytic laminate coated with noncatalytic adhesive. Its process sequence is as follows.

#### 31.3.2.1 Process Steps

1. Noncatalytic laminate coated with noncatalytic adhesive
2. Hole formation
3. Mechanical abrasion of adhesive surfaces followed by chemical roughening (adhesion promotion)
4. Catalyzation of the surfaces and hole walls
5. Application of plating resists

The rest of the process is essentially the same as the CC-4 process (steps 6 through 9).

**31.3.2.2 Advantages/Disadvantages.** This catalyzing version of the pattern-plating additive process has one advantage over the CC-4 process, that is, the use of noncatalytic base laminates which are cheaper than catalyzed laminates. On the other hand, this process has a disadvantage also in that pattern repair before plating is not possible because resist which

protrudes sideways and makes the conductors narrower cannot be removed since the Pd catalyst underneath the protruding part of the resist tends to be removed as well if repair is attempted, resulting in plating voids. However, in a really fineline conductor case such as 4 mil (0.1 mm) or below, repair attempts will not be made; hence, this disadvantage does not usually impede this catalyzing version of the pattern-plating additive process.

**31.3.2.3 AP-II Variation AAP/10.** A variation of the AP-II process called the AAP/10 process has been developed and practiced by Ibiden Co., Ltd., of Japan to fabricate high-layer-count MLBs with fineline conductors down to 3 to 4 mil.<sup>23,24</sup> The AAP/10 process is essentially the same as AP-II except that the adhesive used for the AAP/10 process has better insulation characteristics, suitable for higher performance.

### 31.3.3 Foil Process

Although an adhesive-coated surface provides adequate insulation characteristics for most applications, some boards, such as ones used for mainframe computers, require higher insulation resistance than adhesives can render. When IBM decided to use fully electroless plating to form fineline conductors on innerlayers of high-aspect-ratio MLBs in the mid-1970s, it took an approach different from the adhesive system.<sup>1</sup>

**31.3.3.1 Process Steps.** The process developed at IBM is as follows:

1. Copper-clad laminate (5- $\mu$ m copper foil).
2. Drill holes.
3. Treat copper surface with benzotriazol.
4. Catalyze the panel.
5. Dry film laminate for conductor pattern (reverse pattern).
6. Do fully electroless copper deposition on the conductor track.
7. Metal overplate as etch resist (tin-lead, tin, nickel, etc.).
8. Strip dry film and etch copper.
9. Strip metal etch resist.
10. Do oxide treatment for subsequent lamination.

**31.3.3.2 Process Issues.** This foil process requires strong adhesion of dry film plating resist on copper surface. Benzotriazol treatment of the copper surface improves adhesion of dry film. However, the most crucial step is cleaning the copper surface (virgin copper) to obtain an optimum pH for best reaction between copper and benzotriazol.

Hitachi Ltd. found that the use of compounds having amino and sulfide groups is effective in suppressing delamination between copper surface and plating resist.<sup>21</sup> It uses dry film resist which contains a trace of benzotriazol rather than treating the copper surface with the chemical. Baking the panel after exposure/development of dry film at about 140°C for 1 h is found to improve the adhesion between copper surface and dry film during plating operation and at the same time prevents this chemical from breaching out into the plating bath, which could poison the bath.

Table 31.1 shows representative high-tech MLBs fabricated by means of additive technology. Innerlayer patterns of all MLBs listed in the table are made by the foil process. The outerlayer patterns are formed by the panel-plate additive process, which is the subject to be discussed in the following section.

**TABLE 31.1** Large-Scale MLBs

### 31.4 PANEL-PLATE ADDITIVE

Maintaining uniform thickness on the panel surface in a galvanic plating operation is difficult. As the aspect ratio becomes higher, maintaining uniform thickness on the hole wall is also a problem.

Electroless plating offers two distinctively superior features in this respect:

1. Its excellent throwing power for high-aspect-ratio holes (Fig. 31.5)
2. Its ability to deposit copper film of even thickness over the entire circuit panel.

**FIGURE 31.5** Excellent hole coverage is achieved by fully additive plating. This shows the cross section of a hole with a 27:1 aspect ratio. (Photo courtesy of Hitachi Ltd.)

These features of fully electroless plating are ideal for the fabrication of high-tech MLBs, as described in Table 31.1. All signal conductors of the MLBs are formed on innerlayers and the outerlayer surfaces provide pads only for through holes and some bonding pads for decoupling capacitors. The process steps of the panel-plate additive method are essentially the same as those of the galvanic panel-plate method:

#### 31.4.1 Process Steps

1. Copper-clad laminate (thin copper foil is preferred).
2. Perform hole formation.
3. Catalyze holes.
4. Perform fully electroless copper deposition (panel-plate).
5. Perform dry film tent-and-etch.

### 31.4.2 Process Issues

Tenting with dry film becomes difficult when annular rings are very small or in some cases when there are no annular rings at all. In such cases, a positive electrodeposition system may be applied to overcome this difficulty.

It should be cautioned, however, that there is a limitation to this panel-plate additive approach, even though the thickness of deposited copper film is much more even across the panel. If very fine conductors are to be formed by this method, the conductor cross section becomes intolerably distorted from the ideal rectangular shape as the ratio of the width to the height of the conductor approaches unity, as shown in Fig. 31.6.

**FIGURE 31.6** Formation of fineline conductors by etching process results in undesirable, nonrectangular conductor cross section. (Photo courtesy of *Ibiden Co., Ltd.*)

## 31.5 PARTLY ADDITIVE

As in the case of the panel-plate additive method, the partly additive process starts with copper-clad laminate.<sup>11-14</sup> The essence of this process is to minimize the problem encountered in etching fineline conductors through thick copper which results from through-hole plating (in the conventional etched foil process, through-hole is plated first), by forming conductors first, prior to through-hole plating.

### 31.5.1 Process Steps

1. Copper-clad laminate.
2. Perform hole formation.
3. Catalyze hole walls and remove catalyst sites from the surfaces by brushing.
4. Perform image transfer by screen print or dry film tenting.
5. Form conductor pattern by etching and stripping the resist.
6. Apply plating resist over the entire surface, but leaving pads and holes uncovered.
7. Perform electroless copper deposition onto the pads and hole walls.

### 31.5.2 Process Issues

By proper selection of catalysts and etching solutions, the catalyst on the hole walls survives during the etching operation, posing no problem in the subsequent plating step.

In step 6, plating resist can be applied by screen printing when the circuit density is not so high. When the density becomes higher, dry film or liquid photoimageable resist can be used. Liquid resist can be applied by open screen coating, roller coating, or curtain coating.

In some cases, step 6 can be bypassed when sideways line growth is not a problem (Fig. 31.3). In such a case, the plating speed is reduced by 20 to 30 percent, from the normal speed of 2.0 to 2.5  $\mu\text{m}$ , in order to avoid copper deposition on unwanted areas (bare laminate areas). Conductors must be made narrower than the intended final width at the design stage to compensate for the side growth.

### 31.5.3 Fine-Pitch Components

As the lead pitch of multipin devices becomes narrower than 20 mil (0.5 mm), bridging between adjacent pads during plating can occur even when plating resist is placed between them. As a result, the practitioners of the partly additive process are abandoning this process and converting to the panel-plate additive method based on the experiences they gained from practicing partly additive technology.

## 31.6 CHEMISTRY OF ELECTROLESS PLATING

---

Chemical reactions which take place in electroless plating have been treated well in the literature.<sup>4,21</sup> However, they are discussed again here because some of the due comments are relevant to the chemistry of electroless plating.

### 31.6.1 Electroless Plating Solution Chemical Reactions

Main ingredients of most electroless plating bath formulations consist of

NaOH	pH adjustment
HCHO	Reducing agent (formaldehyde)
CuSO <sub>4</sub>	Source of copper iron
EDTA	Cheleting agent

**31.6.1.1 Copper Deposition.** The chemical reaction of copper deposition may be represented by

Under the alkaline pH condition, the cupric ions would normally combine with OH<sup>-</sup> to produce cupric hydroxide [Cu(OH)<sub>2</sub>], a useless precipitate. When a cheleting agent such as EDTA is added, it prevents cupric hydroxide formation by maintaining the Cu<sup>2+</sup> in solution. Once the deposition of metallic copper starts through catalytic sites, the reaction in Eq. (31.1) continues because of the autocratic nature of the reaction.

**31.6.1.2 Cannizzaro Reaction and Formaldehyde Concentration.** While this main reaction, represented by Eq. (31.1), takes place, other undesirable side reactions proceed, also in

competition with the reaction. One of the major difficulties is the lowering of formaldehyde concentration in the solution due to its disproportionate consumption in alkaline solution. This is known as the *Cannizzaro reaction*, which may be characterized by

This reaction continues independently. Fortunately, methanol ( $\text{CH}_3\text{OH}$ ) one of the by-products of the Cannizzaro reaction, tends to shift the equilibrium of the reaction in Eq. (31.2) to the left and thus prevents the decrease of formaldehyde concentration by an unproductive reaction. By controlling the plating conditions properly, the wasteful consumption of formaldehyde by the Cannizzaro reaction can be retained within 10 percent of the consumption in the reaction in Eq. (31.1).

**31.6.1.3 Fehlings-Type Reactions.** In addition to the Cannizzaro reaction, the following side reaction also competes for formaldehyde:

**31.6.1.4 Other Formaldehyde-Related Reactions.** Under conditions which would favor the Fehlings-type reaction [Eq. (31.3)], spontaneous decomposition of uncatalyzed plating solutions produces precipitation of finely divided copper with attended vigorous evolution of hydrogen gas. The finely divided copper produced is due to the disproportionate quantity of  $\text{Cu}_2\text{O}$  under alkaline conditions:

Furthermore, formaldehyde may act as a reducing agent for the cuprous oxide to produce metallic copper:

**31.6.1.5 Filtering.** The  $\text{Cu}^0$  nuclei thus produced according to Eqs. (31.4) and (31.5) are not relegated to deposition on substrate but are produced randomly throughout the solution and become the catalytic sites for further undesirable copper deposition. Continuous filtration with a filter of pore size  $20 \mu\text{m}$  or smaller can improve extraneous copper due to these catalytic sites.<sup>25</sup> The use of continuous filtering also improves the ductility of copper by eliminating codeposition of impurities. In most mass production facilities of PWBs by additive technology, two or three stages of filtering with filters of pore sizes down to  $5 \mu\text{m}$  are common.

## 31.6.2 Use of Stabilizers

Since the reaction represented in Eq. (31.3) indicates the greatest degree of instability of the plating bath, various measures are taken to counteract this reaction. Alkaline cyanide has been a popular stabilizer used for the CC-4 bath, since cyanide forms strong complexes with  $\text{Cu}^+$  ( $\text{Cu}^+ + 2\text{CN}^- \rightarrow \text{Cu}(\text{CN})_2^-$ ), but relatively unstable complexes of  $\text{Cu}^{2+}$ . However, since cyanide also reacts with  $\text{HCHO}$ , it is difficult to control. 2,2'-dipyridil also chelates  $\text{Cu}^+$  and does not react with  $\text{HCHO}$ . Hence, it is a more favored stabilizer, particularly for those baths used in Japan. On the other hand, a dipyridil bath deposit begins to have less ductility after several plating cycles and weekly bath makeup may be necessary.

Aeration of the plating bath is known to stabilize the solution, and vigorous aeration is commonly used to operate modern full-build electroless baths.

### 31.6.3 Surfactant

Reduction in surface tension assures that the plating solution is in intimate contact with the catalyst nuclei and permits thorough surface solution interaction. For this reason, a wetting agent or surfactant is included in bath formulations. Polyethelene oxide, polyethelene glycol (PEG), etc., are popular surfactants. Proper usage of surfactants also prevents the accumulation of gaseous material (air and hydrogen bubbles) on the surface of the board, particularly around the entrances of holes, which would also tend to lower the surface-solution interaction and thus seriously impair proper metal deposition.

### 31.6.4 Reliability of Deposited Copper and Inorganic Compounds

Generally, copper film with high elongation and reasonable tensile strength is preferred for through-hole reliability, although the relation between through-hole reliability and ductility and tensile strength is still not understood clearly.

The use of inorganic compounds containing vanadium or germanium as a part of chemical ingredients in plating baths enhances the quality of deposited copper.<sup>13</sup> Most full-build electroless baths used today contain either  $V_2O_5$  or  $G_2O_5$  to improve the physical properties of deposited copper.

**31.6.4.1 Typical Copper Properties.** Typical physical properties of reliable electrolessly plated copper are (as plated):

Elongation	8 to 10 percent
Tensile strength	35 to 45 kg/mm <sup>2</sup>

After annealing the copper, elongation increases to 12 to 18 percent and tensile strength decreases slightly. These properties are equivalent to the ones resulting from acid copper. Since all panels are baked at about 140 to 160°C for 30 to 60 min during the course of the production process after plating, deposited copper gets annealed, thus assuring high through-hole reliability.

### 31.6.5 Removal of Impurities

Use of continuous filtering has been mentioned to remove some of the impurities. In addition there are other methods.

**31.6.5.1 Electrodialysis.** Electrodialysis<sup>26,27</sup> is effective to remove formate ions, sulfate ions, and carbonate ions which are by-products of reactions defined in Eqs. (31.1), (31.2), (31.3), and (31.5).

**31.6.5.2 Overflow Method.** Another very effective way to remove these unwanted by-products is the *overflow* method. Since essential components of the plating solution are consumed continuously, they must be replenished to maintain desirable plating conditions. In so doing, a considerable amount of the solution overflows because of the addition of water. The overflow also contains the reaction by-products as well as chelated copper ions.

After a certain amount of overflow solution is accumulated, sodium hydroxide and formaldehyde are added to the overflow solution and heated to promote spontaneous decomposition of the plating solution to precipitate copper metal. Addition of copper powder accelerates the precipitation. This so-called *chemical bomb-out* recovery method can be operated in bulk or continuously. The remaining solution can be treated with sulfuric acid to

recover over 95 percent of the EDTA in the solution. Usually, the purity of EDTA thus recovered is higher than that of purchased EDTA.

Ninety-eight percent of the solution is recovered as permeate and is used in such processes as rinsing. The concentrate, the other two percent, is high in salt content ( $\text{Na}_2\text{SO}_4$  and  $\text{HCOONa}$ ) and may be evaporated to produce a small amount of solid waste or discharged into the ocean, if the plant is located near the ocean and locally approved.<sup>6</sup> This chemical bomb-out method can achieve two objectives at once: removal of unwanted impurities and recovery of chemicals. With this system, it is easy to maintain Baume at the desired 9°.

### 31.6.6 Environmental Issues of Formaldehyde

Formaldehyde is considered to be a carcinogen. If exposed to formaldehyde fumes of certain concentration for a long time, it can cause allergy conditions and perhaps cancer, although cancer due to long-time exposure to formaldehyde in the PWB industry has never been reported.

With a good exhaust system and scrubbing through water and peroxide solution, formaldehyde can be made quite harmless. It is a matter of economy. EDTA can be treated as previously mentioned.

Reducing agents alternative to formaldehyde such as glyoxylic acid<sup>27</sup> and hypophosphite ( $\text{M}_3\text{PO}_2$ )<sup>28</sup> have been suggested and tried, but they have not been able to replace formaldehyde as an effective reducing agent at this stage.

## 31.7 FULLY ELECTROLESS PLATING ISSUES

---

### 31.7.1 Efficiency of Electroless and Galvanic Plating

PWB manufacturers which are not familiar with electroless plating often have the misconception that electroless plating takes “too long.” On the contrary, electroless plating is faster than galvanic plating, and its volumetric efficiency is twice as much as galvanic plating.

Electroless plating baths operate at the speed of 2.0 to 5.0  $\mu\text{m}/\text{h}$ , 2.5  $\mu\text{m}$  being the medium speed. Because of its high throwing power, a deposition thickness of 25  $\mu\text{m}$  on the panel surface also assures 25  $\mu\text{m}$  in the hole. That is, 10 h are needed to plate this thickness. The loading factor in electroless plating can be maintained at 4  $\text{dm}^2/\text{liter}$ . A 2500-gal (10,000-l) tank can plate about 400  $\text{m}^2$  (4000  $\text{ft}^2$ ) of panels in one shot in 10 h. That is, 400  $\text{ft}^2/\text{h}$ , or approximately 130 (18-in  $\times$  24-in) panels/h from a 10- $\text{m}^3$  tank. This is equivalent to twice the speed of galvanic plating from the same volume of plating solution. When small, high-aspect-ratio holes are involved, this figure becomes more favorable to electroless plating because the current density of galvanic plating must be reduced to 10 to 12  $\text{A}/\text{ft}^2$ , which requires more than 2 h of plating for 25  $\mu\text{m}$  in the hole.

Figure 31.7 shows the plating racks filled with panels waiting to be placed in electroless plating tanks. In large-volume operations, the panel-racking operation is fully automated.

### 31.7.2 Photochemical Imaging Systems

Various photochemical imaging systems have been developed and tried to be put into practice.<sup>6</sup> However, no photochemical imaging systems are used for real production today. They are all unstable and the lateral growth of conductors poses a problem for the fineline applications for which they are intended.

### 31.7.3 Molded Circuit Application

A handful of three-dimensional molded circuit manufacturers (or, the preferred identification, *molded interconnection device* or MID) have continued their quest for market with this

**FIGURE 31.7** Plating racks filled with panels to be plated. (Photo courtesy of Adiboard, Brazil.)

product and have met with some success. (See Fig. 31.8.) There are several alternative methods to manufacture MIDs, of which the *two-shot* molding method can produce the most sophisticated three-dimensional interconnection devices.

A part which is to be metallized (circuitized) is molded first. Then, a portion of the first mold which is not desired for metallization is surrounded by the second molding, exposing

**FIGURE 31.8** An example of a three-dimensional molded circuit application, in this case a light pen for computer input. (Photo courtesy of Mitsui Pathtek.)

only the portion desired to be metallized. This two-shot molding method can be classified further into two alternative methods, which are similar to CC-4 and AP-II.

One is to use catalyzed engineering plastic for the first molding and noncatalyzed plastic for the second molding. Adhesion promotion consists of a swell-and-etch step followed by chromic acid etch. The other alternative is to mold the first part with noncatalyzed plastic materials and expose the molded part to an adhesion promotion process and catalyze. The second part is then molded, as in the first case.

These parts are placed in an electroless plating bath for circuitization. A high rate of growth is expected for MIDs, with the automotive market being the most promising application area.

# PRINTED CIRCUIT BOARD SURFACE FINISHES

---

**Don Cullen**

*MacDermid, Incorporated, Waterbury, Connecticut*

---

## **32.1 INTRODUCTION**

---

### **32.1.1 Purpose and Functions of Surface Finishes**

The printed circuit board (PCB) conductor surface finish forms a critical interface between the component and the interconnection circuitry. As its most essential function, the final finish process is intended to provide exposed copper circuitry with a protective coating in order to preserve solderability. In a more expanded view, the final finish coating must meet dozens of functional criteria, including solderability, environmental, electrical, physical, and durability demands, as summarized in this chapter. Perhaps no other step in the PCB manufacturing process has undergone more change in the era of surface mount manufacturing than the final finish chemical process. A wide variety of functional, environmental, engineering, cost, productivity, and failure mode issues have contributed to this frequent change.

### **32.1.2 Impact of the Lead-Free Transition**

The impact of lead-free manufacturing, as a result of the Waste Electrical and Electronic Equipment (WEEE) directive and Restriction on Hazardous Substances (RoHS), has changed surface finish specifications for PCBs and the soldering of those surfaces at assembly.

Lead-free assembly has changed just about every aspect of the surface finish technology. The elimination of lead (Pb) in most designs has rendered the standard surface finish hot air solder level (HASL) increasingly obsolete. At assembly, the use of new solder alloys affects the compatibility of the finishes with the metallurgy of the final solderjoint. Many of the assembly issues related to surface finishes, such as surface-mount technology (SMT) pad wettability, plated through hole (PTH) fill, and voiding are exacerbated by the Pb-free assembly process. Finally, the temperature of Pb-free soldering has a major impact on the shelf-life and solderability of the Pb-free finishes.

### 32.1.3 Technology Drivers

Each company in the manufacturing supply chain has needs specific to its manufacturing step. The methods used to achieve these goals have evolved with developments in PCB technology. Historically, technicians were able to solder components directly to copper using very active fluxes. When PCBs were first made in large production quantities, chemists devised ways to protect the copper using metal or organic coatings. Electroplated tin-lead became a popular coating as a metallic layer that could be subsequently reflowed. Design changes forced the era of solder mask over bare copper (SMOBC). With SMOBC, reflowed plated tin-lead was no longer possible because the tin-lead liquefies during the soldering process. HASL, the successor to plated tin-lead, became the surface finish of choice worldwide. Increasing PCB circuit density inspired the reemergence of organic coatings, such as new formulation organic solderability preservatives (OSPs) and metallic layers such as electroless nickel/immersion gold (ENIG.) The environmental initiative to eliminate ozone-depleting chemicals led to the next change in surface finish preference. Use of no-clean assembly operations prompted a decline in OSP and an increase in ENIG. Both ENIG and OSP continue to be widely used, but each has its own weakness, allowing for the proliferation of new low-cost, high-functional immersion metal finishes such as immersion silver and immersion tin.

**32.1.3.1 Fabrication Requirements.** The company producing the bare printed circuit board—that is, the PCB fabricator—has needs that are specific to that business, as follows:

- Low chemical and process cost
- Simple operation (low engineering demands)
- Reworkability
- Easily measured thickness
- Conveyorized equipment
- Electrically testable surface
- No sensitivity to poor handling
- Long shelf-life
- Inexpensive processing equipment and high throughput
- No attack of soldermask
- No toxic chemicals (waste should be easily treated)
- Specification by most original equipment manufacturer (OEM) customers
- Capability of being selectively coating with electroplated gold

**32.1.3.2 Assembly Requirements.** The assembly engineers, whether contract Electronics Manufacturing Services (EMS) provider, independent original design manufacturer (ODM), or captive OEM, have requirements that are very different from those of the PCB fabrication customer:

- Flat surface for stenciling paste
- Low contact resistance for in-circuit test (ICT)
- Tolerance for paste misprint cleaning
- Long incoming shelf-life (more than one year)
- Long midassembly shelf-life (more than two weeks)
- Compatibility with all pastes and fluxes
- Capability of bonding with Al and/or Au wire

- The ability to be visually inspected (prevents solder mask residue non-wetting)
- Ease of handling
- Excellent and predictable wettability
- Fiducial recognition
- No warp and twist of the PCB
- Good compliant pin and connector contacts
- Good Pb-free soldering with no need for nitrogen
- No solder bridging or plugged holes

**32.1.3.3 OEM Requirements.** The original equipment manufacturer has the following additional requirements:

- Best solderjoint reliability; strong intermetallic
- No impact on cost of bare board
- Prevention of defects (black-pad, voiding, whiskers)
- Corrosion resistance in uncontrolled field environments
- Usefulness as an electrical test point and EMI shield
- Functionality as a touchpad/keypad contact
- Good electrical performance of high-speed signals
- Adherence to industry-consensus specifications
- Complete documentation from the chemical supplier
- Established supply base of installed fabricators
- Audited fabricators

## 32.2 ALTERNATIVE FINISHES

---

Surface finishes available in the PCB industry are as follows:

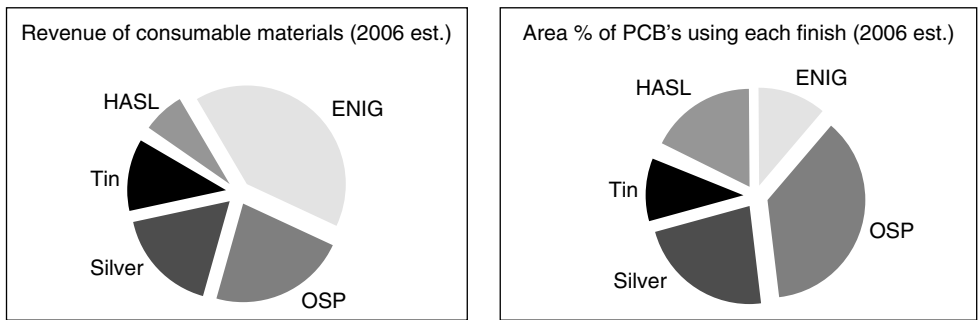

- HASL
- Reflowed tin-lead
- ENIG
- OSP
- Antitarnish and preflux
- Immersion silver
- Immersion tin
- Electroless palladium (Pd)
- Electrolytic nickel/electrolytic gold
- Electroless gold
- Direct immersion gold
- Solid solder deposit

Table 32.1 shows these alternative surface finishes and their typical thicknesses.

**TABLE 32.1** Major Surface Finish Options with Typical Thickness

PCB surface finish	Typical thickness
Hot Air Solder Level	2–40 $\mu\text{m}$ (80–1600 $\mu\text{in}$ )
Organic Solderability Preservative	0.1–0.6 $\mu\text{m}$ (4–24 $\mu\text{in}$ )
Electroless Nickel/Immersion Gold	Nickel: 3–5 $\mu\text{m}$ (120–200 $\mu\text{in}$ )
	Gold: 0.05–0.15 $\mu\text{m}$ (2–6 $\mu\text{in}$ )
Immersion Silver	0.1–0.4 $\mu\text{m}$ (4–16 $\mu\text{in}$ )
Immersion Tin	0.6–1.2 $\mu\text{m}$ (24–48 $\mu\text{in}$ )

Figure 32.1 shows the estimated usage of these surface finishes, indicating that no single finish will satisfy all needs. These are discussed in the following sections.

**FIGURE 32.1** Worldwide surface finish usage estimates by (a) dollar amount and (b) area share of PCBs manufactured.

### 32.3 HOT AIR SOLDER LEVEL (HASL OR HAL)

HASL is the process of immersing a circuit board into molten solder. For the vast majority of HASL applications, the solder alloy is tin-lead. For Pb-free applications, the main alloys include tin-copper, tin-silver-copper, tin-copper-nickel, and tin-copper-nickel-germanium alloys. The thickness and texture of the HASL surface result from the surface tension of molten solder. As such, the thickness varies from 2 to 20  $\mu\text{m}$  or more. HASL boards demonstrate excellent shelf-life, solderability protection, and resistance to poor handling, but they do tend to have higher levels of residual ions left over from fluxing. The HASL operation forms an intermetallic with copper circuitry at the PCB shop. This extra thermal step, with the associated loss in copper, is a concern for Pb-free assemblies. Expansion of the PCB substrate at high temperatures can warp and twist the board. The dimensional movement, along with uneven pad flatness and plugged vias, makes assembling dense circuitry (less than 0.5 mm pitch) difficult or impossible. The worldwide decline of HASL is partly due to assembly concerns and partly due to Pb restrictions.

#### 32.3.1 Fabrication Process

HASL can be applied in vertical or horizontal equipment. As a pretreatment, the copper is cleaned, microetched, and fluxed. It is common for the HASL pretreatment steps to be carried out in conveyORIZED equipment, and then the panel to be transferred to a vertical machine that dips the individual panel into molten solder. As the panel is raised, air knives

blow off excess solder. To handle the very high temperatures of the molten alloy, equipment is manufactured from stainless steel, titanium, and other alloys. Aggressive rinsing is needed to remove flux residues, as the HASL process is potentially much dirtier than other surface finish processes. Surface finishing engineers must be aware of safety concerns, such as exposure to Pb and the possibility of equipment fires.

### 32.3.2 Advantages and Disadvantages

Table 32.2 compares advantages and disadvantages of HASL.

**TABLE 32.2** Advantages and Disadvantages of HASL

HASL Advantages	HASL disadvantages
Inexpensive relative to other finish options	Not flat
Cu/Sn solderjoint	Paste misprints
Widely available	Poor fine-pitch assembly
Reworkable	Thick intermetallics
	May contain Pb
	Thermal damage to board
	Solder bridging
	Plugged PTHs

### 32.3.3 Failure Modes

HASL involves a delicate balance between sufficient solder coverage and excess solder. Inadequate solder results in exposed copper intermetallics and reduced shelf-life. Excess solder (which is more common) forms bridging among fine-pitch features. If the solder is not removed sufficiently from through holes, pin components do not place at automated assembly. A chief failure mode is due to HASL’s lack of flatness. At assembly, stencils do not gasket well to the board surface, so paste misprints and skips can be problematic. Assemblers find difficulty stenciling paste on HASL finished PCBs using technology below 0.5 mm pitch. Positioning a HASL board (see Fig. 32.2) in the fixture for stenciling can be challenging if the PCB dimensions changed during HASL thermal steps.

**FIGURE 32.2** (a) HASL equipment (b) surface scanning electron micrograph (SEM).

### 32.4 ELECTROLESS NICKEL IMMERSION GOLD (ENIG)

Chemically, gold is the ideal element for the external coating of PCBs. Gold does not form an oxide, so it is virtually unaffected by temperature and storage conditions that might reduce the shelf-life of other finishes. In addition, gold dissolves nearly instantaneously into solder, promoting superior wettability.

Gold is limited, however, in other ways. Gold embrittles solderjoints when present in excess of about 3 percent by weight, so gold coatings of 0.3  $\mu\text{m}$  maximum thicknesses should be used in soldering. Gold dissolves very quickly into copper as well. To prevent the mixing of gold with copper, and the eventual solderability problems caused by oxidized copper at the PCB surface, a layer of nickel is deposited to separate the metals. ENIG does not rely on electrolytic plating with outside power; in practice, nickel is deposited as a phosphorous-reduced "electroless" nickel.

#### 32.4.1 Chemistry

ENIG deposition is dependent on the electromotive series of elements. Gold readily deposits directly on copper as an immersion bath, but as stated previously, a barrier of nickel is needed. In common practice, 3 to 5  $\mu\text{m}$  of nickel is used in ENIG, with a thin gold coating of 0.05 to 0.15  $\mu\text{m}$  (typically) to prevent nickel oxidation.

Nickel does not deposit directly on copper without prior catalysis. Palladium or ruthenium metal forms an immersion deposit on copper as the catalysis or activation step of ENIG. Catalysis baths employ the immersion (galvanic displacement) chemical mechanism.

As with all finishes, extra steps are required before the deposition of catalyst, Ni, and Au. All commercial ENIG processes rely on a cleaner and microetch prior to catalysis in order to remove trace residues from the solder mask and tin strip processes before final finish. Microetch is normally based on peroxide, persulfate, or monopersulfate systems.

#### 32.4.2 Fabrication Process

Table 32.3 shows the process flow for ENIG surface finish.

**TABLE 32.3** Process Flow for ENIG

Process	Chemicals	Time (min.)
Cleaner	Aqueous solvents, detergents, and emulsifiers. Acid can help undercut residues and remove thick copper oxides.	2–5
Microetch	In acidic environments, copper is oxidized by persulfate ( $\text{S}_2\text{O}_8^{++}$ ), peroxide ( $\text{H}_2\text{O}_2$ ), or proprietary monopersulfate acid mixes. Sulfuric acid is common to all types of microetch. 1–2 $\mu\text{m}$ of Cu is oxidized to $\text{Cu}^{++}$ and dissolved.	1
Catalyst	Immersion deposit (galvanic displacement) $\text{Pd}^{++} + \text{Cu}(0) \rightarrow \text{Pd}(0) + \text{Cu}^{++}$ (or) $\text{Ru}^{+++} + \text{Cu}(0) \rightarrow \text{Ru}(0) + \text{Cu}^{++}$	1–5
Electroless Nickel	Nickel is deposited through chemical (sodium hypophosphite) reduction. Rate control, by pH and temperature, determines phosphorous content, usually 8–11% by weight.	10–20
Normally, automated controllers are needed to maintain this dynamic bath. Nickel can be measured optically or with titration. Ammonia maintains pH.		
Immersion Gold	Immersion deposit (galvanic displacement) $\text{Au}^+ + \text{Ni}(0) \rightarrow \text{Au}(0) + \text{Ni}^{++}$	8–15
Gold is added as $\text{KAu}(\text{CN})_2$ . Do not use gold salts containing Co or Ni.		

Due to the long dwell times, high operating temperatures, and complicated chemical reactions, the ENIG process is always conducted in vertical tanks. To achieve the throughput required in production, many ENIG systems make use of two or three electroless nickel (EN) tanks, which allows for heating new baths or nickel stripping. Using two active EN tanks greatly improves throughput, but the total process ordinarily exceeds 1 hour in cycle time.

In addition to the normal plastic materials used in tank construction, stainless steel can be used for EN tanks. This is possible only with the use of anodic passivation, which employs an electrical bias applied to the steel to prevent reduction of nickel ions on the steel. By using steel tanks, fabricators avoid the frequent stripping of plastic tanks required due to the slow plate-out of nickel on rough surfaces and localized hot spots.

### 32.4.3 Advantages and Disadvantages

Table 32.4 shows comparison of advantages and disadvantages of ENIG surface finishes.

**TABLE 32.4** Advantages and Disadvantages of ENIG

ENIG advantages	ENIG disadvantages
Flat; fine-pitch assembly	Expensive
Surface contacts	Brittle Ni/Sn solderjoint
Widely available	Not reworkable
No copper dissolution	Solder mask attack
No Pb	Black-pad, black-line nickel
Strong PTH “rivet”	Signal loss at RF frequencies
Long shelf-life	Very complicated process

### 32.4.4 Failure Modes

ENIG failure modes at fabrication are mainly due to the activity of the chemical process steps. Underactive catalysis yields skip plating in the subsequent nickel bath. Nickel skips allow copper to migrate through gold and prevent solder wetting. Overactive catalysis can lead to extra metal between circuit features, known as extraneous plating. This can cause short circuits. Overactive nickel baths deposit low phosphorous content, leading to the interconnection failure mode known as black-pad (described in Sec. 12.2). Overactive gold chemistry attacks nickel along nodule boundaries and produces black-pad. Such gold conditions may be detected with frequent x-ray fluorescence (XRF) thickness measurement. Underactive nickel and gold baths pose skip-plate problems. Peeling of gold films can result from too much rinse time after nickel or from poor rinse quality. Tape testing of ENIG is mandatory. Very rough nickel deposits are possible when the electroless nickel bath is not closely maintained. Nickel baths can destabilize, plate onto the tank walls, and produce inferior coatings. Lastly, soldered ENIG surfaces result in a nickel-tin solderjoint. This structure has been demonstrated to be less tolerant of physical shock than the copper-tin solderjoint. The brittle intermetallic is unavoidable with ENIG, so mobile devices usually do not employ ENIG solderjoints.

## 32.5 ORGANIC SOLDERABILITY PRESERVATIVE (OSP)

As the name connotes, OSPs are very thin organic coatings used to preserve the solderability of PCB surface copper. Differing from alternative surface finishes that attempt to serve other PCB functions, OSPs are generally limited to solderability preservation only. The most widely used OSPs, benzimidazoles and phenylimidazoles, have evolved from earlier antitarnish coatings and can endure multiple soldering operations. OSP is the least expensive and simplest of all major surface finish options, so it enjoys wide use throughout the world. OSP use is limited, however, due to poor contact functionality for ICT and electrical test. Also, it suffers from degradation after multiple thermal operations, so solder wetting on Pb-free assemblies can pose problems.

### 32.5.1 Chemistry

OSP is the simplest chemical process of the surface finishes, but the chemical itself is actually quite complicated. In brief, a large organic molecule (see Fig. 32.3) is dissolved into a solution of water and organic acid. The circuit board is exposed to the solution, and the OSP molecule attaches to the PCB's exposed copper surfaces. A chemical bond is formed between copper and a nitrogen group in the OSP. Copper is present in the chemical bath, so multiple layers of an OSP-copper complex can deposit on the surface, reaching a thickness of 0.10 to 0.60  $\mu\text{m}$ .

**FIGURE 32.3** OSP molecule types.

Another generation of OSPs is designed to survive exposure to multiple high-temperature soldering operations. These chemicals are normally based on benzimidazole with attached functional groups to add molecular weight and thermal resistance. Substituted phenylimidazole and OSP systems with metal codeposits have been used as well. The intent of the new generation of OSP is to withstand Pb-free soldering temperatures. These "high-temperature" OSP coatings, made for use with Pb-free alloys and the associated fluxes, can be deposited at higher thicknesses and may be measured as high as 1.0 micron.

### 32.5.2 Fabrication Process

Table 32.5 show the fabrication process for OSP, including chemicals and dwell times.

Almost universally, OSP is applied in conveyORIZED equipment. The cleaner and microetch may use flood or spray application, but OSP is applied using flood. Because the OSP process is very mild to the PCB materials, rinsing is very important to ensure that contamination from all prior fabrication steps is removed. Often, OSP is applied when the PCB is in part form after the PCB has been electrical tested, routed, and depanelized. This is to preserve the

**TABLE 32.5** Process Flow for Organic Solderability Preservative

Process	Chemicals	Time (min/)
Cleaner	Aqueous solvents, detergents, and emulsifiers. Acid can help undercut residues and remove thick copper oxides.	1–4
Microetch	1–2 μm of Cu is oxidized to Cu <sup>++</sup> and dissolved.	1.0
Pre-Dip	Normally, the predip employs ingredients of the OSP bath without the OSP chemical itself.	0.5
OSP	OSP, acetic or formic acid, source of copper or other metals.	0.5–1.0

fragile OSP surface, which is sensitive to handling, contamination, and fingerprints. The OSP parts should stabilize at room temperature and controlled humidity before packaging, as any moisture in the package can turn the OSP surface black.

OSP thickness is normally determined by indirect sampling. No method exists for determining the OSP thickness during production on the actual PCB. Instead, a sample coupon is processed along with the production parts. The coupon is immersed in an acid/solvent solution that dissolves the coating. The solution is transferred to a UV-VIS cell, where the absorbance of light allows the estimation of the thickness of OSP on the coupon. That measurement is used as a quality control for the production boards.

The lack of a true thickness measurement control is a key issue to OEMs that require control metrics. If the OSP coating is too thin, the PCBs will have inadequate protection. If the coating is too thick, there is a possibility for poor solder wetting and poor PTH filling. The OSP coating is invisible to the eye, so there is no way to inspect for unprotected copper if the OSP coating was not applied correctly.

### 32.5.3 Advantages and Disadvantages

Table 32.6 compares the advantages and disadvantages of using OSP as a surface finish.

**TABLE 32.6** Comparing the Advantages and Disadvantages of OSP

OSP Advantages	OSP disadvantages
Flat; fine-pitch assembly	No direct thickness measurement
Least expensive finish	High surface contact resistance
Simple process	Poor PTH soldering
Widely available	Shorter shelf-life
Cu/Sn solderjoint	Exposed copper on final assembly
No Pb	Not inspectable before assembly
Reworkable	Degrades with multiple reflow
High productivity at fabrication	Handling-sensitive
	Problems with paste misprint cleaning

### 32.5.4 Failure Modes

The OSP process is simple, so few failure modes exist at fabrication due to chemical stability. Aggressive microetch and poor rinsing can result in attack at the junction of solder mask and exposed PCB metal, especially if nickel-gold has been selectively deposited on edge fingers. Galvanic attack at this interface can cause electrical opens. PCBs using selective nickel-gold can also suffer from deposition of OSP on the gold surface. OSP on copper prevents good

electrical test contact and in-circuit testing. OSP deposition on selective gold can prevent the intended contact functionality of the gold pad. Skip plating can be a concern. Very thin solder mask residues will prevent OSP coating. Because the OSP coating is invisible, it cannot be inspected, so skip plating will lead to non-wetting at assembly. OSP is the coating most sensitive to handling, storage, and shelf-life. Copper under OSP oxidizes with time and heat, so weak fluxes present soldering issues. The Pb-free temperature increase has narrowed the OSP process window to the point where PTH solderability may not meet IPC standards.<sup>[1-3]</sup>

## 32.6 IMMERSION SILVER

Silver was chosen as a PCB surface finish from the earliest days of PCB fabrication due to some inherent advantages. Silver is the best electrical conductor and exhibits the lowest contact resistance of any metal. As a precious metal, it is more resistant to oxidation than other more base metals. On early PCBs, electroplated silver was discovered to form metal dendrites between conductors. During the 1990s, new immersion silver was introduced as an HASL alternative, and users developed data showing that dendrite formation was not an issue. With the Pb-free transition, immersion silver gained widespread use. OEMs with specific needs specified silver to overcome issues with other finishes. Immersion silver is a galvanic displacement process with a typical thickness range of 0.1 to 0.4  $\mu\text{m}$ . The fabrication process is easy, but the coating can suffer from tarnish when left exposed after assembly in field use. Heavy tarnish can be a predictor for corrosion and functional loss.

### 32.6.1 Chemical Coating

The PCB copper is prepared using separate cleaning and microetch steps. Over time, these steps can be taken for granted, but improper use can cause many defects. The predip bath removes excess acidity from the PCB and prevents chlorides from entering the silver bath, where silver chloride would quickly precipitate. The silver bath is quite simple chemically, relying on the galvanic displacement of less noble copper with two atoms of more noble silver. Proper rinsing and drying is essential.

### 32.6.2 Fabrication Process

Table 32.7 shows the fabrication process for immersion silver surface finish, including the chemicals used and dwell times.

**TABLE 32.7** Process Flow for Immersion Silver

Process	Chemicals	Time (min)
Cleaner	Aqueous solvents, detergents, and emulsifiers. Acid can help undercut residues and remove thick copper oxides.	1–4
Microetch	1–2 $\mu\text{m}$ of Cu is oxidized to $\text{Cu}^{++}$ and dissolved.	0.5–1.0
Predip	Normally, the ingredients of the silver bath without the silver metal itself.	0.5
Silver	Silver, acid, grain refiners, chelation $\text{Ag}^+ + \text{Cu}(0) \rightarrow \text{Ag}(0) + \text{Cu}^{++}$	0.5–3.0
Postdip (optional)	Can be an antitarnish or an extra cleaner for demanding ionic cleanliness applications.	

Most immersion silver in large production is applied in conveyORIZED equipment. The cleaner and microetch may use flood or spray application, but the silver solution is applied using flood. Because the silver process is very mild to the PCB materials, rinsing is very important to ensure that contamination from all prior fabrication steps is removed. Often, silver is applied in part form after the PCB has been routed, depanelized, and electrically tested. This is to preserve the silver surface, which can be sensitive to handling, contamination, and fingerprints. In smaller-scale production and prototype manufacturing, silver can be applied in vertical process tanks.

### 32.6.3 Advantages and Disadvantages

Table 32.8 compares the advantages and disadvantages of using immersion silver as a surface finish.

**TABLE 32.8** Advantages and Disadvantages of Immersion Silver as a Surface Finish

Silver advantages	Silver disadvantages
Flat; fine-pitch assembly	Handling-sensitive
Inexpensive finish	Solderjoint microvoid history
Simple process	Exposed silver on final assembly can corrode
Widely available	Tarnish
Cu/Sn solderjoint	Silver had a history of dendrite formation
No Pb	Attack at the solder mask interface
Reworkable	
High productivity at fabrication	
Easy thickness measurement	
Excellent surface contact functionality	
No degradation with multiple reflow soldering	

### 32.6.4 Failure Modes

The silver surface readily shows tarnish from exposure to sulfur and chloride environments. Excessively tarnished parts have limited solderability. As a galvanic process, aggressive silver baths can attack copper circuitry. Attack can occur at the interface with solder mask or at the electroless copper layer on sidewalls. The attack is more severe at high thicknesses over 0.50  $\mu\text{m}$  and if the PCB is reworked with multiple passes through immersion silver. Copper attack can result in electrical opens. Aggressive silver baths, when deposited on rough copper, can also attack on pad surfaces, causing “caves” in the copper. Studies show that caves can result in layers of very small voids at the copper-solder interface after soldering. These structures, termed *microvoids*, can dramatically reduce solderjoint strength and produce electrical opens. Each of the preceding failure modes is worsened when the silver bath plates nonuniformly. The chemicals need to be formulated and operated in such a way to provide uniform galvanic exchange metal deposition.

## 32.7 IMMERSION TIN

Immersion tin is a thin coating of pure tin, typically 0.6 to 1.2  $\mu\text{m}$  thick, which protects the underlying copper from oxidation and provides a highly solderable surface. Tin is deposited using a galvanic displacement process and can be applied in vertical or conveyORIZED equipment. Tin boards are used primarily for solderability and have very good compliant pin connector functionality.

Tin readily forms an intermetallic with copper, so tin can pose challenges with shelf-life, multiple soldering operations, and contact functions. Tin is also restricted in some regions due to environmental concerns over the use of the bath ingredient thiourea.

### 32.7.1 Chemical Coating

As with all immersion metal systems, the copper needs to be perfectly clean and textured before the tin plating step. A predip is used to maintain proper chemical balance in the tin bath and prevent contamination. The tin deposition is not a direct galvanic displacement, since tin is more electronegative than copper. Thiourea is used in tin chemical formulation to create a copper-thiourea complex on the surface. This complex becomes more electronegative than tin, and then participates in the immersion reaction. Because of the need to drive the reaction, the tin bath contains relatively high concentrations of chemicals, which must be thoroughly rinsed. Waste treatment of the system is complicated due to high levels of thiourea.

### 32.7.2 Fabrication Process

Table 32.9 shows the fabrication process for the immersion tin surface process, including chemicals used and dwell times.

**TABLE 32.9** Process Flow for Immersion Tin

Process	Chemicals	Time (min.)
Cleaner	Aqueous solvents, detergents, and emulsifiers. Acid can help undercut residues and remove thick copper oxides.	1–4
Microetch	1–2 $\mu\text{m}$ of Cu is oxidized to $\text{Cu}^{++}$ and dissolved.	0.5–1.0
Predip	Normally, the ingredients of the tin bath without the tin metal itself.	1.0
Tin	Tin, thiourea, acids, whisker inhibiting trace metals, chelation.	4.0–12.0
Postdip (optional)	Can be an extra cleaner for demanding ionic cleanliness applications.	

Few production installations use immersion tin in horizontal conveyORIZED applications due to the chemical process time and the higher temperatures used. ConveyORIZED lines are long and therefore expensive. The use of vertical tanks carrying baskets of panels for immersion tin plating makes better use of production floor space. Due to the high sulfur reactivity of the thiourea ingredient, tin lines should be dedicated to the tin process only and not mixed in with OSP, silver, or ENIG lines where sulfur can harm the surfaces.

### 32.7.3 Advantages and Disadvantages

Table 32.10 compares the advantages and disadvantages of immersion tin used as a surface finish.

**TABLE 32.10** Advantages and Disadvantages of Immersion Tin Surface Finish

Tin Advantages	Tin Disadvantages
Flat; fine-pitch assembly	Handling-sensitive
Inexpensive finish	Use of thiourea (a carcinogen)
No Pb	Exposed tin on final assembly can corrode
Cu/Sn solderjoint	Whiskers
Excellent compliant pin functionality	Degradation with time/ heat and multiple reflow soldering
Less visible tarnish	Solder mask attack
Reworkable	Difficult thickness measurement

## 32.8 OTHER SURFACE FINISHES

---

Other surface finishes include reflowed tin-lead, electrolytic nickel/electrolytic gold, antitarnish and reflow, electroless palladium, electroless gold, direct immersion gold, and solid solder deposit.

### 32.8.1 Reflowed Tin-Lead

Before the widespread use of solder mask, a primary method for protecting copper circuitry was to electroplate a coating of tin or tin-lead on the copper. After component insertion, the tin plating could be liquefied with oven or vapor-phase reflow to form solderjoints. The use of solder mask over bare copper to take advantage of surface mount, wave soldering, and mixed assembly restricted the use of tin plate finishing. For simple technology product, tin or tin-lead plate and reflow remains a viable fabrication and assembly method.

### 32.8.2 Electrolytic Nickel/Electrolytic Gold

The electrolytic nickel-gold process employs galvanic electroplating. The circuit board is placed on a rack and electrically connected to a power supply (rectifier). When immersed in a solution of metal ions, the metals are reduced as a metal coating on the PCB by the supply of electrons. The metal thickness grows in a very predictable way depending on the time, current, area plated, and efficiency of the reaction. Relatively few PCBs are plated “full-build” with nickel-gold as the only finish. More frequently, the coating is applied selectively in combination with another finish such as OSP. For a large number of PCBs that employ edge tab connection, the PCB is electroplated in a special plating line where only the exposed edge features are immersed into the plating cell. Electroplated nickel-gold is expensive and difficult to use in high production, so it is commonly used only on features requiring high-force physical connections or gold wirebonding. Several micrometers of nickel are deposited, and 0.50 to 1.5  $\mu\text{m}$  of gold protects the nickel from oxidation. Thick gold forms gold-containing phases in the solderjoint. The embrittlement of these phases has prevented the wide use of electrolytic nickel-gold as a solderable finish.

### 32.8.3 Antitarnish and Preflux

Antitarnish surface finishes are thin, organic coatings designed to prevent copper oxidation. Antitarnish chemicals include imidazole and benzotriazole. Preflux coatings are resins or rosins. These materials cannot endure long storage times and normally can be used only for single-sided soldering operations. Much of the use of simple organic coating was replaced by OSP as the cost of OSP declined, but antitarnish and preflux chemicals are still used in simple PCB fabrication.

### 32.8.4 Electroless Palladium

The original concept for electroless palladium was as an alternative to the high cost of gold. Palladium shows some of the oxidation resistance similar to precious metals, and can offer a good physically strong deposit for electrical contacts and wirebonding. However, palladium is a very difficult metal to deposit electrolessly, causing substantial engineering support and yield problems. The rise in the cost of palladium metal nearly removed it from any market share worldwide. Electroless palladium reemerged in OEM testing as a possible cure for ENIG black-pad, but it is not widely used. Palladium is sensitive to the environment, so a flash

of immersion gold may be used over palladium. The coating is considered not reworkable. Palladium phases in the solderjoint pose an embrittlement hazard.

### 32.8.5 Electroless Gold

Gold can protect copper and resist oxidation like no other metal. But electrolytic nickel-gold and ENIG both suffer from certain limitations. Electroless nickel with a coverlayer of electroless gold is intended to overcome these limitations. As with ENIG, electroless nickel underlayer is needed as a barrier layer to prevent copper to gold interdiffusion. Electroless gold can achieve a sufficient thickness to allow gold wirebonding and some physical connection functions. It also deposits much more uniform thickness than electrolytic gold. Better thickness control allows somewhat thinner coatings, so gold embrittlement can be prevented. Cost and process control considerations prevent more widespread use. In addition, all the limitations of the use of electroless nickel still apply when considering this finish.

### 32.8.6 Direct Immersion Gold

Because electroless nickel is the cause for many of the disadvantages of ENIG, some designers have considered the use of immersion or electroless gold directly on top of underlying copper. This process works for boards that are assembled without a long shelf-life and do not require multiple thermal excursions. Without the barrier coating of nickel, however, the copper and gold soon dissolve into each other and form an unsolderable oxidized intermetallic. As direct gold costs more than immersion silver or tin coatings, its main advantage is its improved possibility for gold wirebonding.

### 32.8.7 Solid Solder Deposit

Technologies exist for the deposition of solder onto the bare PCB at the fabrication shop using non-HASL techniques. One method employs the deposition of tin-lead with a physical flattening of the solder meniscus. Other methods have been proposed as well. The use of these deposition methods has not penetrated widely into the production market.

## 32.9 ASSEMBLY COMPATIBILITY

---

Figure 32.4 shows a PCB as it progresses through the assembly and soldering process, showing the resulting intermetallics in cross section.

### 32.9.1 Solderability Test Methods

Refer to Chap. 42 for detailed information on solderability of PCB surface finishes. Testing methods are contained in the comprehensive joint industry specification ANSI/IPC J-STD 003. Surface finishes are commonly tested in production at the board fabricator using a solder float or solder dip method. When qualifying the finish, an OEM or assembler uses more equipment-specific tests such as wetting balance, rotary dip, or paste spread methods. Solderability should be consistent from day to day and lot to lot, with very little degradation after exposure to at least three assembly thermal exposures.

**FIGURE 32.4** A surface finish progressing through assembly; the bare finish, with stenciled paste, as soldered, and in cross-sectional view of resulting intermetallics.

### 32.9.2 Misprints

For many years, a primary failure mode in PCB assembly was solderpaste misprints. Misprints occur when the solder stencil or screen does not form a close contact or good gasketing with the circuit features. If there is a gap between the stencil and the copper, or if the screen is slightly mis-registered, solderpaste squeezes between the features, causing solder bridging and resulting in a lack of solder where the paste deposition was intended. The uneven surface of HASL is a chief cause of paste misprints. Flat surface finishes such as silver, tin, and OSP virtually eliminate solderpaste misprints. If misprints do occur for other reasons such as misalignment, the finish should be able to be cleaned, staged for reprinting, and soldered without any lack in wetting. OSP may be removed during misprint cleaning; the PCBs should be assembled immediately if this occurs.

### 32.9.3 Shelf-Life, Storage, and Handling

Each finish is vulnerable to solderability loss if the PCB is handled or stored in non-ideal environments. OSP, generally given a 6 to 12 month shelf-life, is degraded with time and temperature, as the organic and underlying copper can oxidize. Silver, with a shelf-life of 12 months, is affected by exposure to sulfur and chloride environments that can cause excessive tarnish. Tin, with a shelf-life of 6 to 12 months, forms intermetallics with copper over time and at elevated

temperature. ENIG has a shelf-life exceeding 12 months and can withstand most environments, but is sensitive to steam aging and degrades more quickly than other finishes in mixed flowing gas testing. HASL is considered to have virtually unlimited shelf-life. The shelf-life of any PCB, with any surface finish, can quickly degrade if the parts are exposed to contaminating materials. Any contaminant film that prevents flux and solder from coming into intimate contact with the surface finish will result in non-wetting.

### 32.9.4 Solderjoint Metallurgy

The basic function of the circuit board is to act as a mechanical and electrical connection between components of an electrical device. Application of solder to a PCB surface results in the formation of an intermetallic compound. The metals in the solder and the metals on the PCB participate in the intermetallic formation. The intermetallic acts as the physical glue holding the solder to the circuitry. The type of intermetallic depends on the type of solder and the type of PCB finish.

The vast majority of solders used in electronics (SnPb, SnAgCu, SnCu, SnCuNi) is based on tin. Most of the time, the tin forms an intermetallic with copper ( $\text{Cu}_3\text{Sn}$  and  $\text{Cu}_6\text{Sn}_5$ ). The primary exceptions are ENIG and electrolytic NiAu finishes. Soldering to nickel-based finishes results in  $\text{Ni}_3\text{Sn}_4$  and  $\text{NiSn}_3$  intermetallic compounds. The physical and electrical performance differences between copper and tin intermetallics do influence the design of electronic devices. In general, solderjoints formed using intermetallics of nickel are more brittle and lead to earlier failure in physical shock testing.

HASL begins to form copper-tin intermetallics when the HASL is deposited at the PCB shop. When HASL is soldered at the assembly house, the HASL coating liquefies and mixes with the molten solderpaste or wave solder. The intermetallic formed at the PCB interface deepens with each thermal excursion. HASL intermetallics can reach thicknesses of concern to reliability engineers. Intermetallic layers formed using high tin content solders (Pb-free) grow more quickly due to the increased availability of tin and the elevated temperatures. With the consumption of copper into intermetallics, there is a concern with the thinning of copper, especially at the knee of plated through holes.

The OSP coating is displaced by the flux during SMT and wave soldering. The exposed copper forms a copper-tin intermetallic with the solder. If the flux exposes more copper than the solder spreads, a ring of unprotected copper results. Some engineers consider this ring of exposed copper to pose a corrosion risk. For Pb-free soldering, best results are achieved by selecting a flux system that maintains activity throughout the entire soldering temperature range.

Immersion silver dissolves into the tin phase of molten solder. The silver does not melt, but rather forms a solid solution. The dissolution rate of silver is in the range of 0.5 to 1.5  $\mu\text{m}$  per sec. at standard soldering temperatures. Once the silver is dissolved, the underlying copper forms intermetallics with tin as discussed previously. Flux has little effect on silver, but can help clean trace contaminants and reduce surface tension.

Immersion tin dissolves very quickly into SMT and wave solder. The tin may not melt (m.p. 232°C) but dissolves into the liquefied solder readily. Even before soldering, the immersion tin begins to form intermetallics with the copper beneath. In fact, with extended storage, the tin may be completely consumed by intermetallics before soldering. At soldering temperatures, the copper-tin intermetallics form at much higher rates. Areas of the PCB exposed to the assembly temperatures, but not soldered, will form thicker and thicker intermetallic layers until the pure tin is consumed.

ENIG is a special case. When exposed to solder, the top layer of gold very quickly dissolves into the tin phase at a rate of about 3  $\mu\text{m}$  per sec. at standard assembly temperatures. Once the underlying nickel is exposed, it begins to form intermetallics with tin. Nickel dissolves very slowly in solder (<0.002  $\mu\text{m}$  per sec.) so the nickel remains as a barrier between solder and

copper. The intermetallics formed between nickel and tin are very thin and more physically brittle than the copper tin Intermetallic Compound (IMCs).

Electroless palladium can also act as a barrier layer if used in sufficient thickness. Automotive PCBs produced in the 1990s specified a maximum of 0.2 micron of Pd metal with the goal to incorporate the entire Pd layer into the solderjoint.

Figure 32.5 shows the interaction of four surface finishes with solder during the assembly process.

**FIGURE 32.5** Displacement of PCB surface finishes during component assembly and soldering. (a) HASL: PCBs show some intermetallic formed during the HASL operation. Upon subsequent assembly, the HASL coating melts into the solderpaste or wave solder, and the intermetallic grows in thickness. (b) OSP: The OSP coating is removed by the flux during component assembly. The underlying copper forms the intermetallic with tin during soldering. (c) ENIG: Gold dissolves quickly into the tin phase of solderpaste or wave solder. The intermetallic is formed between tin and nickel because the rate of dissolution into nickel is slow. (d) Silver or Tin: Silver and tin coatings dissolve very quickly into the tin phase of solder. The intermetallic is formed with underlying copper.

## 32.10 RELIABILITY TEST METHODS

Reliability is determined using a variety of methods, usually used in combination. Often an unassembled PCB is exposed to a conditioning or aging environment. The conditioning may consist of time, temperature, humidity, and contamination metrics. The conditioning is normally at a higher level than the environment in which the device is intended to be used so that the test environment imparts an accelerated age condition.

Temperature exposure for PCBs is commonly conducted at 155°C for 4 or 8 hours to study shelf-life. To study the effect of soldering, simulation is conducted at the actual reflow temperature, without contact with flux or solder. Temperature cycling of assembled devices reflects the difficulty of the intended end-use environment. Although some cycling may occur at 0°C to 100°C, more severe cycling may require -55°C to 125°C. Assembled parts may also undergo physical testing conditions such as physical shock, vibration, bending, twisting, and impact.

Environmental exposure testing is common for PCB surface finish evaluation. Exposure to ambient air during reflow is common, as is long-term exposure to polluting environments such

as mixed flowing gas. Physical contact with contaminating materials such as fluxes, assembly materials, fuels, and even diesel fuel and carbonated beverages has been documented.

Electrical testing is another class of reliability testing. The function of a solderjoint formed with the surface finish can be measured by burn-in testing, electrical functional tests, and/or high-current-density application for extended periods. The contact resistance of an unassembled surface finish is an important measurement. The PCB finish, when exposed to heat and humidity metrics, as well as environmental exposure, may need to pass a sensitive four-point probe contact resistance check.

## **32.11 SPECIAL TOPICS**

---

### **32.11.1 High-Speed Signals**

Electrons travel along the outer regions of a conductor. This phenomenon, known as the skin effect, is most pronounced at the high signal frequencies of Global Positioning Systems (GPS), aerospace, navigation, mobile telephony, computer servers, and crash avoidance devices. At high frequencies, the skin depth of electron travel is of a thickness similar to that of the PCB surface finish. For example, at 10 GHz, the skin depth is less than 1 micron. Therefore, the electrical conductivity of surface finish materials is important at those higher frequencies. Above 2 GHz, circuit designers find that the use of electroless nickel hinders signal integrity. Silver, the most conductive element, is used for devices operating at higher frequencies.

### **32.11.2 Inspectability**

To ensure good soldering, it is necessary for the assembler to ensure that all copper is protected and no solder mask residue remains on solderable features. By inspecting the bare board, the engineer can reject parts that show bare copper due to skipped surface finishing or mask residue. A special case is OSP, where inspection of the protected copper is impossible because OSP-protected areas have the same visual appearance of uncoated copper with or without thin solder mask contamination.

### **32.11.3 Contact Functionality**

Many circuit board assemblies rely on surface contact functionality to operate. Examples include touchpads, edge contact rails for grounding/shielding, test probe contact points, zero insertion force connectors, chassis and enclosure bolts, and surface contacts for mating with nonsoldered connectors/interposers. OSP does not meet the demands of surface contact, so selective plating or soldered contact designs must be used. Immersion tin may lose contact functionality as the intermetallic oxidizes. HASL will maintain contact ability, but suffers from material creep under load, which may allow loose connections after field use. Silver maintains contact functionality even when tarnished, but loses contact ability if heavily corroded by the environment. ENIG maintains contact functionality over long periods of time, but is also susceptible to excessive corrosion. Electroplated Ni/Au is the best performing finish for long-term contact functionality.

### **32.11.4 Wirebonding**

Some device designs call for wirebonding directly to the PCB or laminate chip carrier. In general, most surfaces are wirebondable with aluminum wire. Al wirebonding may be impossible

with OSP or HASL finishes. For gold wirebonding, only electrolytic Ni/Au is widely used. Good bond strengths have been achieved on ENIG, Ni/Pd/Au, electroless gold, direct gold, and silver, but most production uses “soft” electrolytic Ni/Au to meet gold wirebonding demands.

**32.11.5 Compliant Pin, Press-Fit Connectors**

Compliant pin, or press-fit, connectors rely on contact with the surface finish in plated through holes. The main concern is the dimension of the finished hole size. When using HASL, the PCB designer must allow for the extra thickness of solder that will reduce the diameter of the PTH. HASL alternative finishes are flat, so will have negligible effect on finished hole size, since the thickness of the finishes is less than the tolerance of the drilling and plating operations. The material properties of the finish have some affect on compliant pin capability. Soft materials such as HASL and immersion tin perform better by providing low insertion force. Hard materials, such as copper and nickel, yield higher insertion force. OSP and silver act like copper due to the thinness of the coating.

**32.12 FAILURE MODES**

See Table 32.11 for descriptions of failure modes of specific surface finishes

**TABLE 32.11** Failure Modes Specific to PCB Surface Finishes

OSP	HASL	ENIG	Immersion Tin	Immersion Silver
PTH Hole Fill	Solder Bridging	Black-Pad,	Tin Whiskers	Post-Assembly
Exposed Copper	Plugged Holes	Black-Line Nickel	Ionic cleaning	Corrosion of
after Soldering	Equipment Safety	Brittle Fracture	Failures	Exposed Surfaces
Post-Assembly Corrosion	Paste misprints	Solder Mask Attack	Solder Mask Attack	Tarnish
of Exposed Surfaces		RF Signal Loss	Post-Assembly Corrosion	Solderjoint
Handling Defects		Post-Assembly	of Exposed Surfaces	Microvoids
		Corrosion of		Electrochemical
		Exposed Surfaces		Migration

**32.12.1 Whiskers**

Whiskers form as a single crystal growth from the surfaces of mainly pure tin coatings (see Fig. 32.6). The whiskers are tiny, but can form lengths exceeding the spacing between electrical features on the circuit board or components. As pure tin is electrically conductive, reliability engineers fear that tin whiskers will form short circuits. In fact, there have been several high-profile failures attributed to tin whisker growth.

Whiskers form more quickly from pure deposits of tin over copper and brass. Although they have been reported in literature from other elements, the vast majority of whiskers in electronics have resulted from tin plating.

**FIGURE 32.6** Tin whiskers on fine-pitch contacts.

The use of lead in tin plating and solder has been used to inhibit tin whisker growth. Rare reports of tin whiskers have been reported from tin-lead coatings. Whiskers evolve from tin surfaces as a stress-relief mechanism between tin crystals. Most stress in tin deposits arises from the growth of copper-tin intermetallics at the interface with underlying copper. With a much slower rate of nickel-tin intermetallic formation, tin whiskers form at a much lower rate than tin coatings on nickel underplate.

Several tin-whisker mitigation techniques have been proposed:

- Inclusion of lead, silver, and other metals in the tin deposit
- Use of a nickel tin coating as a barrier between copper and tin
- Annealing of tin as a stress relief
- Conformal coating as a barrier to whisker growth

In practice, the only effective whisker mitigation strategies involve nickel barriers and contamination of the tin deposit with a sufficient amount of metal, such as 2 percent Pb.

### 32.12.2 Interfacial Fracture

Interfacial fracture is a failure mode usually associated with ENIG, and is also known as black-pad, brittle nickel, and black-line nickel (See Fig. 32.7). Technically, interfacial fracture simply refers to the location of physical separation when a solderjoint is tested to failure. Black-pad (black-line nickel) is a phenomenon of ENIG that, when sufficiently severe, results in interfacial fracture. Brittle nickel refers to the inherent weakness of solderjoints formed from nickel-tin intermetallics, regardless of the mechanism of failure.

Black-pad is a name given to the surface of a circuitry feature after interfacial fracture. The separation occurs between the solder and an underlying surface of irregular, high-phosphorous, rough nickel. Aggressive gold displacement corrodes the rough nickel selectively along the nodule boundaries of the electroless nickel. The nickel is easily corroded due to the low phosphorous content of the as-deposited electroless nickel coating. Low phosphorous deposits (less than 9 percent) are far more easily corroded than higher phosphorous (10 to 12 percent by weight) EN coatings. The simple remedy in prevention of black-pad is the use of high phosphorous coatings, based on the operating parameters and chemical formulation of the nickel bath. However, any nickel bath can be destabilized with contamination such as divalent sulfur from undercured solder mask. Less stable EN baths plate at a higher rate and result in low phosphorus deposits.

**FIGURE 32.7** The result of black-pad and the microstructure of a black-pad nickel interface.

Even with good chemical formulation, correct operating conditions, and good inspection, black-pad still occurs in PCB assembly. Certain PCB designs are more vulnerable to black-pad due to galvanic effects set up in the plating bath in areas of extreme anode/cathode ratio. Users should be aware that there is no complete solution to black-pad, but adoption of the following measures is highly recommended:

- Cure the solder mask as much as practical to prevent photoinitiator contamination of the nickel bath.
- Use a cleaner before the nickel bath capable of removing material from the solder mask that may be leached out in the nickel bath.
- Operate the nickel bath to result in 9 percent phosphorous or higher.
- Test the corrosion resistance of the nickel deposit using nitric acid exposure.
- Use a mild gold bath that delivers a gold thickness target of 0.07 to 0.15  $\mu\text{m}$ .
- Use function testing such as tape test and XRF to screen for black-pad.

### 32.12.3 Dendrites and Electrochemical Migration

Metals, when patterned as conductors and placed under electrical bias, can suffer from a vulnerability to electrochemical migration. When exposed to an electrolyte (such as dirty water), PCBs form an electrochemical cell. At the anode, metal is stripped of electrons (ionized) and can dissolve in the electrolyte. The corrosion, movement, and redeposition of metals is termed *electrochemical migration*, and can form interesting structures such as metal dendrites. All metals are susceptible to dendrite formation. Indeed, dendrites formed from PCB circuitry usually contain copper sourced from the patterned outerlayer copper. Groups such as IPC, Battelle, and Underwriters Laboratories have studied electrochemical migration. Documents issued by these groups show the causes of migration to include surface cleanliness, electrical bias, environmental humidity, and conductor spacing. The selection of surface finish material is not a leading factor in vulnerability to dendritic growth. However, a metal will corrode and migrate more quickly than others depending on the type of contaminating environment. In general, more noble metals such as gold resist corrosion better than copper. This is a main reason for the use of a protective surface finish. Metals such as silver and tin are attacked by sulfur, leading to corrosion. Electroplated

silver, used to some extent in component terminations, does have a higher propensity for dendritic growth. Electroplated silver was abandoned as a PCB finish in the 1960s due to dendritic growth. Immersion silver does not behave in the same way as electrodeposited silver.

#### 32.12.4 Solderjoint Voiding

Solderjoint voiding can result from various causes, including flux type, PTH blowholes, poor wettability, the Kirkeldall effect, and improper surface finish deposition. Surface finishes contaminated with organic materials have been shown to exhibit solderjoint voids after assembly. Silver has been connected with the void phenomenon termed *microvoids*, *champagne voids*, or *planar microvoids*. The mechanism for microvoiding has been determined to result from overaggressive silver bath deposition on improperly treated substrate copper. When the silver exchange reaction attacks the copper nonuniformly, a cave can be created in the copper from the localized galvanic attack. The cave entraps flux or moisture, resulting in a series of voids just above the intermetallic layer. If too many voids form at the pad interface, the reliability of solderjoint strength is compromised. Following the chemical suppliers' exact operating recommendation resolves this problem. Other types of voids, such as process voids, pinhole voids, and microvia voids, are not caused by the type of surface finish selected, but depend on the PCB design and assembly parameters.

#### 32.12.5 Solder Mask Attack

The chemicals involved in depositing PCB surface finishes can attack the solder mask. Immersion tin directly attacks the mask by chemical dissolution. Thiourea in the tin bath acts as a solvent for the mask. Exposure time and temperature of contact with the bath should be carefully watched. The surface should be tape-tested for mask adhesion. ENIG processing creates an environment that can lift slivers of solder mask. The temperature of the nickel bath is not the culprit; rather, the generation of hydrogen bubbles as a by-product of nickel plating at the interface is alleged to cause lifting of the mask. Immersion metals such as gold, silver, and tin remove metal as part of the chemical reaction. If the immersion bath removes copper from underneath the edge of the solder mask, slivers of mask lose adhesion and show up in tape testing.

In all cases, the mask preparation steps are critical. If the copper is treated well to adhere to solder mask, the interaction from surface finish chemicals is greatly reduced. It is imperative that there is no wedge between the mask and the copper into which the surface finish chemicals can creep. In extreme cases of chemical entrapment, the chemical reactions are accelerated in the wedge, leading to nonuniform plating. Immersion silver, tin, and OSP can lead to excessive copper corrosion at the solder mask edge and result in electrical opens. This phenomenon is also known as *solder mask interface attack*.

### 32.13 COMPARING SURFACE FINISH PROPERTIES

---

Table 32.12 compares surface finishes by type and property and summarizes the material presented in this chapter.

**TABLE 32.12** Comparison of Surface Finishes by Type and Property

	HASL	OSP	ENIG	Pd	Tin	Silver
Flat	No	✓	✓	✓	✓	✓
Solderjoint	Cu-Sn	Cu-Sn	Ni-Sn	Ni-Sn	Cu-Sn	Cu-Sn
Contact	E-test, ICT	No	E-test, ICT, keypad	E-test, ICT, keypad	E-test	E-test, ICT, keypad
Wirebond	No	No	Al	Au, Al	No	Au, Al
Cost	\$	0.7 × \$	3 × \$	5 × \$	0.8 × \$	0.8 × \$
OEMs	All	All	Most	Few	30	150
Fabs	Most	Most	200	Few	40	250
Reflows	6	2–4	6	6	2–3	6
Shelf-life (months)	18	6	24	24	6	12 mos.
Compliant Pin	+	–	–	–	++	+

---

## **33.1 INTRODUCTION**

---

### **33.1.1 Definition and Terminology**

The term *solder mask*, as used in this chapter, is the same as the terms *mask*, *soldermask*, or *solder resist*, which are frequently used interchangeably in the printed circuit board (PCB) fabrication industry. The Association of Connecting Industries (IPC) has standardized on the use of *solder mask*, since that is the term most widely used in the industry. The existing definition for “Solder Resist” from IPC-T-50 is, “A heat-resistant coating material applied to selected areas to prevent the deposition of solder upon those areas during subsequent soldering.” With the evolution of PCB technology, solder mask coatings are now asked to provide much more functionality than simply a soldering aid.

### **33.1.2 Purpose**

When solder masks were first used, their purpose was to protect the circuitry of the PCB from solder during the assembly operation. Eliminating short circuits was the main objective. As the use of solder mask became more prevalent and the material properties improved, solder mask was used for other functions, such as to provide environmental protection to the assembled board, and to serve as a plating resist for final finishes, dielectric protection, and other functions that take advantage of the properties of the cured mask.

### **33.1.3 History**

Solder mask began with the use of two-part epoxy, thermally curable inks that were an offshoot of inks that were used in the printing industry. These inks were applied by screen printing with the use of a patterned screen, since these materials were not photoimageable. One-part inks that were ultraviolet (UV) curable were available soon after, but these also had to be applied by a patterned screen because they could not be imaged and developed.

Photoimageable solder masks were developed in the mid-1970s and were offshoots of photoresist materials used for patterning the circuitry. Photoimageable solder masks were developed in both liquid (LPI) and dry film (DFSM) and both were used widely. Today, more than 98 percent of the solder mask used is applied in liquid form, and most is photoimageable.

## **33.2 TRENDS AND CHALLENGES FOR SOLDER MASK**

---

The use of solder mask continues to evolve with the technology. This section discusses some of the issues involved.

### **33.2.1 Circuit Density**

Since the development of circuit boards, the dimensions of the holes and features have been decreasing. Smaller component attachment dimensions require corresponding decreases in solder mask features that challenge the solder mask materials and processes.

**33.2.1.1 Feature Size.** Smaller solder mask features have eliminated non-photoimageable solder masks from all but the lowest technology designs, and continue to require ongoing improvements in resolution and image reproduction. A very high percentage of solder mask being used is photoimageable.

**33.2.1.2 Hole Size.** Holes in boards that have been coated with LPI solder mask will have some solder mask material in the holes after application. Typically this material must be removed in the development process. There are very significant differences in how easily different solder mask materials develop from holes. There is also a difference in the amount of solder mask material that is in the holes between application methods, with spray and curtain coating leaving less material than screen printing.

### **33.2.2 Component Attachment in a Lead-Free Environment**

As many PCB fabricators and assemblers transition to lead-free processing, they are faced with solder alloys that have an operating temperature up to 30°C (54°F) hotter than the traditional eutectic tin-lead solders. These increased soldering temperatures raise concerns about the ability of the solder mask (as well as all other materials) to resist embrittlement, discoloration, loss of adhesion, and cracking with repeated exposures to the higher temperatures. Some existing products may not be acceptable for lead-free processing.

### **33.2.3 High-Density Interconnection (HDI)**

HDI technology creates small blind microvias that are plated to provide interconnects to buried layers of circuitry. These small holes can either be coated with solder mask or filled and plated over so that the real estate of the hole can be utilized for a circuit or a component mounting pad (via-in-pad).

If the hole is simply coated with solder mask and the solder mask is not developed from the hole, the air trapped in these small holes may expand and create a bubble or blister, or may erupt, exposing the copper in the hole to potentially corrosive chemistries. These holes should be developed cleanly so that they receive the final finish, should be protected before solder mask application with an inert final finish or be completely plugged.

Plating over microvias requires that they are totally filled, planarized, roughened, and catalyzed before the plating process. If a conductive plugging material is used, the catalysis step typically can be eliminated. Material selection for this application is particularly important because not many materials can withstand the roughening and plating and still maintain good adhesion of the copper to the plugging material after exposure to soldering temperatures. If the via is in a component mounting pad (via-in-pad), the plugging material must not shrink and cause a significant depression (dimple) in the pad. This is especially true for wire bonding applications that require a very flat planar surface.

### 33.2.4 Environmental

The Restriction of Hazardous Substances (RoHS) Directive 2002/95/EC places restrictions upon specific materials that may be included in PCB fabrication materials, including solder masks. These requirements may require some products to be reformulated. Some products and/or markets may require low-halogen materials to comply with company or industry specifications. Again, these requirements have required some solder masks to be reformulated or new products to be developed.

Many localities have strict air emissions regulations that limit the materials and the amount that may be exhausted to the atmosphere. Individual processes or pieces of equipment may require a permit to exhaust any volatile materials. Hazardous air pollutants (HAPs) and volatile organic components (VOCs) are of particular concern. Limits on these parameters can limit mask selection and application processes. For example, curtain coating and spray mask application are not viable in some areas due to the higher percentage of solvent needed for proper application. Screening utilizes solder mask at a much higher percent solids (less dilution), so air emissions may be only half that of other methods.

### 33.2.5 Technical Service and Troubleshooting

The solder mask process is quite complex. It relies upon all PCB fabrication processes that preceded it and plays a key role in all processes after it has been applied, through assembly and the life of the PCB. As a result, it is recommended that the specifying authority choose companies that can provide technical expertise and troubleshooting assistance. Companies that offer service and experienced engineering personnel in the PCB fabricators are becoming scarcer, making the supplier's ability to provide service a key issue in solder mask selection.

## 33.3 TYPES OF SOLDER MASK

---

### 33.3.1 Non-Imageable

Early solder masks could not be photoimaged—that is, placed in its exact location with a photographic process. They could not be hardened selectively in one area and then be removed from other areas. These masks had to be applied in the final pattern desired, typically through a patterned screen. The “silk screening” process (the screens are actually nylon) is limited in that it can neither resolve the fine features nor meet the registration requirements and tolerances needed for today's PCB designs. The use of these materials is limited to lower technology products.

### 33.3.2 Imageable

Higher-density circuitry, with its close tolerances and image reproduction requirements, has mandated the use of photoimageable solder mask. Assemblers need fine dams (or “webs”) of

**FIGURE 33.1** An example of fine solder dams, or “webs,” imaged between fine pitch SMT pads.

solder mask between fine-pitch component leads (see Fig. 33.1) to enable assembly with low defect rates. These webs are frequently as narrow as 0.003 in. and can be as narrow as 0.001 in. A photoimageable mask is required to meet these needs.

Photoimageable masks are available in either liquid or dry-film forms. Liquids account for more than 98 percent of the products used, due to their lower cost, greater availability, ease of use, and acceptability in assembly processing. Dry-film masks require special application equipment, are expensive, are often not robust when used as a resist for final finishes such as ENIG or immersion tin, and are too thick for use in some assembly processes.

### 33.3.3 Temporary

A number of temporary masks are used in PCB fabrication and assembly processing. The properties of these masks vary considerably depending upon the purpose for which they have been used. The typical application for these masks is to protect circuitry from plating and/or soldering. Various products can be removed mechanically by peeling (“peelable mask”) or by dissolving in cleaning chemistry. Since they do not become a permanent part of the finished assembly, there are no industry standards for these products. PCB fabricators and assemblers should be careful to verify the compatibility of any temporary mask with their solder mask(s) to avoid problems such as swelling, blistering, and so on.

## 33.4 SOLDER MASK SELECTION

---

### 33.4.1 Availability and Consistency

There are ongoing changes in the makeup of the supplier base of electronic materials, including solder mask. Many acquisitions have taken place and several products eliminated in the recent past, so users must have confidence that they will have a continued source of supply of solder mask that is the same lot to lot for the future. International Organization for Standardization (ISO) qualification for the manufacturing operation as well as for environmental considerations are good indicators of a supplier with a long-term view.

### 33.4.2 Performance Specifications

**33.4.2.1 IPC-SM-840.** This is the predominant solder mask material specification used globally. Most manufacturers test their products to verify that their products are capable of

meeting the requirements of this document. The SM-840 includes physical, chemical, thermal, and electrical requirements for two classes of application.

**33.4.2.2 Underwriters Laboratories UL94.** This specification defines the degree of flammability of a material. Solder mask suppliers generally test their products for flammability according to UL94. The solder mask is applied to a specific type of base material or construction before burn testing. The main variables in this test are the specific base material and construction, the mask type, and the thickness of each. Since most solder mask has no flame retardant, thinner mask and thicker base material will give better results.

**33.4.2.3 Telcordia GR-78-CORE.** This specification, from Telcordia, is commonly referred to by its previous name, BellCore. With the introduction of the C Revision to IPC-SM-840, the Class T requirements were accepted by the BellCore as equivalent to meeting the GR-78-CORE specification. This specification is still available as part of a package of documents from Telcordia that is quite expensive. However, since Telcordia recognizes the IPC-SM-840 Class T specification for solder mask, it is typically not necessary to purchase a copy of the GR-78 specification.

**33.4.2.4 Military Applications.** The military specification that applies to solder mask is MIL-P-55110. Since the mid-1990s, the revisions of this document refer to the IPC-SM-840 specification for solder mask requirements.

**33.4.2.5 NASA Outgassing.** Materials that will be used in space applications are tested under extremely high vacuum conditions. To be acceptable, they must exhibit a maximum total mass loss (TML) of 1.0 percent and have a maximum collected volatile condensable material (CVCM) of 0.10 percent. A list of tested products is available from the NASA web site at <http://outgassing.nasa.gov>. This site features “Outgassing Data for Selecting Spacecraft Materials,” which lists products that the Goddard Space Center has tested (and the tests’ results). Not all materials tested have passed the TML and CVCM specifications. Independent test labs can also be used to test for this property.

**33.4.2.6 Other Customer Industry Application Specifications (AABUS).** Often PCB customers have special requirements for their solder mask. These can be a modification of the IPC criteria or some additional requirement not included in the SM-840 document. There is a term used to describe these requirements: as agreed between user and supplier (AABUS). The key word here is “agreed,” since both parties must be completely aware of the requirement and what it takes to achieve the required result.

### 33.4.3 Environmental and Health Considerations

**33.4.3.1 RoHS Compliance.** Most PCB fabricators now insist that any solder mask products they use be compliant with Directive 2002/95/EC of the European Parliament and of the Council of 27 January 2003 on the restriction of the use of certain hazardous substances in electrical and electronic equipment, the RoHS directive, and Directive 2003/11/EC, the 24th amendment to Council Directive 76/769/EEC. This directive places requirements on specific materials and amounts of each that may be included in a formulation. Meeting this criterion is essential for most printed wiring board (PWB) fabricators.

**33.4.3.2 Lead-Free.** One of the materials eliminated with RoHS compliance is lead. The largest impact of eliminating lead is the higher soldering temperatures required for lead-free solders. Soldering temperatures for these alloys are typically 10 to 20°C hotter than for eutectic tin-lead solders. For example, one of the current alloys of choice is SAC-305 (tin-silver-copper solder) has a melting point 34°C higher than eutectic solder. Higher temperatures place

additional stress upon the solder mask and could potentially lead to adhesion loss, color change, embrittlement, or cracking.

**33.4.3.3 Low Halogen.** The low-halogen requirement came about due to concerns about incineration of scrap PCBs generating dioxins under some conditions, and originally centered on some brominated flame retardants used in base laminates. It progressed from that into an additional concern over the chlorine content. This requirement is sometimes referred to as “halogen-free,” but in reality, the true requirements place a limit on the amount of bromine, chlorine, and their sum in the content of the material. Current low-halogen requirements on the cured solder mask are as follows:

Organization	Spec-test method	Chlorine	Bromine	Total Halogen
JPCA	JPCA-ES-01-1999	<900 ppm	<900 ppm	
IEC	IEC 61249	<900 ppm	<900 ppm	<1,500 ppm

Although solder masks do not typically contain flame retardants, and hence no bromine, they often contain chlorine. The chlorine generally comes from pigments that give the mask its desired color, and also from residual catalyst from the resin (solder mask raw material) manufacturing process. A number of manufacturers offer low-halogen solder mask materials that meet the specified criteria.

### 33.4.4 Circuit Density Issues

As the pitch of circuitry and packages has decreased, it has also generated the demand for smaller holes and finer solder mask features.

**33.4.4.1 Hole Size.** As mentioned in Sec. 33.2.1.2, small hole sizes are a significant challenge for the solder mask process. All application processes introduce some solder mask into the holes, and this material must be removed (developed) from the holes before curing. There are two primary considerations in achieving finished PCBs with no mask in the holes. First, it is easier to achieve mask-free holes when less solder mask is introduced into the holes during the application process. In general, spray applications put the least mask into holes, and single-sided screening introduces the most. Curtain coating and simultaneous double-sided screen printing produce more moderate levels of solder mask in holes.

The ability to remove all solder mask from the holes is dependent upon the solder mask material itself, the tack drying, and the developing processes. Some solder masks inherently develop faster than others, so the choice of products has a significant impact on development. If the solder mask is subjected to an overly aggressive (too hot and/or too long) tack drying process, the mask may not develop at its optimum speed. The developing equipment and process should be set up according to the solder mask manufacturer’s recommendations. This includes the chemistry, pressures, flow rates, nozzle type(s), process cycle times, and so on.

**33.4.4.2 Solder Dams (“Webs”).** To reduce soldering defects in assembly, designers have placed fine solder dams, or “webs,” between attachment pads. The width of these dams is frequently in the 2.5 to 3.0 mil range, with some designs requiring dams as narrow as 1.0 to 1.5 mils wide. Producing features this fine is not possible with all solder mask materials, and the imaging process for very fine features will typically be modified from normal production with wider dams.

### 33.4.5 Assembly Considerations

**33.4.5.1 Thickness.** When PCBs had all through hole components, solder mask thickness was not of much concern. However, with the advent of surface-mount technology in the 1980s, excessive solder mask thickness caused assembly problems, including:

- Tombstoning of discrete devices in reflow soldering
- Excessive opens with discrete devices in wave soldering
- Solder paste printing problems (excessive paste, solder balls, paste on back of stencil, etc.)

Flip-chip assembly, with its finer pitch, has placed further restrictions on the maximum mask thickness. These thickness restrictions effectively eliminated dry film solder mask in most applications and relegated it to a specialty product for special applications.

**33.4.5.2 Cleanliness.** After PCBs have been assembled, they must meet specific ionic and visible cleanliness requirements. It is important that PCBs produced with the specific solder mask through the normal process be qualified through the assembly process to ascertain whether the production parts will meet expectations. Each solder mask and flux combination throughout the assembly process may give a different cleanliness result.

**33.4.5.3 Solder Balls.** Some assembly processes are more prone to generate solder balls than others. Prequalification of the solder mask with the assembly chemistries and processes is essential to predict production performance. If solder balls occur during assembly, in some cases they can be reduced by using a mask with a different surface finish. Satin or matte products sometimes have less of a tendency to have solder balls. Modifying the solder mask cure can have an effect on the level of solder balls also—consult with the solder mask supplier before deviating from its recommended cure process.

**33.4.5.4 Assembly Material and Process Compatibility.** When qualifying a new solder mask or new PCB supplier, it is critical that all existing materials and processes be evaluated for compatibility before production is scaled up. This should help avoid major issues where there is a large quantity of PCBs awaiting assembly that cannot be assembled with the existing assembly materials and processes. Care should be taken to include evaluation of:

- Soldering fluxes and pastes
- Cleaning agents
- Multiple heat exposures
- Adhesives
- Underfills
- Temporary solder masks
- Tapes
- Anything else in assembly that depends upon the surface of the solder mask

**33.4.5.5 Conformal Coating Compatibility.** Again, qualification of the solder mask, through all of the fabrication processes, is required to ensure that no problems with production boards arise. Since conformal coating is applied after assembly, a significant amount of processing and exposure to other chemistries will have happened since the solder mask has been applied. The conformal coating compatibility testing should be done on a board that has been through all of the assembly processing. The cleanliness of the PCB surface after the final assembly process has a great impact upon the adhesion of the conformal coating. One cannot

expect conformal coating to adhere well to a dirty board. These coatings were not meant to be applied over a no-clean flux, but over a clean substrate.

#### 33.4.6 Application Method for Installed Equipment

Choose solder mask that is compatible with the existing or proposed application method. Not all solder masks can be screen printed, sprayed, and curtain-coated. Consult with the solder mask supplier for the appropriate solder mask for your application method.

#### 33.4.7 Gloss

Solder masks are available in different levels of gloss. Typical terminology for finishes includes gloss, semigloss, satin or semimatte, and matte. These finishes represent a certain level of reflectivity of light and microroughness. Gloss level is generally specified by end users for assembly or cosmetic reasons.

#### 33.4.8 Color

Likewise, different levels of color may be available. Most solder mask is green, but many other colors, such as red, blue, black, yellow, and white, are often specified. Some solder masks are specified to be clear.

#### 33.4.9 Packaging versus PCB

When solder mask is used on substrates that will become part of a semiconductor package. The JEDEC Solid State Technology Association (once known as the Joint Electron Device Engineering Council) specifications apply in addition to the IPC specifications. JEDEC specifications include additional, more aggressive testing that generally requires a more robust solder mask. Low moisture absorption is important for a mask used in packaging applications.

#### 33.4.10 Surface Finish Compatibility

The choice of the final surface finish for the copper has an effect upon how the solder mask performs. And, with the elimination of lead in solder, the compatibility of new final finishes needs to be confirmed before their implementation. Most of these finishes are applied after the solder mask so the process for mask application can have a significant impact upon final quality of the PCB:

- **Hot air solder leveling (HASL)** This has been the most common final finish, utilizing 63/37 eutectic or 60/40 tin/lead (Sn/Pb) alloys. The PCB is coated with flux, immersed into molten solder, and withdrawn through air knives to remove excess solder. Lead-free solders are expected to require solder temperatures significantly hotter than what has been required for eutectic solder. The higher temperatures are expected to place higher stress on the solder mask and may also present more difficult post-HASL cleaning challenges.
- **Electroless nickel/immersion gold (ENIG)** ENIG is typically applied to the metal surfaces of the PCB after the solder mask process. Each plating chemistry supplier has its own ENIG bath, and each has a different level of aggressiveness to the solder mask. Consequently, the solder mask and ENIG chemistry must be qualified together to avoid breakdown of the solder mask over circuits or around openings on metal. A thicker coating of

solder mask may alleviate solder mask breakdown problems. Excessive microetching before plating can undermine the solder mask and induce tape test failure as the overhanging mask is broken off.

- **Immersion tin** The same comments from ENIG also apply to immersion tin.
- **Immersion silver** Immersion silver is relatively benign to the solder mask, and few, if any, issues are known as of the writing of this book.
- **Organic solderability preservative (OSP)** This is another process and chemistry that has little impact on the solder mask.

## 33.5 SOLDER MASK APPLICATION AND PROCESSING

---

### 33.5.1 Surface Preparation

Solder mask should be applied to a clean, dry surface. The cleaning step should remove all particulates, oils and greases, and unwanted oxides. In the case of bare copper, this step should provide some “tooth” to the copper to enhance the mechanical bond of the mask to the copper. The cleaning step is followed by a rinse and drying step that leaves the panels ready for coating with mask. The surface preparation technology chosen is dependent upon the metallization of the circuitry and, to a lesser extent, the base laminate material.

**33.5.1.1 Copper Circuitry.** A large majority of panels produced have solder mask coated over bare copper (SMOBC). The goals of the surface preparation process are to remove all unwanted oxides and contaminants from the copper and to impart a microroughness or “tooth” to the surface, and to leave a clean, dry surface for coating.

**33.5.1.1.1 Incoming Copper.** The quality of the surface of the copper is very important for achieving good solder mask adhesion. All traces of the etch resist metallization, typically tin or solder, must be removed prior to the solder mask surface preparation process. Solder mask does not adhere well to tin or solder residues or tin-copper intermetallic surfaces.

**33.5.1.1.2 Preparation Methods.** The most common surface preparation method is pumice scrubbing with either a silica or aluminum oxide media. Most equipment in use is brush pumice, but jet pumice may be used also. With this method, the main considerations are keeping the pumice concentration within recommended levels, periodic changing of the media, and good equipment maintenance. A prepared surface from a proper pumice cleaning will have a uniform rosy pink, matted surface that is free from stains. Considerations in pumice-based preparation techniques include the following:

- **Brush pumice versus jet pumice** Both techniques utilize a slurry of pumice in water. With brush pumice the slurry is pumped onto the panel surface under low pressure, and rotating brushes scrub the pumice against the panel surface to clean and roughen it. With jet pumice, the slurry is sprayed through nozzles at high pressure onto the panel surface; the impact of the particles against the panel surface provides the cleaning and roughening.
- **Silica versus aluminum oxide** The media used in pumice scrubbing degrades with usage. Silica pumice is softer than aluminum oxide and must be changed more frequently, but it is much less expensive; thus relative cost differences in operation may not be significant. Silica pumice particles degrade by fracturing into smaller pieces and not providing the needed impact to roughen the surface. Aluminum oxide particles become rounded with age and will “peen” the surface instead of roughening it. Both conditions lead to a less than optimum solder mask adhesion.

Chemical cleaning, usually in the form of a microetch, may be used to prepare the copper surface. Not all microetch chemistries will provide the proper tooth for best adhesion, so a

product should be selected that provides some tooth (a matte surface is a good indicator) instead of a bright shiny surface. Good rinsing and drying, and possibly a passivation chemistry, are important to avoid rapid staining of the copper since it is very active after chemical cleaning.

Abrasive brush or compressed pad technology is generally acceptable for solder leveled panels, but if other final finishes such as ENIG or immersion tin are used, it may not provide sufficient adhesion. The abrasive in the brushes leaves directional scratches in the copper that can lead to the wicking of plating chemistries under the mask that will cause loss of adhesion around mask openings on copper. If this method is to be used, it should be followed by a chemical cleaning that will provide the microroughness needed for good adhesion.

A very good alternative to abrasive or chemical cleaning is to impart an oxide to the copper surface. If the copper has not been cleaned or if there are residual etch resist metals on the surface, the copper will not oxidize. The oxide provides a fine structure and microroughness for very good adhesion. When using this technique, the fabricator should use a “reduced oxide” so that cleaning chemistries in subsequent processes will not attack the oxide layer and cause adhesion loss at the mask-copper interface.

**33.5.1.1.3 Rinsing and Drying.** After the cleaning step, the panel surfaces must be thoroughly rinsed with good quality water. City or well water is often inadequate due to high levels of minerals, particulates, and other contaminants. Poor water quality can lead to blistering of the mask and/or discoloration of the copper under the solder mask. Deionized (DI) water is the best rinsing agent, but reverse osmosis (RO)-treated water is also used effectively.

After the panels have been rinsed, the drying step should remove the water from the panels—both from the surface and from the holes. Air knives should be incorporated to blow out the holes and sweep the water from the surface. It is undesirable to dry water on the boards since any droplets that are dried will leave behind any dissolved minerals and other contaminants that had been in the water.

### **33.5.1.2 Other Metals**

**33.5.1.2.1 Gold, Tin, or Solder.** If the gold-plated surface is perfectly clean, no surface preparation is required. However, if there is any question about cleanliness, or if the panels have been exposed to any chemical vapors or particulates, or have been awaiting solder mask for any appreciable time, they should be cleaned. Depending upon the extent of surface contamination, the panels can be only rinsed and dried, or may be cleaned in a mild detergent solution before rinsing and drying. Abrasive cleaning is not recommended.

**33.5.1.2.2 Mixed Metals.** Two good examples of the use of mixed metals are for panels that have been selectively solder-stripped and for panels that have had fingers or contacts plated with gold before the solder mask process. The surface preparation process must be selected based upon the most delicate of the metals on the panel.

## **33.5.2 Solder Mask Application**

**33.5.2.1 Liquid Masks.** Solder masks applied in liquid form can be either photoimageable or not. Most solder mask in use today is photoimageable, meaning that after application it will be patterned in a photolithographic process. A non-imageable product must be applied only to those areas to be coated, and areas where metal or base material must be exposed cannot be coated.

**33.5.2.1.1 Application—Liquid Photoimageable (LPI) Solder Mask.** LPI solder masks are applied typically by screen printing, spray, or curtain coating. Although each method has pros and cons, all are used successfully in the industry.

*Screen printing* is the most common technique of applying solder mask. This technique utilizes a non-imaged, tightly stretched screen of precise construction and a squeegee to apply the solder mask through the screen onto the panel. The screening technology includes a wide range of equipment and techniques, from single-sided hand screening to fully automated double-sided equipment:

- **Single-sided coating (hand or flat bed)** In this application, each side of the panel is fully coated (except for a border on each side) with solder mask, one side at a time. The panel may be tack dried between coating the two sides, or the second side may be coated immediately using a dimple plate to protect the coating on the first side. It is advantageous to coat both sides of the panel before tack drying so that both sides see the same tack-drying cycle. One concern about this technique is the amount of solder mask that is pushed into the holes. Since this is a single-sided process, there is nothing to restrain the amount of mask that gets pushed into the holes, so it may be more difficult to develop all of the mask out of the holes.
- **Double-Sided Coating** Vertical double-sided screen printing applies solder mask to both sides of the panel or panels simultaneously. The screening units used are available in various levels of automation, up to fully automated screening units that are integrated with tack drying ovens. Because they apply mask to both sides at the same time, the units put less mask into holes, making it easier to develop mask out of holes—a particularly important consideration when working with small holes that must be free of solder mask. Front-to-back squeegee alignment is critical for putting the least amount of solder mask into the holes.

A key variable in screen printing is the screen mesh. Most applications utilize a non-calendared, nylon mesh material. These products are designated with the number of threads per inch and the diameter of the threads in microns. Typical examples of commonly used mesh counts are 86-120, 83-100, 86-100, 92-100 or 110-80. Supplier literature will provide a theoretical ink volume for each type that can be used to determine the relative difference in coating weight to be applied to the panel.

Table 33.1 provides an overview of the screen process key variables and the effect of operating a process at the extreme of that variable.

*Spray coating* accounts for a limited percentage of the solder mask coating. There is renewed interest in spray coating since it can allow more latitude in removing solder mask from holes. As the holes become smaller, some solder masks and processes have difficulty achieving clean holes after development. At the same time, because the solder mask is sprayed at reduced viscosity, the amount of solvent (VOCs) that is exhausted to the environment is significantly higher than for screen printing, the use of spraying may be limited in some localities.

**TABLE 33.1** Screening Process Variables and Effect Operating at the Extremes

Process variable	Effect of low	Effect of high
Mesh Tension	Mesh sticking to screen Poor quality printing Low coating thickness	Nonuniform coating across panel
Squeegee Pressure	Skips (areas with no solder mask)	Low coverage over circuits
Squeegee Speed	Lower circuit coverage	Higher coverage
Squeegee Shape	Very sharp edge, lower coverage	Slightly rounded edge, higher coverage
Squeegee Angle (from panel surface)	Lower coverage, Less ink in holes	Higher coverage, More ink in holes
Snap-off	Screen sticking to panels	Skips or difficult printing
Ink Viscosity	Lower coverage, More flow or sagging if too low	Higher coverage, Bubbles if too high

Two basic types of spray equipment have been used for spray coating PCBs with solder mask, HVLP (high volume, low pressure), and electrostatic. HVLP spray systems are most common. Single- and double-sided spray units are available.

The solder mask is sprayed at a reduced percent solids compared to screen printing, so circuit coverage and tack drying can be more of a problem, especially if the ink and/or spray guns are not heated. Heating of the ink allows more solvent to evaporate between the nozzle and the panel, resulting in a higher viscosity liquid on the panel. The higher viscosity theoretically allows greater circuit coverage with less ink.

The conventional HVLP spray process utilizes a low pressure stream of solder mask liquid that is atomized by a high volume stream of air. The atomized solder mask is directed to the PCB surface in a specific pattern so that as either the panel or the spray head(s) move, a uniform coating is applied to the panel. In some systems, the ink is heated just before spraying to lower its viscosity and aid in the evaporation of solvent between the spray nozzle and the panel. Typical process variables for HVLP spray include ink viscosity, ink (pot) pressure, atomization air pressure, conveyor speed, and ink and atomization air temperatures.

In a typical electrostatic spray application, the ink is atomized and given an electrostatic charge while the PCB panel is grounded to attract the ink particles. The intent is to limit the amount of overspray and provide a more even coating. In reality, with the infinitely variable PCB designs to be coated, there are often many ongoing adjustments required to minimize Faraday effects that cause uneven distribution of the spray. Often solder mask formulations need to be modified for effective use in electrostatic spray applications. The main process variables in electrostatic spraying are solder mask temperature and viscosity (dilution), bell speed and voltage, back plane voltage, and shaping air pressures. These variables are adjusted to provide a uniform coating of the desired thickness or weight.

Table 33.2 lists the process variables and the effect of operating at the extremes of that variable.

*Curtain coating* is an application method where the panel to be coated is rapidly passed through a continuous falling "curtain" of solder mask. The curtain is created by pumping the solder mask through a die with a slot of controlled opening. The curtain falls vertically through an opening between two conveyors that carry the panels horizontally through the curtain, thus coating the panel on its upper side. Solder mask that is not coated onto the circuit board panels falls into a trough between the conveyors and is recirculated. The pump and conveyor speeds and the gap in the die control the coating thickness. Solder mask used in curtain coating applications must be coated at reduced viscosity or percent solids (as in spray applications), so the increased VOCs emitted to the atmosphere may limit curtain coating's acceptability in some localities.

**TABLE 33.2** Key Variables for Spray Coating and Effect of Low and High Levels for Each Variable

Process variable	Effect of low	Effect of high
Ink Viscosity	Low circuit coverage, Tack drying difficulties	Mottled or "orange peel" coating, excessive atomization, and overspray
Ink Temperature	Low circuit coverage	Possible clogging of lines or nozzle
Ink (Pot) Pressure	Thin coating, low coverage	Thick coating, drying problems
Atomization Air Pressure	Mottled surface	Excessive overspray
Wet Weight or Wet Film Thickness	Low circuit coverage	Thick coating, insufficient drying, and/or bubbling

**TABLE 33.3** Key Variables for Curtain Coating Solder Mask Application and the Effect If the Process is Operated at the Extremes of That Variable

Process variable	Effect of low	Effect of high
Ink Viscosity	Low circuit coverage, dewetting, Streaks or breaks in the curtain (“blips”), Sagging of the coating	Unstable curtain, streaks, improper leveling, skips
Ink Temperature	Coat at incorrect percent solids, Sagging of the coating, Thin coverage	Unstable viscosity, high solvent evaporation, Inconsistent leveling
Pump Pressure	Thin coating, low coverage	Thick coating, drying problems
Conveyor Speed	Excessive coating	Insufficient coating, Ink in holes, Teardropping on bottom side
Wet weight or wet film thickness	Low circuit coverage	Thick coating, Insufficient drying and/or bubbling, Sagging of coating
Air flow around the curtain	None	Unstable curtain, “blips,” Nonuniform coating

Curtain coating is a highly productive process that gives uniform coating across panels. It has good flexibility for coating panels of different sizes (above a minimum) and gives very high material utilization.

The quality of the coating from this process is highly dependent upon the ability to maintain a uniform, stable curtain of solder mask. The solder mask must be maintained at the specified temperature and viscosity to avoid coatings that are too thick or thin, streaks, skips, or breaks in the curtain that cause no coating in localized areas, commonly referred to as “blips.” Curtain coating is sensitive to circuit height and typically requires process changes as height increases to avoid skips in the coating. Thin panels may become airborne at high conveyor speeds, and thick panels may slip on the conveyor and not accelerate to proper coating speed.

Typical process variables for curtain coating include solder mask viscosity and temperature, pump pressure, die (gap) opening, conveyor speed, and air flow. Table 33.3 lists the key variables for curtain coating and the effect of operating the process at the extremes of each variable.

**33.5.2.1.2 Tack Drying—Photoimageable Solder Mask.** LPI solder mask inks received from the supplier contain solvents to control the viscosity in the correct range for their intended application process. These solvents must be removed to harden the surface of the coating so that it may be handled and processed through the exposure step. Because the coated solder mask is wet and tacky, tack drying should closely follow the mask-coating process to reduce the possibility of handling damage and airborne debris becoming embedded in the wet ink. Care must be taken that panels do not touch each other in tack drying because they will mark each other and will not dry properly due to localized inadequate air flow across the panel surface. (Dry film, UV, and thermally cured solder masks do not require tack drying.)

Panels that have had insufficient tack drying will be sticky (phototools will stick to the solder mask); they may also exhibit “artwork marking,” where the pressure from the exposure process causes the mask surface to be smoothed, changing the cosmetic appearance of the surface. If solder mask has excessive tack curing, it will become difficult or impossible to develop—a condition called “lock-in.”

Oven types used for tack drying include batch ovens, tunnel ovens, and infrared (IR) ovens.

*Batch ovens* can be as small as a bench-top unit where panels may be inserted individually or as large as a walk-in oven that may be loaded with many panels in racks or carts. The wet panels are loaded through a door or doors that are gasketed or sealed to the operating area so that the vapors emitted are not exhausted into the work environment.

Total tack drying time in a batch oven is the sum of the ramp-up time plus the desired time at temperature. Ramp-up time of the panels is dependent upon the initial temperature of the oven, the heating capacity of the oven, the amount of makeup or purge air, and the loading (thermal mass) of the panels, racks, and carts placed in the oven at start-up.

Cure times are generally specified to be a specific time at temperature. Once the ramp-up time has been determined for the specific temperature and worst-case loading (generally a full oven load), the total time for the cure process is the ramp-up time plus the cure time. Oven doors should not be opened during a cure cycle because cure volatiles may escape into the environment and temperature will be lost and potentially cause incomplete curing.

Pros of using batch ovens include the ability to load large quantities of panels of any thickness or design at one time with minimal labor. Cons include having to wait for the oven to be empty before starting a new cycle. Opening of doors causes significant drop in temperature and may cause under curing if the time is not adjusted for the time below curing temperature.

In conveyORIZED *tunnel ovens*, panels are generally placed in slots in the conveyor or in racks that ride on the conveyor. The main controls are temperature and conveyor speed. Exhaust from the oven serves the same purpose as purge air and should be regulated per the oven manufacturer’s specification. Curing is typically uniform and is independent of panel design and construction.

With IR ovens, panels typically lay flat and are processed one at a time, and cure times are very rapid. Multiple cure recipes are usually needed to compensate for differences in panel design, materials, and construction. Proper handling of the exhaust is important, as with all curing ovens.

Several issues must be considered in the tack drying process:

- **Time at temperature** Proper curing requires specified time at temperature. Ovens should be set up with a profiler to ensure that variables such as oven loading, heating capacity, ramp-up time, and so on, compensated for when establishing process conditions.
- **Air flow** Air flow in ovens must be parallel to the panel surface so that there is uniform temperature across the panels and the solvent is swept away from the coated surface.
- **Debubbling time** With some solder mask applications, it is important to have some time (usually 5–10 min. maximum) for the coating to debubble before the tack drying occurs. This allows time for the bubbles to break and for the coating to heal itself.
- **Purge air** All ovens need fresh air to be drawn into the oven to replace solvent-laden air that is exhausted. Without sufficient purge, air panels will not dry properly.
- **Condensate** Volatiles from the solder mask can condense on cool surfaces of the oven and ductwork. This material must be cleaned periodically so that it does not plug air passages. Proper safety equipment should be worn during cleaning.

See Table 33.4 for a list of oven types and their advantages and disadvantages.

**33.5.2.1.3 Exposure.** Exposing photoimageable solder mask requires equipment that provides the needed intensity of light of the proper wavelength to expose the solder mask to an extent that the exposed mask will withstand the developing process without washing away, lifting, or getting surface attack.

**TABLE 33.4** Solder Mask Drying Ovens and Their Associated Advantages and Disadvantages

Oven type	Pros	Cons
Batch	Productivity—large quantities with minimal manpower Low investment Not dependent on panel design, materials, or construction Consistency	Potential for nonuniform temperature Opening oven doors causes temperature to drop Cure time may be oven-loading dependent
Tunnel	Consistency Uniformity Not dependent on panel design, materials, or construction	More handling Higher investment Thin panels may need a fixture to prevent them from bending
Infrared (IR)	Very fast cycle time Productivity	Multiple recipes usually required to compensate for different materials, designs, and constructions Cannot cure every PCB design/construction Requires automation or extra handling High investment

Exposure equipment must provide a means of holding a phototool in intimate contact with the surface of the panel being exposed and provide the required amount of light (millijoules/cm<sup>2</sup>) of the needed wavelength distribution (which may depend on the solder mask) at the appropriate intensity (mW/cm<sup>2</sup>). Unfortunately, many exposure devices that are used for exposing solder mask are substandard, including many units that were designed many years ago for exposing primary imaging photoresist. Modern units have high-intensity lamps (7 kW or higher) and sufficient lamp and exposure frame cooling to provide a high-quality image very quickly.

Lamp intensity and energy output should be monitored routinely with a radiometer sensitive to the appropriate wavelength to verify that the lamps are performing as expected. Intensity will decrease with lamp hours, making exposure times become longer. At the same time, the infrared output will increase, potentially causing frame cooling issues. Hot exposure frames cause artwork to stick to the mask, resulting in artwork marking or mask to transfer to the phototool.

Laser units are available for exposing photoresist that have been used for exposing solder mask. These solder masks may be specially formulated to be sensitive to the laser wavelength. Laser imaging eliminates solder mask registration problems, but is not as productive as conventional exposure. Equipment cost is very high compared to conventional lamp exposure equipment.

Underexposure will result is insufficient polymerization to withstand the development process properly without damage to the solder mask. Typical symptoms may include a dull or chalky surface, lifting of small features (e.g., solder dams), excessively undercut sidewalls, or lifted mask.

Overexposure causes image growth where the exposed feature is larger than on the artwork and openings in the solder mask will be smaller. If the growth is excessive, the mask may grow onto the pads.

**33.5.2.1.4 Development.** Development of the unexposed solder mask material must be sufficient to clean out completely the smallest holes that must be free of mask.

Photoimageable solder masks may be developed in either aqueous or solvent chemistries. The developer chemistry needed depends on the mask formulation. In the development process, solder mask that has not been exposed to UV light and polymerized is washed away, or developed, from the PCB panel to reveal the desired pattern of solder mask.

For aqueous development, the chemistry is a warm, mildly alkaline (pH 10.6–11.3) solution of sodium carbonate ( $\text{Na}_2\text{CO}_3$ ) or potassium carbonate ( $\text{K}_2\text{CO}_3$ ). Proprietary chemistries are also available. Antifoam is generally used to control foaming as the development solution loads with developed mask.

Solvent-developing chemistry typically uses gamma-butyrolactone (also known as “GBL” or butyrolactone) or butyl carbitol (2-(2-Butoxyethoxy)ethanol) solvent.

The development process must be set up to ensure that the smallest holes are free of undeveloped solder mask. This is very different from photoresist because the breakpoint will often be 10 to 15 percent of the development chamber instead of nearly 50 percent with photoresist.

Key process variables for the development process are the time in the developer and rinse sections; solution temperature, pressure, and nozzle type; flow rate; and configuration.

It is very important to have an inspection step immediately after development to check for registration, mask in holes, feature resolution, dam retention, lifting, and so on. Once the panels have been cured, it is significantly more difficult to strip and rework the solder mask, and the rework process is more likely to cause the panels to be scrapped.

**33.5.2.2 Dry-Film Solder Mask (DFSM) Application.** The process for DFSM differs from LPI solder mask only in the application step. Surface preparation, exposure development, and cure are the same as for LPI solder masks.

**33.5.2.2.1 Application with Vacuum Lamination.** DFSMs typically have no solvent in them to enable them to conform to circuits without entrapping significant amounts of air along or between circuit traces. To apply these films to circuit topography, a laminator must be able to laminate panels in a vacuum chamber. The predominant type of vacuum laminator has heated upper and lower platens. The panel or boards to be coated will have DFSM gently applied (without any pressure) to one or both sides and are placed into the vacuum chamber formed between the upper and lower platens. The platens are closed together and a seal is formed. Vacuum is drawn in the chamber. When a specified time has been reached (determined by the board type and thermal mass, DFSM type and thickness, and board/panel plated circuit height), the flexible diaphragm on the upper platen (which had been held tightly against the upper platen surface by vacuum) is released to slap down onto the panel surface. The heat will have made the DFSM plastic so that it will conform to the circuits, and the vacuum prevents poor lamination along circuits. The lamination is completed when the platens separate and atmospheric pressure forces the DFSM into all voids.

**33.5.2.2.2 Roll Lamination.** Lamination of DFSM with a standard hot roll laminator is unacceptable for all except the least demanding applications. It is impossible to laminate a flat film of solder mask to PCB topography without trapping air along circuits. There are vacuum hot roll laminators that will work satisfactorily, but these are not widely available.

### **33.5.2.3 Non-Imageable**

**33.5.2.3.1 UV and Thermally Curable Solder Masks.** Because these products are not photoimageable, they must be applied with patterned screen printing in the exact pattern that is needed on the finished PCB. After their application, they are cured by the appropriate cure recipe as dictated by the supplier. There is no opportunity to develop off solder mask from areas where it is unwanted, so registration of the screen to the panel is very important.

**33.5.2.3.2 Ink Jet Application.** This technique utilizes digital data and ink jet technology to coat solder mask only in areas where it is wanted. This eliminates the photoimaging steps and should reduce or eliminate registration problems. As of the writing of this book, no such machines are being used in production for solder mask application.

### 33.5.3 Curing

**33.5.3.1 Cure Purpose.** All solder mask products require a cure step or process for the solder mask to achieve the desired material properties. Curing typically increases hardness and the thermal and chemical resistance. The desired curing process is determined by the specific solder mask used. Consult the technical data sheet for the product and follow the supplier's recommendations for the appropriate cure.

#### 33.5.3.2 Types of Cure—UV, Thermal, IR.

**33.5.3.2.1 Thermal Cure.** Nearly all solder masks require a thermal cure. It is generally specified as a specific time at temperature. When calculating the correct time, the fabricator must add the temperature ramp-up time to the required time at temperature to arrive at the total time in the oven. For a conveyorized oven, a thermal profile will show the time above the minimum temperature.

If the thermal cure is to be accomplished with an infrared oven, the time will be much shorter but temperatures will be far greater than for a convection oven. Also, a number of recipes are usually needed to compensate for materials with different IR absorbance and panels with different thermal mass or thickness.

**33.5.3.2.2 UV Cure.** Some solder masks require high-intensity UV light to cure. This is typically applied in a conveyorized UV curing unit. Calibration of the curing unit is important to ensure the solder mask is cured properly.

**33.5.3.3 Effects of Undercure and Overcure.** Improperly cured solder mask can exhibit poor properties that will become apparent in subsequent processing. Care must be taken to ensure that the solder mask is cured according to the supplier's recommendations. The following are some of the potential problems caused by improperly cured solder mask.

Undercure problems include:

- Blistering or adhesion loss in final finish or assembly
- High ionic contamination
- Residues from assembly soldering
- Solder balling
- Handling damage and soft coating

Overcure problems include:

- Embrittlement and cracking
- Adhesion loss

### 33.5.4 Stripping Solder Mask

Stripping of solder mask is something to be avoided, but at times is required due to problems such as misregistration, incorrect or wrong sized artwork, handling damage, and so on. It is important to recognize problems as early in the process as possible since the stripping process must be more aggressive after each process step.

**33.5.4.1 Stripping after Coating.** At this stage, the solder mask may be removed easily. An LPI solder mask can simply be developed off. (*Note:* The mask should be tack dried first to avoid contaminating the developer with wet mask and/or solvent.). UV and thermal mask must be removed manually with an appropriate solvent.

**33.5.4.2 Stripping after Photoimaging.** The stripping task becomes more difficult. Aggressive chemistries, typically highly caustic and at high temperature, are required.

These chemistries are aggressive and the process, if not controlled, can damage the butter coat of the laminate and render the panel scrap. Small holes filled with solder mask may not be able to be cleaned out in the stripping operation without damaging the panel.

**33.5.4.3 Stripping after Cure.** Stripping solder masks is most difficult at this stage, and doing so in fact may be impossible for some solder masks. The time required to strip the solder mask may allow exposed portions of the laminate to become damaged and cause the panel to be scrapped. Every effort should be made to identify panels needing stripping before curing.

## 33.6 VIA PROTECTION

---

Via protection is an increasingly complex issue for PCB designers and fabricators. There are multiple options for protection—organic and conductive, platable or not, before or after final finish, and more. The materials and processes for each type are not the same, so there is no single answer, and few answers that are easily performed with high productivity. Inks for plugging come in a variety of processing types, including thermal cure, UV cure, photoimageable, conductive, platable, and so on. The panel design will narrow the choice for the specific application.

### 33.6.1 IPC-4761, “Design Guide for Protection of Printed Board Via Structures”

IPC-4761, published in July 2006, gives excellent guidance for how best to protect vias and what not to do. It does not give specifications for the plugging materials themselves, but a future document is expected to do so. This document calls out a number of classes of via protection that can be used by designers and fabricators.

One very important message from this document is that vias should be protected from both sides, not only one side. If single-sided protection is used before an “inert” final finish, a ring void of copper results at the barrel-plug interface that is subject to corrosion due to entrapped microetch, flux, or other corrosive chemistry. Also, some of these materials leach out in subsequent processes and can kill plating baths, cause high ionics, induce electrochemical migration, or present other long-term reliability concerns.

### 33.6.2 Material Specifications

Although there are no “official” specifications for the materials used for plugging, there are some specifications that apply to solder mask that should be considered when using a material other than solder mask to protect vias. UL94 flammability and IPC-SM-840 tests—including especially resistance to solvents and cleaning agents, as well as non-nutrient testing—may be necessary. Dependent upon the specific circuitry design, other specific tests from IPC-SM-840 or other specifications may be appropriate.

### 33.6.3 Material Selection Considerations—Solder Mask versus Specialty Inks

**33.6.3.1 Shrinkage—Percent Solids.** LPI solder masks have solvent in the formulation to control viscosity and tackiness. Drying the solvent causes the plug of mask in the via to shrink, typically causing a dimple and some thinning of the coverage on the knee of the hole. This may not be a problem if the plug is covered with another coating of solder mask or if the annular ring of the via does not pick up solder or other final finish. Specialty hole plugging inks are available that are very high in solids and shrink very little, as are 100 percent solid inks that eliminate this concern.

**33.6.3.2 Platability—Cu Adhesion.** More frequently, designers are specifying that the material used to plug the hole be platable so the real estate can be reclaimed as in via-in-pad designs or in subcomposite structures. Such applications require a material that can be roughened, catalyzed, and plated with good copper adhesion.

**33.6.3.3 Image Definition.** If the vias to be filled are in very close proximity to areas that must be solderable (e.g., surface-mount technology [SMT] pads) it may be desirable or, mandatory to utilize a plugging product that is photoimageable to ensure the ink does not encroach upon solderable surfaces.

**33.6.3.4 Other Properties.** One property important for vias needed to conduct thermal energy is thermal conductivity. Products used to fill such vias are generally highly loaded with a material with good conductivity such as silver or copper. Some designers believe that boards that must operate at high temperatures should have plugging materials with low coefficient of thermal expansion (CTE) and high glass transition temperature ( $T_g$ ), but there is little data to substantiate benefits of such materials.

## 33.7 SOLDER MASK FINAL PROPERTIES

---

Final properties are often characterized into physical, electrical, mechanical, and chemical properties. Most people who specify solder mask utilize the criteria in the IPC-SM-840 document when specifying desired mask performance. There are other industry and regional specifications but the IPC specification is recognized worldwide.

## 33.8 LEGEND AND MARKING (NOMENCLATURE)

---

Many boards still require legend and marking to identify part numbers and component locations, for company logos, date codes, and a multitude of other reasons. These can be etched into the copper or, more typically, added in a separate process after solder mask. For good legibility, materials are of a color that contrasts with the solder mask color.

### 33.8.1 Types

**33.8.1.1 UV.** These materials are not photoimageable, but are applied in the specific desired pattern through a patterned screen and then are cured with high-intensity UV light.

**33.8.1.2 Thermal.** These materials are not photoimageable, but are applied in the specific pattern desired through a patterned screen and then are thermally cured, generally in a batch or conveyORIZED oven.

**33.8.1.3 Photoimageable.** These inks are applied to large areas of panels or over complete panels, as with an LPI solder mask. They are tack dried, imaged, developed, and cured, often at the same time as the solder mask is cured. The advantages of these products are that they eliminate expensive screen making and achieve excellent resolution, even over the topography of circuits.

Special inks have been formulated for LPI legend applications that have higher pigment loading. The advantage of these inks is that they can be coated much thinner while achieving good color contrast. This increases the productivity through the tack and developing processes and gives a more robust finished product since it is thinner and less likely to be chipped.

Standard solder masks of contrasting color may be used but they will have to be coated thicker to achieve similar contrast. The higher sidewall thickness makes the legend more susceptible to chipping.

**33.8.1.4 Ink Jet.** These are actually UV and/or thermal inks that are applied with an ink jet. A limited number of these machines are in production as of early 2007. Initial equipment cost is very high, as is the price of ink, and progress in productivity is expected in the future.

### 33.8.2 Legend Specifications

**33.8.2.1 IPC.** No approved IPC specification exists for legend inks. A committee is drafting a specification, IPC-4781, that should be issued in 2008.

**33.8.2.2 Military.** The military has an obsolete specification that was written years ago around a two-part epoxy ink that most MIL applications still specify. Many of the criteria (such as shelf life, pot life, composition, etc.) in this specification are irrelevant to the final legend performance, but they are still enforced as long as the specification is used. More recently the specification for legend ink called out for many military applications is CID A-A-56032D, entitled “Commercial Item Description—Ink, Marking, Epoxy Base.” Although military specifications call out epoxy-based marking inks, a number of fabricators have had other inks approved on a waiver basis for military applications.

**33.8.2.3 UL94.** When areas of legend ink on the board are larger than a UL flame strip ( $1/2 \times 5$  in.), it is treated as if the legend is another coating that needs UL qualification. If all areas are smaller than the flame strip dimension, no separate UL qualification is needed.

### 33.8.3 Legend Performance

**33.8.3.1 Legibility and Resolution.** The legend must be readable to be useful. As circuitry becomes more dense, the feature sizes needed for legend become smaller also, causing processes to be reestablished to give the desired quality. Some fabricators have switched to a photoimageable (LPI) legend to give the desired resolution for the legend on high-density circuitry.

**33.8.3.2 Adhesion.** The legend must be applied to a clean, dry surface and be properly cured to achieve optimum adhesion. This can be a challenge when legend is applied after HASL or other final finish that could leave a residue (such as HASL flux) on the surface. Legend adhesion must be evaluated in combination with the solder mask and its processing. Different legend materials have different adhesion to different solder masks.

**33.8.3.3 Final Finish Compatibility.** Like solder mask, legend materials that are applied before the final finish must survive the final finish processes and chemistries. Not all legend materials will survive all finishes and these must be qualified together, the same as with solder mask.

---

# CHAPTER 34

---

## ETCHING PROCESS AND TECHNOLOGIES

---

**Marshall I. Gurian, Ph.D.**

*Marshall Gurian Consulting, Tempe, Arizona*

---

### 34.1 INTRODUCTION

---

One of the major steps in the chemical processing of subtractive printed boards is *etching*, or removal of copper, to achieve the desired circuit patterns. Etching is also used for surface preparation with minimal metal removal (microetching) during innerlayer oxide coating and electroless or electrolytic plating. Technical, economic, and environmental needs for practical process control have brought about major improvements in etching techniques. Batch-type operations, with their variable etching rates and long downtimes, have been replaced completely with continuous, constant-etch-rate processes. In addition, the need for continuous processing has led to extensive automation along with complete, integrated systems.

The most common etching systems are based on alkaline ammonia and cupric chloride. Other systems include peroxide–sulfuric acid, persulfates, and ferric chloride. Process steps include resist stripping, precleaning, etching, neutralizing, water rinsing, and drying. This chapter describes the technology for etching high-quality, fine-line (0.003 to 0.005 in) circuits in high volume at a practical cost, as well as continuous processing, constant-etch rates, and control at high dissolved copper capacities. Increasingly, the production of uniform and constant feature geometries calls for precision and statistically robust control of the circuitization processes and materials.

There remains the ever increasing need to balance the process selection according to the factors of cost, environmental and regulatory compliance, stable factory productivity, low worker intervention requirements, compatibility with board design, and construction innovations. It is significant that environmental concern has eliminated the use of chromic–sulfuric acid and ammonium persulfate etchants and chlorinated solvents. Limitations on chlorine gas and volatile organic emissions loom as a significant factor in determining future process choices, and pressure to eliminate brominated compounds and lead content may have consequences for processing mandated by material developments. More than ever, the simplification of process selection and vendor support appear to drive process selection in the industry.

Typical procedures are given for etching organic (i.e., dry film) and metal-resist boards, and for innerlayers. Strippers and procedures for resist removal are described based on resist selection, cost, and pollution problems. The properties of available etchants are also described in terms of resist compatibility, control methods, ease of control, and equipment maintenance. Other considerations include chemical and etchant effects on dielectric laminates, etching of

thin-clad copper and semiadditive boards, solder mask on bare copper (SMOBC), equipment selection techniques, production capabilities, quality attained, and facilities.

## 34.2 GENERAL ETCHING CONSIDERATIONS AND PROCEDURES

---

Good etching results depend on proper image formation in both organic innerlayer print-and-etch and plated-metal etch resists. Etch personnel must be familiar with screened, photosensitive, and plated resists commonly used. The etching of printed boards must begin with suitable cleaning, inspection, and pre-etch steps to ensure acceptable products. Increasingly, metal foil or plating uniformity in structure thickness and freedom from coatings and defects must be maintained to achieve uniform small-feature definition. Plated boards also require careful and complete resist removal. The steps after etching are important because they remove surface contamination and yield sound surfaces. This discussion considers the various types of resists and outlines typical procedures used to etch printed boards using organic and plated resist patterns.

### 34.2.1 Screened Resists

Screen printing is a common method for producing standard copper-printed circuitry on metal-clad dielectric and other substrates. The etch-resist material is printed with a positive pattern (circuitry only) for copper etch-only boards or with a negative image (field only) when plated through-holes and metal resist are present.

The type of resist material used must meet the requirements for proper image transfer demanded by the printer and for stripping chemistry compatibility. From the metal etcher's point of view, the material needs to provide good adhesion and etch-solution resistance; be free of pinholes, oil, or resin bleed-out; and be readily removable without damage to substrate or circuitry.

Typical problems are excessive undercutting, slivers, unetched areas, and innerlayer shorts in multilayer boards. In addition, conductor line lifting may occur when the copper-to-laminate peel strength (or surface contamination) is below specification.

### 34.2.2 Hole Plugging

Plugged-hole, copper-only boards use alkaline-soluble screen resists in a unique manner. The technique, called *hole plugging*, makes the SMOBC board possible. This technique can be used with screened images and to augment *tent-and-etch* processing for small annular ring structures.

### 34.2.3 UV-Cured Screen Resists

Ultraviolet-cured solventless systems are available for print-and-etch and plating applications. These products are resistant to commonly used acidic plating and etching solutions. Stripping must be evaluated carefully.

### 34.2.4 Photoresists

Dry-film and liquid photoresist materials are capable of yielding the fine-line (0.003 to 0.005 in) circuits needed for production of surface-mount circuit boards. Like screened resists,

photosensitive resists can be used to print either negative or positive patterns on the metal-clad laminate. Although dry-film and liquid materials differ in both physical and chemical properties, they are considered together for our purpose.

In general, both positive- and negative-acting resists offer better protection in acidic rather than alkaline solutions; however, negative-acting types are more tolerant of alkaline solutions. Negative resists, once exposed and developed, are no longer light sensitive and can be processed and stored in normal white light. The positive resists remain light sensitive even after developing and must therefore be protected from white light. Liquid photoresists, although less durable, are capable of finer line definition and resolution.

Positive-acting resists are subject to the same problems as are negative-acting resists, although they may be easier to remove cleanly, after exposure, from areas to be etched or plated. Problems related to plating photoresist-coated boards are reviewed in Chap. 29.

### 34.2.5 Plated Etch Resists

At present, the most extensive use of metal-plated resists is found in the production of double-sided and multilayer plated-through-hole circuit boards. The most commonly used resists are tin (matte and bright surface). Solder plate (60 percent Sn, 40 percent Pb) continues to be used on some reflow-treated solderable coating situations, but it is not favored for a sacrificial resist that is to be removed for SMOBC processing. Nickel, tin/nickel, and gold are occasionally used. Silver is used to some extent for light-emitting and liquid crystal applications. Details concerning the deposition of these metals are given in Chap. 29. The use of these resists is described in the following paragraphs.

**34.2.5.1 Tin Plating.** Thin tin deposits (0.0002 in) are used to make SMOBC boards where the tin etch resist is stripped after etching. Alkaline ammonia etchants are usually favored. Other etchants, such as sulfuric acid–hydrogen peroxide and ammonium persulfate–phosphoric acid, have been especially formulated for bright tin. Tin plating (directly over barrier layers of nickel or tin/nickel) has been used because of its optimum solderability. Cupric and ferric chloride etchants attack tin and are not used.

**34.2.5.2 Solder Plate.** Tin/lead solder (0.0003 to 0.001 in thick) is the plated etch resist for “fusing” into a solderable finish. The 60Sn/40Pb alloy offers good etchant resistance with few problems but must be treated with a brightening solution to retain solderability. Increased reliability may be achieved by the use of solder plate over tin/nickel.<sup>1</sup> Thin solder deposits (0.0002 in) can be used for the SMOBC process but have no benefit over tin plating for this purpose. The most suitable etchants are alkaline ammonia and sulfuric acid–hydrogen peroxide. Ferric and cupric chloride acid etchants cannot be used because of solder plate attack. Postetch neutralization rinses are needed, especially with alkaline systems, to rinse away etchant residues and to maintain optimum surface properties.

**34.2.5.3 Tin/Nickel and Nickel.** Tin/nickel alloy (65 percent Sn, 35 percent Ni) and nickel plate, used as is or overplated with gold, solder, or tin, are also capable metal resists for etching copper in alkaline ammonia, sulfuric acid–hydrogen peroxide, and persulfates.

**34.2.5.4 Gold.** With an underplate of nickel or tin/nickel, gold provides excellent resistance to all the common copper etchants. Some etchants have a slight dissolving effect on gold.

**34.2.5.5 Precious Metals and Alloys.** Rhodium has been described as being a suitable resist for edge connectors on boards; however, the plating process is difficult to control. When plated over nickel, rhodium tends to be thin and porous and to lift during etching. Because of varying surface properties, 18-karat alloy gold and nickel/palladium must be evaluated carefully when used as substitutes for pure gold systems.

**34.2.5.6 Silver.** Although silver is not used on most printed boards (MIL-STD-275 states that it shall not be used), it has found some applications for camera, light-emitting, and liquid crystal devices. Copper etching using silver as resist can be done with alkaline ammonia solutions. Silver loss is about 0.0001 in/mm.

**34.2.5.7 Etching Procedures for Plated-Metal Resists.** Etching of the metal-resist-plated boards begins with removal of the plating resist using commercial strippers. The stripping process must be sufficient to remove resist trapped under plating edges. Gold, solder, and tin resists must be handled carefully because they scratch very easily. Tin/nickel alloy and nickel plate, however, are very hard and resistant to abrasion.

The procedure after etching includes thorough water rinsing and acid neutralizing to ensure removal of etchant residue on the board surface and under the traces. Alkaline etchants are followed by treatment with proprietary ammonium chloride acidic solutions, ferric and cupric chloride with solutions of hydrochloric or oxalic acid, and ammonium persulfate with sulfuric acid. Alkaline cleaning is used for tin/lead boards etched in chromic-sulfuric acid. Etchant residue not removed before drying or reflow results in lowered electrical resistance of the dielectric substrate and in poor electrical contact and soldering on the conductive surfaces.<sup>2</sup> Care must be taken to minimize undercutting and overplating to eliminate slivers of plating breaking off and bridging circuitry.

A problem common to etching printed boards is not having the entire area etch clean at the same time. This occurs when etch action is more rapid at the edges of printed areas than in a broad expanse of copper. If very fine patterns and lines are required, the result can be loss of the pattern due to undercutting, especially when the board is left in the etcher until all the field copper has etched away. Modern etchers with reduced pooling of etchant have reduced this problem.

Fine-line boards in high-volume production may require special fine-line etchants, high-resolution photoresists, thin-clad laminates, controlled plating distribution, and thin base foil processing. Care must be taken to balance etching and thickness factors. In some cases, fine-line etchant additives have actually made cleanout more difficult in spaces of 0.003 in and narrower.

### 34.3 RESIST REMOVAL

---

The method used for resist stripping must be carefully evaluated when a resist is selected. The effect on board materials, cost and production requirements, and compliance with safety and pollution standards must be taken into account. Solvent-based stripping solutions are under significant environmental pressure. Chlorinated solvents and cyclic compounds (toluene, xylenes, etc.) have been banned, and many glycol ethers are restricted. In spray applications, care must be taken to capture or eliminate VOC emissions. For these reasons, aqueous or primarily aqueous stripping systems are necessarily widely used.

#### 34.3.1 Screen Resist Removal

Alkali-soluble resist inks are generally preferred. Stripping in the case of thermal and UV-curable resists is accomplished in 2 percent sodium hydroxide or in proprietary solutions. The resist is loosened and rinsed off with a water spray. Adequate safety precautions must be taken, since caustics are harmful.

ConveyORIZED resist-stripping and etching machines use high-pressure pumping systems that spray hot alkaline solutions on both sides of the boards. Certain laminate materials such as the polyimides may be attacked by alkaline strippers. Measling, staining, or other

degradation is noted when strippers attack epoxy or other substrates. Control of concentration, temperature, and dwell time usually can prevent serious problems.

Screened vinyl-based resists are removed by a dissolving action in solutions of chlorinated, petroleum, or glycol ether solvents. Methylene chloride and toluene (both currently not usable) were used extensively in cold stripper formulations. The most common strippers are acidic formulations that contain copper brighteners and swelling, dissolution, and water-rinsing agents. The usual procedure for static tank stripping involves soaking the coated boards in at least two tanks of stripper. Excessive time in strippers is to be avoided because of attack on the butter (top epoxy) coat, especially on print-and-etch or single-sided boards. Water is a contaminant in most cold strippers.

### 34.3.2 Photoresist Removal

**34.3.2.1 Dry Film.** Dry-film resists have been formulated for ease of removal in aqueous-alkaline solutions. Strippers are available for both static tank and conveyORIZED systems, although conveyORIZED systems are preferred because the spray action aids in separating the resist from the copper surfaces and washing it off the panel. Prompt processing after etching avoids resist adhesion “lock-in,” which can make removal difficult. Aqueous-alkaline stripping results in partially undissolved residues of softened resist films. These residues are captured in a filter system and disposed off in accordance with waste-disposal requirements. Design and availability of specific filters to match the character of the “skins” can be a significant factor in the selection of the proper resist. Environmental caution must be taken to properly evaluate and dispose of resist residues. Metal content (particularly lead) may lead to classification of these residues as toxic waste.

**34.3.2.2 Negative-Acting Liquid Photoresist Removal.** Negative-acting, liquid-applied photoresist can be readily removed from printed boards that have not been baked excessively. Baking is critical to removal because it relates to the degree of polymerization. Since overbaking is also damaging to the insulating substrates, processes should stress minimal baking—only enough to withstand the operations involved. The negative-acting resists are removed by using solvents and commercial strippers. In this case, the resist may not dissolve; instead, it softens and swells, breaking the adhesive bond to the substrate. Once that has taken place over the entire coated area, a water spray is used to flush away the film.

**34.3.2.3 Positive-Acting Photoresist Removal.** Positive-acting photoresists are removed in commercial organic and inorganic strippers if baking has not been excessive. Removal by exposure to UV light and subsequent dipping in sodium hydroxide, TSP, or other strong alkaline solutions is also effective. Overbaking makes removal difficult. Machine stripping is done in a solution of 0.5*N* sodium hydroxide, nonionic surfactants, and defoamers.

### 34.3.3 Tin and Tin/Lead Resist Removal

In SMOBC processing, the metal-plated resist is removed to present a flat, clean copper surface for solder mask definition. Tin/lead alloys can be stripped in oxidizing fluoride solutions such as fluoboric acid and hydrogen peroxide or ammonium bifluoride with hydrogen peroxide or nitric acid. (Caution: machine construction must be made compatible with fluorides by elimination of titanium and glass components.) Commercial formulations are available to be used inline after the etch machine rinses. Accumulations of spent solution or filtered lead-fluoride deposits must be treated as hazardous waste and have been accepted by solution vendors for treatment and disposal costs. Modern applications usually use lead-free tin plating resists, which can be fluoride containing as previously discussed, or compounds of ferric chloride

followed by nitric acid. In either case, feed-and-bleed solution management with filtration and periodic chamber cleanout has been successful.

## 34.4 ETCHING SOLUTIONS

---

This section is a survey of the technology and chemistry of the copper etching systems in common use. Selection of practically available etchants has been limited by economic, operational, and (environmental) regulatory concerns. Fabricators have been forced into practical trade-off decisions to suit situations. Two etchants in particular, chromic-sulfuric acid and ammonium persulfate, are no longer practical considerations due to environmental pressures. Other formulations and choices have been modified to suit these pressures.

There are two basic etchant needs to be met. The first is traditional foil etching for print and etch, plate/tent and etch, and pattern plate and etch. Virtually all processes in the United States and Europe use constant-rate systems for alkaline ammonia or cupric chloride etchants for this purpose. The second need is developing technology for specific precision very-fine-line etching—including foil thinning and thin metallization clearout for HDI constructions and fine features. (See Sec. 34.7 for additional discussion and mention of additional chemistries that may be useful for these applications.)

Continuous constant-rate systems with process automation represent current practice in production etching. These systems feature feed and bleed of replenishment chemicals under control of process instrumentation that monitors and responds to real-time changes in properties of the working solution. The “bleed” stream of the working composition etchant is usually returned to suppliers for copper reclamation and chemical recycle. The resulting degree of constant etching rate allows for stable and repeatable performance to achieve practical manufacturing processes. However, as demands for higher precision increase, further sophistication in controls will be necessary.

Key factors for selecting an etching chemistry include:

- Board design requirements
- High yield
- Compatibility with resist
- Etch rate (speed)
- Equipment required for process control of etch rate, regeneration, and replenishment
- Ease of equipment maintenance
- By-products disposal and pollution control
- Operator and environmental protection

The preceding factors serve to evaluate copper etchants to be used. Introduction, chemistry, properties, and problems are given in this section, along with suggestions for selection and control.

### 34.4.1 Alkaline Ammonia

Alkaline etching with ammonium hydroxide complexing is increasingly used because of its continuous operation, compatibility with most metallic and organic resists, high capacity for dissolved copper, and fast etch rates. Continuous (open-loop) spray machine chemical control systems are universally used. This operation provides constant etch rates, high work output, ease of control and replenishment, and improved pollution control. However, rinsing after

etching is critical, and the ammonium ion introduced to the rinses presents a waste-treatment problem. On-site closed-loop regeneration with chemical recycling is commercially available but not routinely practiced because of facility requirements, capital cost, fluctuating economics depending on copper commodity pricing, and worker requirements. The general economical and environmentally appropriate operating strategy is to recycle the by-product etchant products under contract to a supplier who reclaims or reconstitutes the copper contained and regenerates the ammoniacal constituents into a reformulated replenisher solution for return to fabricators.

**34.4.1.1 Chemistry.** The main chemical constituents function as follows:

1. Ammonium hydroxide ( $\text{NH}_4\text{OH}$ ) acts as a complexing agent and holds copper in solution.
2. Ammonium chloride ( $\text{NH}_4\text{Cl}$ ) increases etch rate, copper-holding capacity, and solution stability.
3. Copper ion ( $\text{Cu}^{2+}$ ) is an oxidizing agent that reacts with and dissolves metallic copper.
4. Ammonium bicarbonate ( $\text{NH}_4\text{HCO}_3$ ) is a buffer and as such retains clean solder holes and surface.
5. Ammonium phosphate [ $(\text{NH}_4)_3\text{PO}_4$ ] retains clean solder and plated through-holes.
6. Ammonium nitrate ( $\text{NH}_4\text{NO}_3$ ) increases etch rate and retains clean solder.
7. Additional additives are included in most formulations to enhance speed and/or sidewall protection. Thiourea or its derivatives are often used, although a newer thiourea-free formulation with improved undercut protection is available.
8. Continuous operations consist of single-solution makeup buffered to a pH of 7.5 to 9.5.

Alkaline etching solutions dissolve exposed field copper on printed boards by a chemical process of oxidation, solubilizing, and complexing. Ammonium hydroxide and ammonium salts combine with copper ions to form cupric ammonium complex ions [ $\text{Cu}(\text{NH}_3)_4^{2+}$ ], which hold the etched and dissolved copper in solution at 18 to 30 oz/gal.

Typical oxidation reactions for closed-loop systems are shown by the reaction of cupric ion on copper, and air ( $\text{O}_2$ ) oxidation of the cuprous complex ion:

There is strong evidence that the etching rate is dependent on the diffusion of  $\text{Cu}(\text{NH}_3)_2^+$  from the copper surface (Eq. 34.1) into the bulk of the active solution, where oxidation per Eq. 34.2 occurs.<sup>3</sup> Etching can be continued with the formation of  $\text{Cu}(\text{NH}_3)_4^{2+}$  oxidizer from air during spray etching and as long as the copper-holding capacity supported by  $\text{Cl}^-$  ions is not exceeded.

**34.4.1.2 Properties and Control.** Early versions of alkaline etchants were batch operated. They had a low copper capacity, and the etch rates dropped off rapidly as copper content increased.<sup>4,5,6</sup> It was found to be necessary to add controlled amounts of dissolved oxidizing agents to speed up the rate and increase copper capacity at a constant temperature. Batch operation is no longer supported by commercial suppliers.

Etching solutions are operated at 120 to 130°F and are well suited to spray etching. Efficient exhaust systems are required because ammonia fumes are released during operation.<sup>7</sup> Etching machines must have a slight negative pressure and moderate exhausting to retain the ammonia necessary for holding dissolved copper in solution. Care must be taken that sufficient fresh air to supply needed  $\text{O}_2$  is introduced to balance the extraction. Currently available solutions offer constant etching of 1 oz (35  $\mu\text{m}$ ) copper in 1 min or less, with a dissolved copper content of 18 to 24 oz/gal.

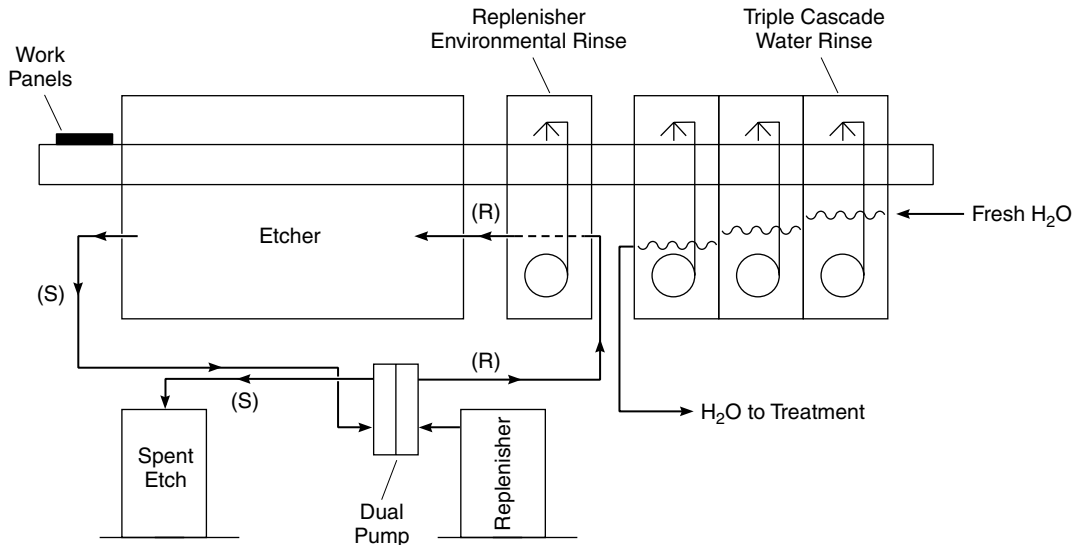

FIGURE 34.1 Automated flow-through alkaline etching system.

**34.4.1.3 Continuous Systems.** A practical method of maintaining a constant etch rate with minimal pollution uses automatic feeding controlled by specific gravity or density.<sup>6</sup> The process, which is generally referred to as *bleed and feed*, is illustrated in Fig. 34.1. As the printed boards are etched, copper is dissolved, and the density of the etching solution increases. The density of the etchant in the etcher sump is sensed to determine the amount of copper in solution. When the density sensor records an upper limit, a switch activates a pump that automatically feeds replenishing solution to the etcher and simultaneously removes etchant until a lower density is reached. An elegant by-product of this technique is the introduction of the replenisher into the first rinse stage following the etcher. The rinse captures the copper from the panel and reintroduces it to the etcher, where it is eventually eliminated to the by-product tank with the rest of the copper. When used with aqueous processing photoresists, it has been found that low pH (7.9 to 8.1) aids etch reliability. However, maintaining this pH by adjustment of exhaust extraction has been difficult. Measurement of pH and controlled addition of anhydrous ammonia into the etchant has improved consistency. It has been established that control of free ammonia as well as ammonium chloride and oxygen levels are needed to stabilize etching rates. Direct injection of oxygen has also been attempted to stabilize the etching rates between low and high copper etching demand process utilization periods.

Typical operating conditions are as follows:\*

Temperature	120 to 130°F (49 to 50°C)
pH	8.0 to 8.8
Specific gravity at 120°F (49°C)	1.207 to 1.227
Baumé, Be°	25 to 27
Copper concentration, oz/gal	20 to 22
Etch rate, 0.001 in/mm	1.4 to 2.0
Chloride level	4.9 to 5.7 mol/L

\* PA Hunt Chemical Corporation, West Paterson, NJ.

A study of the etching rate vs. dissolved copper content shows the following effects:

0 to 11 oz/gal	Long etching times
11 to 16 oz/gal	Lower etch times but solution control difficult
18 to 22 oz/gal	Etch rates high and solution stable
22 to 30 oz/gal	Solution unstable and tends toward sludging

All work must be thoroughly rinsed immediately upon leaving the etching chamber. Techniques such as replenisher rinsing and multiple cascade water rinsing assist in thorough rinsing with controlled effluent and limited water use.<sup>8</sup> Do not allow the boards to dry before rinsing. Etched circuitry with plated tin/lead solder resist also requires an acid application of solder brightener for reflow of the coating. Thiourea-containing brighteners have largely been eliminated due to use of sacrificial plating resist (SMOBC) and environmental pressures. Rinsing must be sufficient to remove etchant from under circuit edges and to completely clean the circuit surfaces and plated through-holes.<sup>8</sup> Multiple-stage cascading water rinsing and air knife drying result in clean, stain-free surfaces (see Fig. 34.1). Modern processes often follow the etching rinse with metal-resist stripping and rinsing chambers before exiting the machine conveyor.

**34.4.1.4 Closed-Loop Regeneration.** True regeneration requires the following:

1. Removal of portions of the spent etching solution from the etcher sump under controlled conditions, according to the amount of copper added to the etch bath.
2. Chemical restoration of spent etchant (i.e., removal of excess by-products and adjustment of solution parameters for reuse).
3. Replenishing of etchant in the etching machine, balancing the actual production use demands. Constant etching conditions are achieved when regeneration is continuous. Regeneration by these methods is expensive and is thus limited to large printed-circuit facilities. The principal methods of regeneration are crystallization, liquid–liquid extraction, and electrolytic recovery.
  - Crystallization reduces the copper level in the etchant by chilling and filtering precipitated salts. This is followed by reformation and adjustment of operating conditions.
  - Liquid–liquid extraction<sup>9,10</sup> is gaining acceptance because of its continuous and generally safe nature. The process involves mixing spent etchant with an organic solvent (i.e., hydroxy oximes) capable of extracting copper. The organic layer containing copper is subsequently mixed with aqueous sulfuric acid, which extracts copper to form copper sulfate. The copper-free etchant is restored, and the copper sulfate is available for acid copper electro-winning. Closed-loop regeneration systems reduce chemical costs, sewer contamination, and production downtime, but require floor space, resources, and technical attention. Economics are directly affected by copper market prices.
  - Electrolytic recovery of copper directly and through membrane cells from an ammonia-complexed copper sulfate etchant yields possible benefits such as reduced waste shipments and cost savings.<sup>11,12</sup>
  - These processes are usually employed by the large-scale vendor/recycling plants that offer a spent removal and replenisher replacement service as part of the product contract. This practice allows for economies of scale and environmental responsibility to be removed from the fabrication plant site.

**34.4.1.5 Special Problems Encountered During Etching<sup>13</sup>**

1. *Low etch rate with low pH, <8.0.* This is caused by excessive ventilation, heating, downtime, and spraying when the solution is hot, under conditions of adequate replenishment or low ammonia. The pH must be raised with anhydrous ammonia. Automatic replenishment equipment must be checked.

2. *Low etch rate with high pH, >8.8.* This is caused by high copper content, water in etchant, or underventilation.
3. *Low etch rate with optimum pH.* This is due to error of copper thickness, oxygen starvation in the etcher, or contamination of the etchant.
4. *Solder attack.* This is caused by excess chloride in the etchant, improper tin/lead deposits, or insufficient phosphate content.
5. *Residue on solder plate, holes, and traces.* These may be caused by etchant solution imbalance or by spent finisher.
6. *Under- or overetching.* This may be due to improper pH or equipment adjustments.
7. *Sludging of etch chamber with low pH, <8.0.* See special problem 1. Sludge will be gritty and dark blue. This may be corrected by the addition of anhydrous ammonia.
8. *Sludging of etch chamber with high pH, >8.8.* See special problem 2. Sludge will be light blue and fluffy. This may be due to the copper concentration exceeding the capacity of the chloride concentration. It may be corrected by adding ammonium chloride. It may also be due to water added to the etchant.
9. *Presence of ammonia fumes.* The cause of this is leaks in the etcher. Ventilate for operator safety.
10. *Pollution.* This results when water coming from the etchers contains dissolved copper. If so, it must be chemically treated and separated from ammonia-bearing rinses. Thin-clad copper laminates present a further problem because their faster movement through the etcher increases the transport of etchant into the rinses. Evaluate isolation roller placement and cleanliness, internal etcher overspray, and proper chemical and water rinsing.

### 34.4.2 Cupric Chloride

Cupric chloride is the second mainstream etchant of choice. (See Table 34.1 for characteristic cupric chloride solutions.) It is more compatible with photopolymer resists and is the etchant of choice for precision etching of small features. Because the cuprous ion buildup renders the etchant impractically slow, this etchant must always be used as a regenerative system with continuous oxidizer management and control. These systems have been the subject of many innovations to achieve continuous regeneration, lower costs, and a constant, predictable etch rate. Steady-state etching with acidic cupric chloride permits high throughput, material recovery, and reduced pollution. Regeneration in this case is somewhat complex but is readily maintained. Dissolved copper capacity is high compared with that of batch operation. Cupric chloride solutions are used mainly for fine-line multilayer inner details, print-and-etch boards, and panel-plate/tent-and-etch boards.<sup>14</sup> In addition to photoresists, screened inks, gold, and tin-nickel have been used. Solder and tin resists are not compatible with cupric chloride etchant.

**TABLE 34.1** Characteristic Cupric Chloride Etching Solutions

Component	Solution 1 <sup>15</sup>	Solution 2 <sup>16</sup>	Solution 3 <sup>17</sup>	Solution 4 <sup>18</sup>
CuCl <sub>2</sub> · 2H <sub>2</sub> O	1.42 lb	2.2 M	2.2 M	0.5–2.5 M
HCl (20°Be)	0.6 gal	30 mL/gal	0.5 N	0.2–0.6 M
NaCl		4 M	3 M	
NH <sub>4</sub> Cl				2.4–0.5 M
H <sub>2</sub> O	*	*	*	*

\* Add water to make up 1 gal.

**34.4.2.1 Chemistry.** The etching reaction is as follows:

Chloride ions, when added in excess as hydrochloric acid, sodium chloride, or ammonium chloride, act to solubilize the relatively insoluble cuprous chloride and thereby maintain stable etch rates. The complex ion formation can be shown as

The formation and diffusion of this chloro-complex form of the Cu(I) ion determine the etching rate for cupric chloride. Thus, the rate is affected by chloride ion concentration as well as the typical diffusion concentration and film thickness variables.

The etchant is regenerated by reoxidizing the cuprous chloride to cupric chloride by several chemical choices as illustrated by the following equations:

*Air*

This method of regeneration is not used because the oxygen reaction rate in acids is slow and the solubility of oxygen in hot solution is low (4 to 8 ppm). Spray etching induces air oxidation, but is not sufficiently reactive to support practical etching rates. An additional option of using ozone can accelerate the rate of this process, but ozone concentrations in an oxygen stream are difficult to maintain at above 3 percent, thus limiting utility.

*Direct Chlorination*

As the traditional regeneration choice, the chlorine reaction is rapid, positive, and easily controlled. Liquefied chlorine gas has been generally available, and standardized commercial addition systems have been available. Recently, pressure on chlorine distribution and use due to safety and environmental regulations have made availability and implementation more expensive and difficult. It is significant that the reaction simplicity indicates that all etched copper is converted directly to cupric chloride (combination of Eqs. 34.3 and 34.6). Thus, there is no effect on water or acid balances from the etching reaction itself.

*Hydrogen Peroxide*

This process is more complicated because both hydrogen peroxide and hydrochloric acid add water in the reaction process. Since hydrogen peroxide is unsafe to store and handle in concentrations above 35 percent, there is considerable water added with both the oxidizer and the hydrochloric acid. The result limits the copper-holding capacity of the etchant. The addition is reasonably and simply controlled as a direct ratio of HCl, and peroxide is added to the bath to maintain the copper oxidation. This formulation has been favored in Europe and to some extent in Asia.

*Sodium Chlorate*

Sodium chlorate has become one of the most widely used formulations. The oxidizer solutions can be mixed from powder and are also commercially supplied as 45 percent solutions. The water balance must also be carefully controlled with this oxidizing plan, and the amount of sodium chloride in the working bath can be boosted by addition with the oxidizer. This can be a rate enhancer by supplying chloride ions needed by Eq. (34.6), and since the chloride ion is separately added from the hydrochloric acid, the free acid can be maintained at very low levels (<0.1 normal).

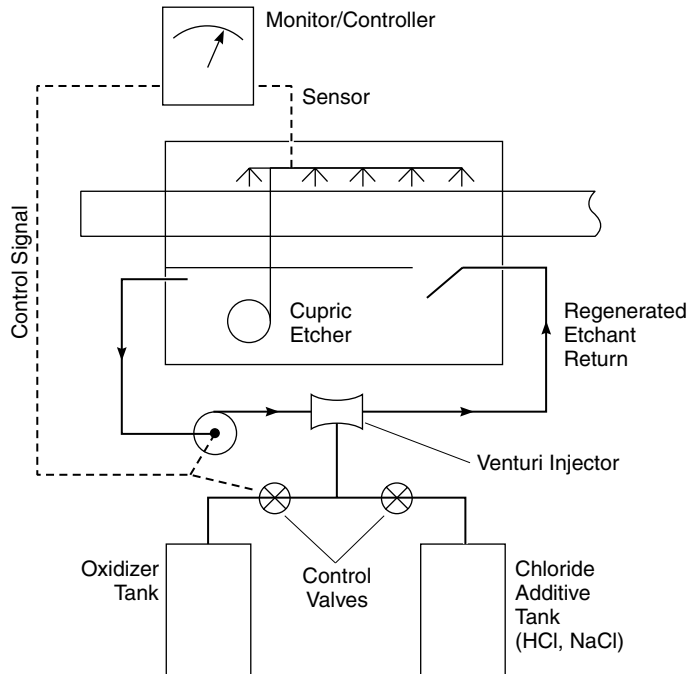

*Electrolytic*

Electrolytic systems of direct and membrane cell design have been employed. However, this technology is not a major factor in current manufacturing practice.

**34.4.2.2 Properties and Control.** Early cupric chloride formations had slow etch rates and low copper capacity and were limited to batch operation.<sup>15-21</sup> Regenerated continuous operation using modified formulations has brought useful improvements. Etch rates as high as 55 s for 1 oz copper are obtained from cupric chloride–sodium chloride–HCl systems operated at 130°F with conventional spray-etching equipment. Copper capacities are maintained at 20 oz/gal and above. However, more recently, higher copper contents and adjusted chemistries at 125°F typically etch at 75 to 90 s for 1 oz copper.

**34.4.2.3 Continuous Etching and Regeneration.** Systems in use include chlorination, sodium chlorate, hydrogen peroxide, and electrolysis.

*Chlorination.* Direct chlorination has been the preferred technique for regeneration of cupric etchant because of its historically low cost, high rate, efficiency in recovery of copper, and pollution control. The cupric chloride–sodium chloride system (Table 34.1, no. 3) is suitable. Figure 34.2 shows a generalized process.<sup>17</sup> Chlorine, hydrochloric acid, and sodium chloride solutions are automatically fed into the system as required. Sensing devices include oxidation-reduction instruments (Cu oxidation state), density (Cu concentration), level sensors,

**FIGURE 34.2** Cupric chloride chlorination regeneration system.

and thermostats. Chlorination is reliable and controllable. Other factors are safety and solution control. Optical colorimetric sensors can be used to detect Cu(I) levels. However, these cells are subject to fogging by organic contamination and crystalline buildup with the hazardous defect of continuing to add chemicals past the proper control points and liberating chlorine into the work area.

**1. Safety.** Use of chlorine gas requires adequate ventilation, tank and cylinder storage, leak-detection equipment, emergency protocols, personal protective equipment, operator training, and fire department approval and inspection of installations.

**2. Solution control.** An increase in pH will cause the copper colorimeter to give erroneous readings caused by turbidity in the solution. Organic deposits can also foul controls. Excess NaCl at 18 to 20 oz/gal copper causes coprecipitation of salts when the solution is cooled. Solution filtration and etch tank cleanliness must be maintained. Replacement of electrodes, instruments, and metering devices should be scheduled regularly.

*Chlorate Regeneration.* This method, currently widely supported, uses sodium chlorate, sodium chloride, and hydrochloric acid and is an alternate method similar to chlorination. A control sequence similar to the one shown in Fig. 34.2 may be used. Sodium chlorate is available in commercial solutions of several strengths with some degree of formulated agents (usually sodium chloride) added to the mixture. These solutions are added with hydrochloric acid either as a coordinated addition or in a special control logic sequence that allows very low free acid. This control system uses a multiple sensor color or turbidimetric optical system. The addition of one component (e.g., oxidizer) to a flowing sample cell occurs when the primary cell senses are triggered. A second cell allows this addition so long as there is a change from the first cell input. When there is no longer a change response and the first cell is still in “triggered” condition, the second component (e.g., HCl) is added. The logic continues to flip-flop until the first cell is satisfied. The etch sump conditions seem to have a partially delayed response to the chemical addition reaction such that oxidizing seems to occur over a longer period. Therefore, proper addition and mixing in the sump must be considered for stable control operation.

**1. Safety.** Sodium chlorate is a potent oxidizing agent that can support combustion. It is necessary to ensure that solution spills are completely cleaned up and that the rags or other materials are not allowed to dry out. Excess addition of reagents above amounts to support the actual copper etched may form chlorine gas that will be liberated into the etch machine and environment. Proper instrumentation and training for this eventuality must be implemented.

**2. Solution control.** If there is insufficient free acid content in the etch sump to react with the oxidizer and copper (Eq. 34.8), a dangerous imbalance can occur. First, the instruments and controls may not respond properly, and the etch reaction may slow down. Second, any subsequent addition of acid or mixing with acid-containing wastes can liberate chlorine gas in an uncontrolled and dangerous manner. Proper chemical balance is another issue. Water is added in all of the chemical streams and is produced in the chemical reaction. Therefore, any excess chemical addition can dilute the chemistry and change the copper-holding ability of the etchant.

*Hydrogen Peroxide Regeneration.* Hydrogen peroxide uses a two-part chemistry much like sodium chlorate. ORP instrumentation is identical in the control of adding proportional amounts of oxidizer and hydrochloric acid. Peroxide tends to decompose on sitting so that the spills are not as dangerous. Older application of colorimetric cells for the control of dosing has largely been eliminated.

**1. Safety.** Hydrogen peroxide solutions can become unstable and disassociate into oxygen and water with the liberation of heat. This can occur with explosive force in a confined vessel such as a drum stored in sunlight or heat. It can also occur in plumbing with closed valving.

The decomposition is catalyzed by many metals, including Cu, Ni, and Fe. If traces of metal or metal salts are allowed to contaminate piping runs, the piping may also rupture explosively. Facilities should be constructed with pressure relief capabilities.

*Electrolytic Regeneration.* The electrochemical reversal of the etching of copper shown in Eq. 34.9 and 34.10 is claimed to be effective and economical. Descriptions of this system are given in the literature.<sup>15</sup> On a large scale, electrolytic regeneration requires a high investment in equipment and materials, as well as high power consumption. The chemical formulation is relatively high in acid content and low in copper, a condition not optimized for etching effectiveness or plating efficiency.

The etchant is a solution of cupric chloride and hydrochloric acid (Table 34.1, no. 1). Etchant flows continuously between spray-etching machines and a plating tank. In the plating machine, two processes take place simultaneously: copper is plated at the cathode, and regeneration of the spent etchant occurs at the anodes. Copper recovery may not return copper value and may be expensive, inconvenient, and cause difficulty with recycling.

#### 34.4.2.4 Problems with Cupric Chloride Systems

1. *Slow etch rate.* Depending on chemical formulation, cupric chloride is inherently slower than ammonia and must be properly evaluated before production expectations are established. Check to ensure no resist residues or chromate coatings remain on the panel surface before etching. A slower than usual rate is frequently due to low temperatures, insufficient sump mixing, or poor solution chemical control. If temperature and agitation are under control, slow etching with a dark green solution may result from a low cupric ion content, indicating insufficient oxidizer. Acid must also be added to clarify cloudy solutions. (Before acid addition, make sure excess oxidizer is not present.) In regenerative systems, the source of oxidation may be depleted. It is advisable to analyze specific gravity, free acid, and total chloride on a regular schedule and maintain control charts to ensure that bath controllers are consistent and operating properly.

2. *Sludging.* This occurs if acid is low or if water dilution occurs.

3. *Etcher goop.* This is a common floating accumulation of photoresist compounds leached into and precipitated from etch baths. Accumulations appear to increase with higher acid formulations. Formation can be limited by proper exposure of photoresists and continuous recirculation of the etch bath through carbon filtration. Periodic, complete drain-down of the etching machinery and thorough mechanical and chemical equipment cleaning with a sulfamic acid-type commercial cleaner can minimize problems.

4. *Yellow or white residues on copper surface.* Yellow residue is usually cuprous hydroxide. It is water insoluble and is left when boards are etched and alkali-cleaned. A white precipitate will probably be cuprous chloride, which can remain after etching in solutions that are low in chloride ion and acid. To eliminate both conditions, the solution in which the board is rinsed just before final water-spray rinsing should be 5 percent by volume hydrochloric acid.

5. *Waste disposal.* Spent or by-product etchant is usually sent off-site for copper reclamation. There is usually a fee for this service depending on copper content and distance to the reclamation facility. The solutions must be free of unreacted oxidizer (see previous chlorate system discussion). Etchant can contain traces of zinc, chromium, and arsenic from the foil treatments.

### 34.4.3 Sulfuric Acid-Hydrogen

Sulfuric-peroxide systems are used extensively for copper surface preparation by microetching the surface to provide texture and active surfaces. These formulations have been used in

the past for primary circuitization etching but are no longer favored because of slow etch rate and needs for accompanying control of exotherm and copper crystallization. However, the increasing need for fine-line etching has renewed use possibilities for this and other etchants (see Sec. 34.7.4). In essence, these call for etching foils thinner than ½ oz and the control precision offered by slower etchants. They are compatible with metal resists and many organics.

**34.4.3.1 Chemistry.** Typical constituents of both immersion and spray etchants and their functions are as follows:

1. Hydrogen peroxide is an oxidizing agent that reacts with and dissolves metallic copper.
2. Sulfuric acid makes copper soluble and holds copper sulfate in solution.
3. Copper sulfate helps to stabilize etch and recovery rates.
4. Molybdenum ion is an oxidizing agent and rate exaltant.<sup>22</sup>
5. Aryl sulfonic acids are peroxide stabilizers.<sup>23</sup>
6. Thiosulfates are rate exaltants and chloride ion controllers that permit lower peroxide content.<sup>24</sup>
7. Phosphoric acid retains clean solder traces and plated through-holes.<sup>25,26</sup>

The etching reaction is as follows:

**34.4.3.2 Properties and Control.** The earlier technical problems of slow etch rates, peroxide decomposition, and foaming in spray systems have been solved, but critical concerns still remain. Among these are process overheating, etchant composition balance with by-product recovery, etchant contamination, and the dangers of handling concentrated peroxide solutions. The specific problem of decomposition of peroxide during idle hours has caused disastrous equipment meltdowns, and thus requires thermal management while equipment is otherwise not in operation.

**34.4.3.3 Closed-Loop Systems.** Production facilities require continuous recirculation of the etchant through the etching tank or machine and the copper sulfate recovery operation. Etchant replenishment is controlled by chemical analysis and by additions of concentrates.

Copper sulfate recovery is based on lowering the solubility of  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  by decreasing the etchant temperature to 50 to 70°F. Crystallizer equipment and conveyORIZED discharge has been available for this process.

**34.4.3.4 Problems Encountered with Peroxide Systems**

1. *Reduced etch rates.* This problem can be caused by operating conditions, solution imbalance, or chloride contamination.
2. *Under- and overetching.* A review of etching conditions, solution control, and the resist stripping process may show deviations from normal. In the case of immersion etching, the solution and panel agitation may need to be increased. When spray-etching, a check of nozzles and line clogging is indicated.
3. *Temperature changes.* Recirculating water rates and thermostats need to be examined regularly. Overheating may be due to high copper content, contamination, or rapid peroxide decomposition.
4. *Copper sulfate recovery stoppage.* Examine solution balance, heat exchanger, and other recovery equipment. Exit conveyor jamming difficulties from thermal excursions and varying crystal size and liquid content cause major shop floor problems.

### 34.4.4 Persulfates

Ammonium, sodium, and potassium persulfates modified by certain catalysts have been adopted for the etching of copper in PC manufacturing. Continuous regenerative systems and a batch system using ammonium persulfate are no longer used. Wide use is made of persulfates as a microetch for innerlayer oxide coating and copper electroless and plating processes. Persulfate solutions allow all common types of resists on boards including solder, tin, tin/nickel, screened inks, and photosensitive films. Formulations of ammonium persulfate catalyzed with mercuric chloride are no longer used, primarily because of environmental issues, costs, and improved alternatives. In general, persulfate etchants are unstable and will exhibit decomposition, lower etch rates vs. copper content, and lower useful copper capacity.

**34.4.4.1 Chemistry.** Ammonium, potassium, and persulfates are stable salts of persulfuric acid ( $\text{H}_2\text{S}_2\text{O}_8$ ). When these salts are dissolved in water, the persulfate ion ( $\text{S}_2\text{O}_8^{2-}$ ) is formed. It is the most powerful oxidant of the commonly used peroxy compounds. During copper etching, persulfate oxidizes metallic copper to cupric ion as shown:

Persulfate solutions hydrolyze to form peroxy monosulfate ion ( $\text{HSO}_4^{1-}$ ) and, subsequently, hydrogen peroxide and oxygen. This hydrolysis is acid catalyzed and accounts for the instability of acidic persulfate etching solutions.

Ammonium persulfate solution, normally made up at 20 percent, is acidic. Hydrolysis reactions and etchant use cause a reduction of the pH from 4 to 2. The persulfate concentration is lowered, and hydrated cupric ammonium sulfate [ $\text{CuSO}_4 \cdot (\text{NH}_4)_2\text{SO}_4 \cdot 6\text{H}_2\text{O}$ ] is formed. This precipitate may interfere with etching.

Solid persulfate compounds are stable and do not deteriorate if stored dry in closed containers. Solution makeup composition includes various catalysts, including organic matter and transition metals (Fe, Cr, Cu, Pb, Ag, etc.). Materials for storage must be chosen carefully. Persulfates should not be mixed with reducing agents or oxidizable organics.

The useful capacity of the etchant is about 7 oz/gal copper at 100 to 130°F. Above 5 oz/gal of copper, it is necessary to keep the solutions at 130°F to prevent salt crystallization. The etch rate of a solution containing 7 oz/gal of dissolved copper is 0.00027 in/min at 118°F.

**34.4.4.2 Batch Operation.** Sodium persulfate is preferred because it has minimal disposal problems and somewhat higher copper capacity and etch rates. A composition of 3 lb/gal sodium persulfate with 15 ppm of  $\text{HgCl}_2$ , 1 gal of proprietary additive, and 57 ml/gal of  $\text{H}_3\text{PO}_4$  has been successfully used for batch-type spray etching.<sup>27</sup> Etch rates vary throughout bath life and range from 0.0018 to 0.0006 in/min for copper content of 0 to 7 oz/gal. Prepared solutions must be aged for 16 to 72 h before etching when proprietary additives are used.

#### 34.4.4.3 Problems with Persulfates

- 1. Low etch rates.** Since the solution may decompose, it will be necessary to replace the bath. If solution is new, add more catalyst and check for iron contamination.
- 2. Salt crystallization.** Salts crystallize on the board and cause streaks, damage the solder plate, and plug the spray nozzles or filters. When copper content is high, blue salts may precipitate.
- 3. White films on solder surface.** This may occur normally or when the lead content in the solder plate is too high.
- 4. Black film on solder.** This condition can result when the solder alloy is high in tin. If solder reflow or component soldering is to follow, activate by tin immersion or with solder brighteners. Adjust phosphoric acid content in etchant and solder-plating conditions.
- 5. Spontaneous decomposition of etch solution.** This breakdown is due to contaminated, overheated, or idle solutions. Ammonium persulfate etchants are unstable, especially at higher temperatures. At about 150°F, the solution decomposes quickly. Use it soon after mixing.

6. *Disposal.* The exhausted etchant consists mainly of ammonium or sodium and copper sulfate with a pH of about 2. Two methods for disposal are:
- Electrolytic disposition of the copper on the surface of passivated 300 series stainless steel is one disposal method. The spent etchant is acidified with sulfuric acid prior to electrolysis. Once the copper has been removed, the remaining solution can be diluted, neutralized, checked, and discarded. The copper can be removed from the cathode. Spent sodium persulfate can be treated with caustic soda.
  - Addition of aluminum or iron machine turnings to a slightly acidified solution is another practical but possibly more difficult means of removing the dissolved copper. The reaction, especially in the presence of chloride ions, will be violent, and considerable heat will be given off if the solutions are not diluted.

#### 34.4.5 Ferric Chloride

Ferric chloride solutions are used as etchants for copper, copper alloys, Ni/Fe alloys, and steel in PC applications, electronics, photoengraving arts, and metal finishing. Current use of ferric chloride etchant in printed wiring fabrication is extremely limited in the United States because of costly disposal of the copper-containing etchant, and the much better commercial support for ammoniacal and cupric chloride etchants. There is still considerable use for alloy etching and photochemical machining applications.

Ferric chloride can be used with screen ink, photoresist, and gold patterns, but it cannot be used with tin or tin/lead resists. However, ferric chloride is an attractive spray etchant because of its ease of use, holding capacity for copper, and ability to be used on an infrequent batch application basis.

The composition of the etchant is mainly ferric chloride in water, with concentrations ranging from 28 to 42 percent by weight. Free acid is present because of the hydrolysis reaction and the need to maintain an acid environment. The natural acidity is usually supplemented by additional amounts of HCl (up to 5 percent) to prevent formation of insoluble precipitates of ferric hydroxide. Commercial formulations for copper alloy etching are usually 36 Be, or approximately 4.0 lb/gal  $\text{FeCl}_3$ , and may contain antifoam and wetting agents. Customary acid operating HCl content is 1.5 to 2.0 percent.

The effects of ferric chloride concentration, dissolved copper content, temperature, and agitation on the rate and quality of etching have been reported in the literature.<sup>28,29</sup>

#### 34.4.6 Chromic-Sulfuric Acids

These etchants for solder- and tin-plated boards were preferred for many years. More recently, their use has been completely eliminated due to Cr(VI) listing as a critical environmental hazard. Other problems with chromic-sulfuric etchants are difficulty in regeneration, inconsistent etch rate, the low limit of dissolved copper (4 to 6 oz/gal), and dangerous degradation of PVC and polypropylene equipment. Chromic acid etchant is suitable for use with solder, tin/nickel, gold, screened vinyl lacquer, and dry or liquid film photoresists. Chromic-sulfuric mixtures etch copper slowly, and additives are needed to increase the etch rate. For example, sodium sulfate and iodine have been used for rate increase. Alkaline etchants have become so well controlled that there is no justification for the risks and costs of chromic acid formulations.

The following listing demonstrates some of the operational difficulties with chromic-sulfuric etchants.

1. *Solder attack.* The protective value of solder depends on the formation of insoluble compounds on the surface. Solder is attacked if the sulfate content of the bath becomes very low or contains chloride or nitrates. The solder plate composition can also cause etchant attack. When the lead content becomes low, the sulfate film protection is lowered, and protection is lost.

2. *Slow or no etching of copper.* This can be caused by low chromic content, low temperature, insufficient acid, or high copper content. The solution is maintained as close as possible to 30 Baumé (pH about 0.1, temperature 80 to 90°F) and should be discarded when copper metal content exceeds 5.5 oz/gal.

3. *Staining of board materials.* The surfaces of dielectric substrates such as paper-based phenolics are attacked by chromic acid etchants. Removal is difficult, and the boards are generally rejected.

4. *Disposal.* Spent chromic acid etchants present a serious disposal problem. Disposal must comply with pollution standards and approved practice.

5. *Safety hazards.* Chromic acid is an extremely strong oxidizing agent. It will attack clothing, rubber, plastics, and many metals. Safety measures require adequate ventilation to keep fumes out of room air, synthetic rubber gloves, aprons, face and eye shields, and storage away from combustible materials. Dermatitis and nasal membrane damage are possible dangers.<sup>7</sup>

### 34.4.7 Nitric Acid

Etchant systems based on nitric acid have not found extensive application in PC manufacture. Copper etching is very exothermic, which may lead to violent runaway reactions. Problems with this system include solution control, attack on resists and substrates, and toxic gas fuming. However, nitric acid has certain advantages. These include rapid etching, high dissolved copper capacity, high solubility of nonsludging products, availability, and low cost.

**34.4.7.1 Chemistry.** Reaction in strong acids is shown by the following equation:

Recent work shows that process improvements are possible.<sup>30,31</sup> Controlled etching has been attained in solutions containing 30 percent copper nitrate, water-soluble polymers, and surfactants. Dry-film resists work well in this etchant. An important finding was that straight wall trace edges were achieved using nitric acid. This could result in higher yields and density of fine-line boards. The major difficulty in obtaining the sidewall results is the requirement for specific crystallographic grain structure to the copper foil that has been difficult to reproduce in production quantities.

## 34.5 OTHER MATERIALS FOR BOARD CONSTRUCTION

---

Printed board laminates are usually composed of copper foils bonded to organic dielectric materials, ceramics, or other metals.

1. *Organic dielectrics.* These are thermosetting or thermoplastic resins usually combined with a selected reinforcing filler. Thermoset-reinforced materials used for rigid and flexible boards provide overall stability, chemical resistance, and good dielectric properties. Thermoplastic materials are also used for flexible circuit applications. A factor in material selection is the effect of process solutions, etchants, and solvents on the material. In addition, the adhesives used in laminating metal to substrate can be softened, loosened, and attacked by some solutions. Flat-surface planarity is an aid to precision etching. This can be improved by selection of laminate with fine glass woven structures that do not express a waviness to the free copper foil surface.

2. *Thin-clad copper.* Etched printed boards with epoxy laminate of ¼ oz (9 μm) copper or less show minimal lateral etching, thus enabling higher fidelity to pattern-plated traces. The problem with very thin copper foils is pinhole density and fragility in the laminate

manufacturing process. One method of avoiding these problems is to start with a more conventional ½-oz (18- $\mu\text{m}$ ) foil and reduce its thickness by etching to a thinner state (3 to 9  $\mu\text{m}$ ).<sup>32</sup> This technique depends on a uniform starting foil and a very well-controlled etching process. Although the particulars of the published process were not disclosed, cupric chloride and sodium persulfate formulations have been used for this process.

**3. Reverse foil laminate.** This construction is receiving attention for improving precision and control of etched lines. In order to achieve this foil structure, the *tooth* or crystalline roughness must also be controlled in the foil. The tooth side is usually placed on the dielectric interface of the laminate to increase peel strength and present a flat surface for processing. However, one variation is to place the *drum* or flat side of the laminate toward the dielectric and leave the tooth side upward. This forms a flat interface so that the etching stops at this surface, instead of the conventional extra etching to remove the teeth that are buried in dielectric.

**4. Semiadditive copper.** A copper thickness of 0.000050 to 0.000200 in with subsequent copper and resist metal plating shows no overhang or sliver formation. These layers must be of sufficient thickness and uniformity to withstand the cleaning and preparation steps for plating the required conductors.

## 34.6 METALS OTHER THAN COPPER

---

### 34.6.1 Aluminum

Aluminum-clad flexible circuits find use in microwave stripline<sup>33</sup> and radiation-resistance applications. Aluminum and its alloys have good electrical conductivity, are lightweight, and can be plated, soldered, brazed, chem-milled, and anodized with good results. Laminate dielectrics include PPO,<sup>33</sup> polyimide,<sup>34</sup> epoxy-glass, and polyester.

Precleaning for resist application includes nonetch alkaline soak, water rinsing for 5 to 10 s in chromic-sulfuric acid, rinsing, and drying. Preferred etchants include ferric chloride (12 to 18° Baumé), sodium hydroxide (5 to 10 percent), inhibited hydrochloric acid, phosphoric acid mixtures, solutions of HCl and HF, and ferric chloride–hydrochloric acid mixture.

Screen-printed vinyl resists and dry-film photoresist are the most durable for deep etching or chem-milling. A dip in a 10 percent nitric or chromic acid solution will remove residues from the surface or edges of conductor lines that may be left on some alloys. Dilute chromic acid has also been used for this purpose. Spray rinse thoroughly with deionized water after etching.

### 34.6.2 Nickel and Nickel-Based Alloys

Nickel is increasingly used as a metal cladding, electroplated deposit, or electroformed structure for printed wiring because of its welding properties. Nichrome- and nickel-based magnetic alloys are other examples of materials requiring special etching techniques.

The methods previously described are adaptable to image transfer and etching of nickel-based materials. Etching uses ferric chloride (42° Baumé) at about 100°F. Other etchants include solutions made from one part nitric acid, one part hydrochloric acid, and three parts water, or one part nitric acid, four parts hydrochloric acid, and one part water.

### 34.6.3 Stainless Steel

Alloys of stainless steel are used for resistive elements or for materials with high tensile strength. Etching of the common 300 to 400 series can be done with the following solutions:

1. Ferric chloride (38 to 42° Baumé) with 3 percent HCl (optional).
2. One part HCl (37 percent) by volume, one part nitric acid (70 percent) by volume, one to three parts water by volume. Etch rate is about 0.003 in/min at 175°F, useful for high 300 to 400 series alloys.
3. Ferric chloride + nitric acid solutions.
4. One hundred parts HCl (37 percent) by weight, 6.5 parts nitric acid by weight, 100 parts water by weight.

#### 34.6.4 Silver

Silver, the least expensive precious metal, has excellent properties, including superior electrical and thermal conductivity, ductility, visible-light reflectivity, high melting point, and adequate chemical resistance. As such, it is widely used throughout the electronics industry. Flexible circuit structures with silver are used in electronic cameras and LED products.

Standard image-transfer methods are suitable. Pre-etch cleaning should include a dip in dilute nitric acid. Mixtures of nitric and sulfuric acids are effective etchants. With silver on brass or copper substrates, a mixture of 1 part nitric acid (70 percent) and 19 parts sulfuric acid (96 percent) will dissolve the silver without attacking the substrate. The solutions should be changed frequently to prevent water absorption and the formation of immersion silver on the copper.

Etching can be done with a solution containing 40 g chromic acid, 20 mL sulfuric acid (96 percent), and 2000 mL water.<sup>35</sup> This is followed by a rinse in 25 percent ammonium hydroxide. Thin films of silver are etched in 55 percent (by weight) ferric nitrate in water or ethylene glycol. Solutions of alkaline cyanide and hydrogen peroxide will also dissolve silver. Use extreme caution. Electrolytic etching is also possible with 15 percent nitric acid at 2 V and stainless-steel cathode.

### 34.7 BASICS OF ETCHED LINE FORMATION

---

The basic process of chemical etching to form features has been studied and modeled extensively. However, the best scientific knowledge can only proceed to an understanding of factors influencing the process. The practical execution of the process to manufacture useful circuits contains elements of experience in the best practice of several processes and choices in the selection of materials and process variations to achieve technically sound, cost-effective, and manufacturable results. In order to make fine-line circuit products, it is necessary to understand the process fundamentals so that the limitations may be understood and then overcome. The intent of this section is to briefly review the underlying science and discuss factors and practices for precision etching.

#### 34.7.1 The Image

**34.7.1.1 Phototools.** It seems obvious that artwork is the first defining step of the image. If the phototool lacks definition, integrity, or dimensional stability, there is no possibility of improving the image in subsequent processing. The edge definition and contrast are particularly important. Images of multiple pulses or *spots* must be overlapped so that there is minimum waviness of edges. As the feature to be resolved becomes smaller, the image must have better and cleaner integrity. It is desired that the artwork be at least an order of magnitude (factor of 10) better than the final tolerance required for the final product. Therefore, if the line tolerance is  $\pm 0.0001$  in, then the artwork should be  $\pm 0.00001$  in.

**34.7.1.2 Image Integrity.** The effectiveness of the image translated from the artwork/exposure process can be best achieved by optimization through all of the processing. Surface preparation, resist application, exposure, handling, development, and cleanliness must be maintained sufficiently to produce images with proper integrity. Image integrity may be gauged periodically with a resource such as the Conductor Analysis Technologies etch evaluation protocol. Defects such as shorts and opens have been determined to be related to resist integrity, and persistent linewidth repeating patterns may be image related. General concepts indicate that the thinner the resist, the shorter the light path; and the less optical interface layers between the light source and the copper surface, the better fidelity of the image to the phototool. However, constant improvement in film, exposure, and phototool products makes fine-image options dependent on proper optimization and constancy of technique and cleanliness as well as choice of technology.

## 34.7.2 Basics of Processing

**34.7.2.1 Diffusion—The Controlling Mechanism.** In Sec. 34.4, the chemical reactions of the etching process are discussed. In order to understand the formation of the actual shapes of the foil cross section, the influences of diffusion and fluid flow must be understood.<sup>32</sup> As a result of the etching reaction at the reaction point on the copper surface, a complex ion concentration is built up and active etching chemicals are depleted. In order to complete the reaction, this complex ion must move through a static *boundary layer* into a place where there is fresh etchant supplied to complete the reaction and carry away the etched product. (See Fig. 34.3.) This boundary-layer shape is dependent on the specific shape of the resist and etching wall, the fluid flow over the surface, and the critical fluid flow in the channels formed by the resist and the etched side wall.

**34.7.2.2 Fluid Flow Contribution.** Examination of Fig. 34.3 shows that the contour of the boundary layer and its thickness vary with the shape and narrowness of the channel. If the surface is flat with no resist image, the boundary layer is thin and only dependent on the fluid properties and velocity across the surface. On the other hand, with resist images forming channels with depth, and the etched copper forming further channels, it is easy to see how the flow of fluid in the channel can be much different than the surface flow. In order to make matters even more confusing, the circuit traces and resist images form actual channels in the surface.

**FIGURE 34.3** Etching dynamics for diffusion.

Much like a river bottom, the fluid flow in these individual channels is influenced by but different from the overall surface flow. In general, the narrower and deeper the channel, the slower the flow; and, critically, the diffusion boundary layer is more significant and etchant slows. In general terms, this is the reason that the middle section of a group of parallel, closely spaced lines etches slower than the outside lines. Similarly, this is the reason why a sharp 90° angle has a slower-etching section in the inside edge of the bend.

The concept of spray etching adds another dimension to the fluid dynamics. The surface of the panel is never really free of a liquid film. The top side of a panel has the etch liquid held up between delivery by the sprays and removal by flow off the edges. This flow is influenced by the number, flow, and pattern of the nozzles, the interaction of the flow between the sprays, the motion of the panels, and the effects of rollers and other contacting and shadowing objects. Even the bottom side retains fluid by surface tension and is influenced by the amount of liquid moving under the direction of the nozzles. The end result is complicated flow patterns that are the result of testing and optimization by the machine manufacturers.

### 34.7.3 Trace Shape Development

**34.7.3.1 Etched Trace Shape Description.** During etching, the gap between resist areas is removed evenly at first, and then progressively cup-shaped until the center area is broken through. After this, the area of exposed laminate opens progressively and the etching works on the side walls, etching in and under the resist as the side wall is relieved to expose more insulation and isolate the desired feature. (It has been noted that very little undercutting is apparent until the center is opened.) Figure 34.4 illustrates the attack with standard definitions for  $R$  (resist width),  $B$  (base of trace),  $T$  (top of trace), and  $t$  (foil thickness). There are two descriptive measures of the etching process—undercutting and etch factor—which are defined in Eqs. (34.14) and (34.15). These definitions are not universal, so it is necessary to clarify the definitions to correctly interpret discussions using these factors. Undercutting defines the average overhang of resist after top width reduction, and etch factor defines the average side wall inward taper of the etched feature per unit thickness. Occasionally, the etch factor is inverted or different measured values are used.

$$\text{Undercut:} \quad U = (R - T)/2 \quad (34.14)$$

$$\text{Etch factor:} \quad F = 2t/(B - T) \quad (34.15)$$

FIGURE 34.4 Trace cross-section measurement.

It is significant that these two units of measure are useful in describing the development of the shape of an etched part. It is desirable that  $U$  be minimized and  $F$  maximized for best feature definition.

**34.7.3.2 Undercut and Etch Factor Development.** The development of trace shapes has been studied by observing etched traces at progressive times.<sup>36,37</sup> This allows one more parameter to be developed, the extent of etch, which is the ratio of  $R/B$ . This factor equals 1.0 when the bottom of the trace equals the resist width, one measure of ideal etching. Note that if  $R < B$ , this implies that the trace is underetched, and  $R > B$  indicates overetching. The traces were etched in cupric chloride using 3.0-mil line and space patterns of 1.0-mil resist on 1-oz (1.4-mil) copper foil. The progression of etch values is found in Table 34.2 and Fig. 34.5.

**TABLE 34.2** Etch Progression

Etch time, S	Undercut, $U$ mil	Etch factor, $F$	Extent of etch, $R/B$
90	0.05	0.90	0.5
110	0.30	1.75	0.75
125	0.45	2.33	1.1
140	0.525	2.67	1.0
165	0.75	3.11	1.25

There is an important conclusion to be drawn from these data. In order to compare or characterize an etch process (etcher to etcher, etchant to etchant, condition to condition, etc.), it is not sufficient to only use the undercut or etch factor alone. The data must be evaluated at a given  $R/B$  point for the same foil, resist, artwork, and panel size. If these factors are not held constant, the statement that “process A gives less undercut” has little meaning—additional etching gives more undercutting and straighter side walls.

**34.7.3.3 Sensitivity Analysis.** One of the extensions of the previous analysis is the ability to evaluate the sensitivity of the process. This is a study of the change in the result ( $R/B$ ) due to the additional etching (relative time). Relative time is the ratio of the actual etching time to the nominal etch time taken to reach  $R/B$  of 1.0. In Table 34.2, it took 140 s to reach  $R/B = 1$ , but only 25 s (18 percent) more etching to achieve 25 percent overetching ( $R/B = 1.25$ ). This sensitivity indicates that a small amount of overetch time could cause overetched 3-mil circuits. In this example, the etching process is slow enough to be controlled with the adjustment of the conveyor speed in the etcher. However, if the etchant were twice as fast (alkaline, for example) with the same sensitivity, it would be difficult to accurately “dial in” the proper result. Further evaluation of the cumulative variation from several variable properties on the overall product capability statistics can be found in the literature.<sup>38</sup>

**34.7.3.4 Implication for Improved Processes.** As a practical process application, it is often desirable to improve the etch factor to get a more square shape of the etched profile. One method for accomplishing this is to design the phototool for wider lines than desired, and then overetch to the desired endpoint. This practice increases  $F$  at the expense of also increasing  $U$ . However, as spaces get smaller, there is no space available for additional resist line-width, because the fluid activity is restricted so that the etchant is stagnant between the traces. Therefore, resist width near the final line specification and precise control of the etch process are required to obtain desired shape profiles within the  $R/B = 1$  degree of etching. As feature specifications tighten, the process to do this may need to be altered. One patented approach is to finish the etch with a specific slower-speed fine-tune etching chemistry to be able to stop the etching process at precisely the correct point.<sup>39</sup>

### 34.7.4 Fine-Line Formation Etching Requirements

**34.7.4.1 Fine-Line Definition.** The term *fine line* is a relative one because the current state of processing by conventional available technology is constantly improving. Therefore, fine lines can be considered the next extension of capability that requires precision higher than that afforded by available technology. This is understood by means of statistics and

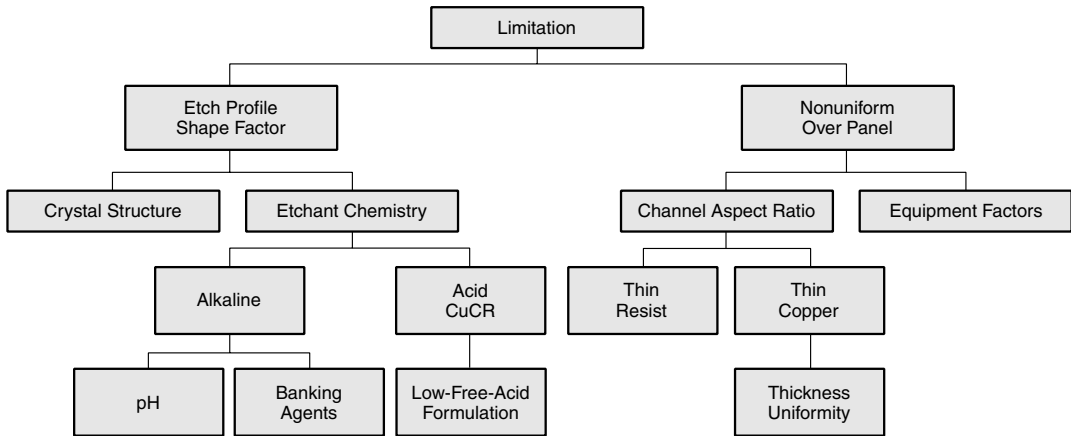

standard gauging tools. The measure  $C_p$  (simple process capability) evaluates the variability of output results ( $6s$ , where  $s$  is the standard deviation of the linewidth distribution) to the specification limits of variation.<sup>40</sup> The data for the performance can be obtained by using a standardized test vehicle (IPC-9251) or a commercial testing program by CAT (see Chap. 36). In general, fine lines can then be defined as the linewidth point at which yield performance begins to drop below the run of production. Note that it is up to the customer and shop to determine what product line variation (usually a percent of line dimension) is allowed. It is apparent that this definition depends on the available technology and operation of the individual shop.
